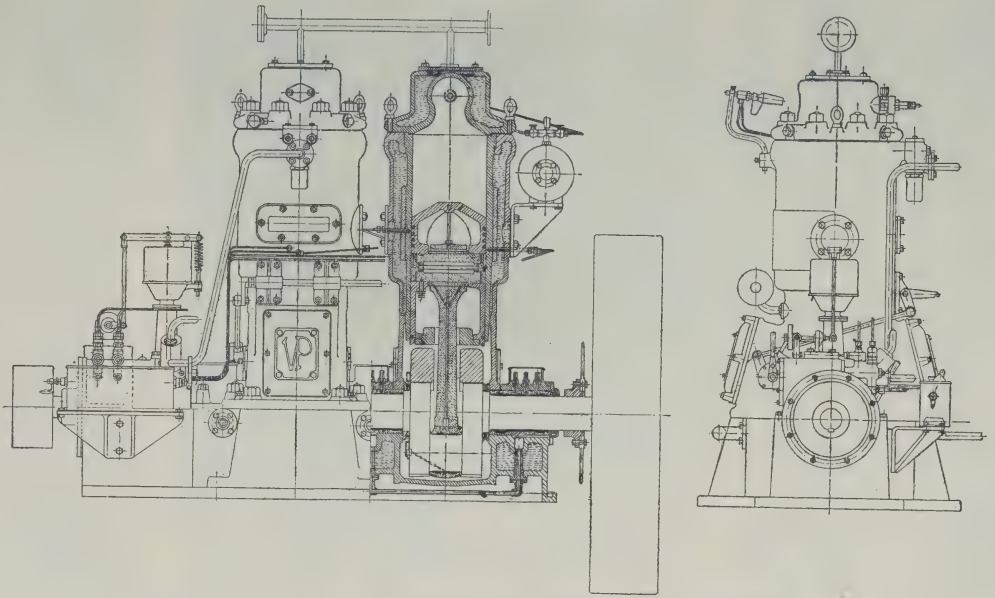

FIG. 21.—**Petter High-Compression Heavy-Oil Engine.** Sectional Arrangement.

injection fuel valve. The crankshaft bearings are ring lubricated, and a mechanically operated lubricator is fitted for the piston and connecting-rod bearings.

The valve gear is their patented eccentric-driven type, which gives a very smooth action to the valves and in a large measure is responsible for the absence of shock and the quiet running of the Paxman engine.

The engines can be converted to work on town, producer, or natural gas, simply by an alteration to the turbulence plate, and the same cylinder heads and valve gear are used. This is of great advantage for oilfields, where natural gas is often obtained before oil is struck.

McLaren-Benz Oil Engine.

High-speed lightweight high-compression oil engines are made by J. & H. McLaren, Ltd., Leeds, in sizes up to 450 b.h.p. for stationary and marine work. They are of the two, four, and six cylinder type, running at 250 to 800 r.p.m., and the weight of the 90 b.h.p. engine is only about 4,800 lbs.

The engines work on the four-stroke cycle, with compressive pressure of 450 lbs., and the fuel is injected into an ignition chamber, which is connected by a funnel-shaped liner with the cylinder. The fuel is completely vaporised, and the vapour passes through three holes in the base of the liner to the larger volume of compressed air in the cylinder.

Messrs. McLaren use these engines on their motor cable ploughing tackles and traction engines, and supply them for rail locomotives, etc., where powerful engines of light weight are necessary.

LOW-COMPRESSION OIL ENGINES.

The early oil engines were all low-compression engines, and the desire to use the heavier grades of petroleum, which are cheaper than the more refined grades, caused the development or higher pressures, so that the increased temperature could completely vaporise the heavier fuels.

The low-compression oil engines still have, and will always continue to have, a wide application, owing to the low working pressures and small cost.

In the normal 'oil engine' a heavy kerosene is usually employed as fuel; Russian oil is, in general, rather preferred, though the ordinary American brands are also used with quite satisfactory results. A standardised oil described as R.V.O. (Russian vaporising oil) of specific gravity 0·825 and flash point 86° F. (close test) is regarded as the normal fuel for these engines; other descriptions commonly used, however, include Rocklight, Russolene, Homelight, Gladiator, Phœbus, Silver Spray, Crown Diamond, Royal Daylight, White Rose, Tea Rose, and Bear Greek. Among the heavier fuels used are refined shale-oils as Broxburn and Scotch Lighthouse, and also the refined heavy oils of Burma, Assam, Roumania, etc.

The average composition of the petroleum oils used is 85½ per cent. carbon, 13½ per cent. hydrogen, and 1 per cent. oxygen, and the mean calorific value, by Berthelot calorimeter, is roundly 19,600 B.Th.U. per lb. When arranged to use either petrol, kerosene, or heavier oils, engines usually develop powers in the proportion of about 100 : 90 : 80, respectively.

It should be carefully noted that the nominal power of internal combustion engines in general is for location at sea-level; when required to work at an altitude a deduction from the nominal power should be made of 3 per cent. for each 1,000 ft. of height, due to the diminished density of the air.

In the ordinary oil engine the heavy kerosene fuel is vaporised in a heated chamber maintained at the necessary temperature either by heat derived from the successive explosions (hot-bulb vaporisers), or from the exhaust of the engine; or, lastly, in a few cases, by means of a separate blow-lamp. In most cases a preliminary heating of the vaporiser by a blow-lamp is necessary for 10 to 15 minutes before the engine can be started. These engines are practically all of the single-acting four-stroke type, and compress a mixture of kerosene vapour and air into the combustion chamber.

Ignition of the charge is sometimes automatic; high and low tension magneto ignition is also used, while in cases where lamp-heated vaporisers are adopted tube ignition is general. On account of the care and attention necessary where lamps are used, and also in some cases due to increased fire risks, makers are in general favouring one or other of the methods of lampless ignition.

Blackstone Oil Engines.

When starting these engines the vaporiser and the igniter are heated by a lamp in from four to six minutes. The flywheel is then turned forward by hand (unless a self-starter is used) to obtain the first explosion, after which the engine works automatically, the necessary heat for the vaporiser and for ignition being maintained by the successive explosions; a continuous burning lamp is therefore dispensed with. A timing or ignition valve is used to regulate the period of ignition. During compression this valve cuts off all heated parts, and the utmost regularity of the explosions under all loads is secured. A patented water drip valve is fitted to enable a small quantity of water to be admitted to the vaporiser to regulate its heat on long, continuous, heavy loads. As long as there is oil in the tank the engine continues to work.

The engine is governed by means of our patent direct-acting shaft governor, which controls the vapour valve—this system having been found to give the most economical and efficient results. It regulates the oil consumption to the power given off. The speed may easily and instantly be regulated whilst the engine is running.

Any ordinary lamp oil may be used, but the efficiency of the engine depends upon the quality.

National Oil Engines.

Oil engines of the horizontal four-stroke cycle type are made by the National Gas Engine Co., Ltd., Ashton-under-Lyne, in sizes from 2½ to 47½ b.h.p. These engines are made in two types: (*a*) the petrol-paraffin engines, which start on petrol and then run on paraffin, and are fitted with electric ignition, and (*b*) the hot-bulb engines, a special feature of which is the vaporiser and ignition timing device, which secures effective vaporisation of the oil and the proper timing of the ignition at all loads. A lamp must be used for starting on the hot-bulb engines, and the vaporiser needs to be heated for about ten minutes to make it hot enough to start the engine.

The engines are supplied both stationary and portable, and are suitable for agricultural and industrial work.

Hamworthy Oil Engines.

Hamworthy oil engines are made in nine sizes—2½, 4, 6, 9, 11, 15, 20, 25, and 30 b.h.p.—and are manufactured on strictly repetition lines by the Hamworthy Engineering Co., Poole.

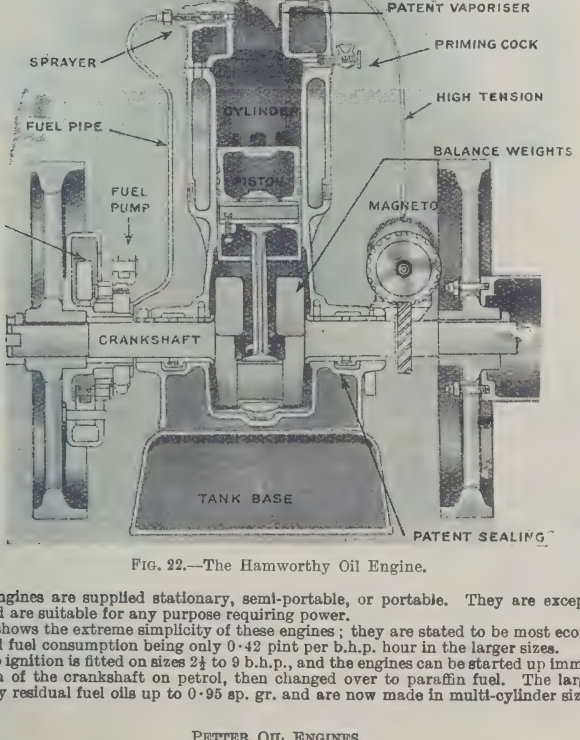

FIG. 22.—The Hamworthy Oil Engine.

These engines are supplied stationary, semi-portable, or portable. They are exceptionally reliable, and are suitable for any purpose requiring power.

Fig. 22 shows the extreme simplicity of these engines; they are stated to be most economical, the full load fuel consumption being only 0·42 pint per b.h.p. hour in the larger sizes.

Magneto ignition is fitted on sizes 2½ to 9 b.h.p., and the engines can be started up immediately by one turn of the crankshaft on petrol, then changed over to paraffin fuel. The larger sizes work on any residual fuel oils up to 0·95 sp. gr. and are now made in multi-cylinder sizes up to 180 b.h.p.

Petter Oil Engines.

Engines of the two-stroke vertical type have been manufactured by Petters, Ltd., of Yeovil, for many years. The small sizes are the well-known Petter 'M' type engines, suitable for farm, estate, and factory machinery, electric lighting, pumping, and other purposes.

The Petter 'M' type engines, fig. 23, are made in three sizes : 1½, 3, and 5 b.h.p. ; and in three patterns : stationary, for fixing on concrete (as illustrated), semi-portable on wood skids, and portable on four-wheeled carriage.

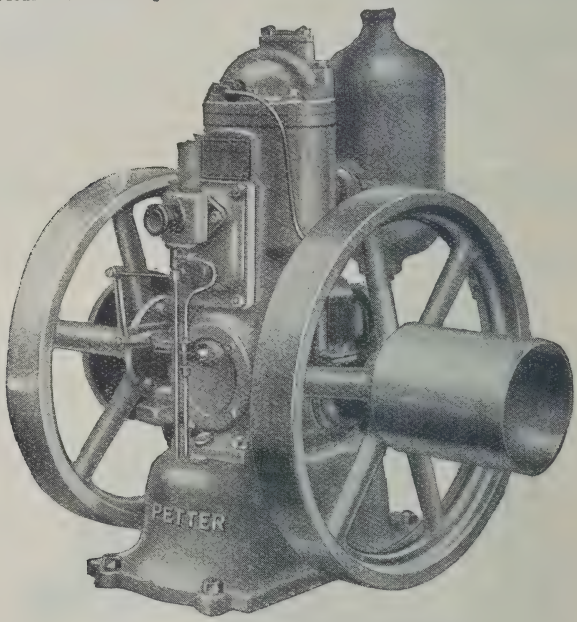

FIG. 23.—The Petter 'M' type Oil Engine.

These engines work on paraffin and have magneto ignition. They are started on a small quantity of petrol, and change over automatically to paraffin after working for a few minutes. By means of the patent fuel injector, the paraffin is vaporised and burnt with the same completeness as in a petrol engine, and at half the cost of fuel. They can also be supplied for running on petrol only.

THE DORMAN ENGINE.

W. H. Dorman & Co., Ltd., Stafford, manufacture two, four, and six-cylinder engines in various sizes developing 8 to 100 b.h.p. at 1,000 r.p.m., as shown in the following table:

No. of Cylinders.	Bore m/m.	Stroke m/m.	Volume c.c.	B.H.P. 1000 r.p.m.	Treasury Rating.
4	66	100	1368	8	10·5
4	69	100	1496	10	11·8
4	80	130	2613	19	15·9
2	120	140	3166	20	17·8
4	95	140	3970	25	22·4
4	100	140	4398	30	24·8
6	95	140	5954	44	33·6
6	100	140	6597	48	37·2
4	120	140	6333	45	35·7
4	120	185	8369	72	35·7
6	120	185	12553	100	53·6

The cylinders are monobloc except on the 100 h.p. six-cylinder engine, where they are cast in two pairs of three each, and on the 45 h.p. engine, where the cylinders are cast in two pairs. The larger sizes are fitted with detachable heads of the Ricardo patent turbulent type. Side-by-side valves have been adopted, owing to their silence in operation, and the inlet valves are 3 per cent. nickel steel, while the exhaust valves are of stainless steel.

These engines are specially designed to meet the demand for increased passenger and weight carrying capacities of vehicles, and the increasing use of internal combustion engines for locomotives and rail cars.

Other Makers of Oil Engines.

Engines of the horizontal four-stroke type are also made by Crossley Bros., Ltd., Manchester; Fielding & Platt, Ltd., Gloucester; and Tangyes, Ltd., Birmingham.

Vertical engines are made by Gardner & Sons, Patricroft; the Parsons Oil Engine Co., Ltd., Southampton; J. I. Thornycroft & Co., Ltd., Basingstoke; the New Pelapone Co., Leeds; and Lister & Co. Ltd., Dursley.

INTERNAL COMBUSTION TURBINES.*

(Contributed by T. B. Morley, D.Sc., M.I.Mech.E.)

The heat engine which has the highest thermal efficiency is an internal combustion engine; the one which can be made in units of maximum power and which, moreover, has many attractive features, such as almost perfect balance due to its purely rotary motion, and small bulk in relation to output, is the steam turbine. It is not to be wondered at, therefore, that engineers have reflected upon the desirability of a prime mover which should combine the merits of both these types. The internal combustion turbine has been the dream of many speculative and inventive minds, but, though many hundreds of patents have been taken out for internal combustion turbines, few have yet been constructed, and none has so far passed the experimental stage.

It is evident, therefore, that there are serious difficulties to be overcome in order to produce a successful internal combustion turbine.

Speaking generally, in all internal combustion turbines, fuel, gaseous or liquid, is burned, and the products of combustion, issuing from the combustion chamber through nozzles at high velocity, impinge upon the blades of a turbine rotor. In comparison with the cycle of a reciprocating engine, the chief difference is that, whereas in that engine the expanding gases do work upon a piston, in the turbine the energy of the gases takes the form of kinetic energy, which is represented in the acquisition of velocity by the jets of gases which are led to the turbine blading.

The combustion, as in the case of the reciprocating engine, may be at constant pressure or at constant volume, or at a combination of the two conditions. If it is at constant pressure, in order to obtain a cycle of reasonable ideal efficiency, the working substance must be compressed before ignition or else the products of combustion must be expanded below atmospheric pressure by an exhauster. In either case, a pump or an exhauster is necessary, and it is the large amount of work necessarily absorbed in this stage of the cycle—relatively much greater than in the corresponding stage of a steam turbine cycle, *viz.* the compression in the air pump and feed pump—which is one of the serious obstacles to the success of this type of internal combustion turbine.

If, as is desirable for a large unit, the compression or exhauster is of the turbo type, its relatively low efficiency compared with a piston compressor greatly accentuates this drawback.

This particular difficulty may be almost entirely avoided by the adoption of a cycle in which the combustion is at constant volume. In this case, however, it is not possible to produce a steady continuous jet; the action of each combustion chamber must necessarily be intermittent, the jets of gas issue at varying velocity, and the blading angles and blade speeds cannot satisfy the conditions for maximum efficiency as they cannot vary in accordance with the varying jet velocities. The loss of efficiency due to this is not, however, of very great magnitude.

The most serious difficulty in the production of a reliable internal combustion turbine is a practical one. In all cases the temperature of the jet of gas striking the blading must be very high in order that the cycle may be efficient; the blading and the rotor must, therefore, be made of materials capable of withstanding temperatures say up to 800° C., at least, without scaling or loss of form, and without undue reduction of strength, as the blades and rotor must run at high speed and are, therefore, subject to considerable centrifugal stresses as well as to the tangential driving effort.

The combustion chamber and nozzles are exposed to still higher temperatures, but as they are stationary and not so severely stressed, nor so delicate in form, the problem of suitable material for them is not so acute.

* See also 'The Internal Combustion Turbine,' by T. B. Morley, *Proc. Manchester Association of Engineers*, February 1925.

In order to reduce the temperature of the jet the gases resulting from the combustion of the fuel may be diluted, with steam for example, before they enter the expansion nozzles leading them to the blading. Interesting types of mixed-fluid internal combustion turbines, *i.e.* turbines in which the working substance is a mixture of gas and steam, are described in Davey's 'The Gas Turbine' (*Constable & Co.*, 1914), but though certain of the turbines proposed, in which the steam is generated partly from the heat of the turbine exhaust and partly from the heat passing through the walls of the combustion chamber, and in which the cycle is carried out at pressures below atmospheric, offer good prospects of success, no actual turbine on these principles has been made.

For a description of experimental machines made before 1914, Davey's book may be referred to.

The type of internal combustion turbine which has most nearly approached practical success is that designed by Herr Holzwarth, and constructed by Messrs. Thyssen, in Germany. This turbine is of the constant volume type. A series of combustion chambers are arranged symmetrically round the shaft, which in the later constructions is horizontal. Gas (or oil) and air at about 20 lbs. per sq. inch abs. pressure are admitted through separate inlet valves; the passage leading from the combustion chamber to the nozzle is closed during the charging operation by a nozzle valve. After the introduction of the charge, all valves are closed, and the charge is ignited. When the pressure has in consequence reached a certain amount it overcomes the spring which holds the nozzle valve shut, the nozzle valve opens and is then held open. The gases pass to the nozzle, expand, and acquire velocity in the nozzle and impinge on the blades. When the pressure in the chamber has fallen sufficiently, scavenging air is passed through it, and then the cycle is repeated. Similar cycles take place in the other combustion chambers. Several Holzwarth turbines have been built and run on gas or on oil fuel, and test results on units in sizes up to 1,000 h.p. have been published: machines up to 5,000 kw. capacity have been built. Unfortunately the earlier published results were incomplete and open to severe criticism. Tests made in 1923 on a 1,700 k.w. unit showed an overall thermal efficiency (based on output at switchboard) of 14·2 per cent. Though Holzwarth turbines have been built from 1908 onwards, and orders were placed in 1919 by the Prussian State Railways, none seems as yet to have been in regular service.

Several other forms of internal combustion turbines are being experimented upon in Germany, U.S.A., and England.

Combinations of reciprocating engine and turbine, the turbine being driven by the exhaust gases from the reciprocating engine, offer good prospects of success. The Rateau exhaust turbine for supercharging aero-engines is one example of this combination.

As regards the internal combustion turbine, considered as a prime mover by itself and not as an adjunct to a reciprocating engine, the prospects of success in the near future are very doubtful, unless the metallurgist can provide a material which will withstand the very high temperatures called for in the blading.

Lloyd's Rules for Marine Internal-Combustion Engines.

The following rules for the survey of internal combustion engines for marine purposes have been drawn up by Lloyd's Register of British and Foreign Shipping :—

General.

Section 1.—In vessels propelled by internal combustion engines the rules as regards machinery will be the same as those relating to steam-engines so far as regards the testing of material used in their construction and the fitting of sea connections, discharge pipes, shafting, stern tubes, and propellers.

Construction.

Section 2.—1. The following points should be observed in connection with the design of the engines :—

2. The shaft bearings, connecting-rod brasses, the valve gear, the inlet and exhaust valves must be easily accessible.

3. The reversing gear and clutch must be strongly constructed, and easily accessible for examination and adjustment.

4. In engines of above 60 b.h.p. which are not reversible, and which are manœuvred by a clutch, a governor or other arrangement must be fitted to prevent racing of the engine when declutched.

5. In vessels intended for open sea service and fitted with engines in which the lubricating oil is circulated under pressure, a spare oil pump is to be supplied with all connections ready for immediate use, and two independent means are to be arranged for circulating water through the oil cooler, where this is fitted.

6. When the engines are of the closed-in type they must be so fitted that the contained lubricating oil can be drained when necessary, and in wood vessels an easily drained metal or metal-lined tray must be fitted to prevent leakage of either fuel oil or of lubricating oil from saturating the woodwork.

7. Carburettors, where petrol is used, and vaporisers, where paraffin is used, should be so designed that when the engine is stopped the fuel supply is automatically shut off. If an overflow is provided in the carburettor or vaporiser, a gauze-covered tray with means of draining it must be fitted to prevent the fuel from flowing into the bilges.

Strong metallic gauze diaphragms should be fitted either between the carburettor (or vaporiser) and cylinders or at the air inlets.

8. If the ignition is electric, either by magneto or by coil and accumulator, all electric leads must be well insulated and suitably protected from mechanical injury. The leads should be kept remote from petrol pipes, and should not be placed where they may be brought into contact with oil.

The commutator must be enclosed, and the sparking coils must not be placed where they can be exposed to explosive vapour.

9. In paraffin and heavy-oil engines, where lamps are used for ignition or for vaporising, these lamps should be fixed by some suitable bracket, and the flame enclosed when in use.

10. The circulating pump sea suction is to have a cock or valve on the vessel's skin placed on the turn of the bilge in an easily accessible position, and the circulating pipe is to be provided with an efficient strainer which can be cleared inside the vessel. The discharge overboard is to be fitted with a cock or valve on the vessel's skin if it is situated under or near the load line of the vessel.

11. The pumping arrangements are to be the same as would be required in the case of a steam vessel of the same size and power, with the exception that no bilge suction need be fitted to the circulating pump. In the cases of vessels fitted with water ballast, the water ballast pump must have, in addition, one direct suction from the engine-room bilges.

In open launches, and in small sailing vessels in which the engines are auxiliary only, a suitable additional hand pump, fitted to draw from the engine-room bilges, may be accepted in lieu of a power-driven pump.

12. Where the cylinder liners are made of hard, close-grained cast iron of plain cylindrical form accurately turned on the outside as well as bored on the inside, so that their soundness can be ascertained by inspection, they need not be hydraulically tested by internal pressure. If, however, they are made of complicated form, the question of testing must be submitted.

13. The water jackets of the cylinders, and the water passages of the cylinder covers and pistons must be tested by hydraulic pressure to 30 lbs. per sq. in. and must be perfectly tight at that pressure.

14. The exhaust pipes and silencer are to be efficiently water-cooled or lagged to prevent damage by heat, and if the exhaust is led overboard near the water-line, means must be arranged to prevent water from being syphoned back to the engine.

15. The machinery must be tried under full working conditions, the report stating the approximate speed of vessel, the number of revolutions of the engines at full power, both ahead and astern, and the lowest number of revolutions of the engines which can be maintained for manœuvring purposes.

Rules for Determining Sizes of Shafts.

Section 3.—1. The diameter of the crank shaft must not be less than that given by the following formula:—

$$\text{Diameter of crank shaft} = \sqrt[3]{D^2 \times (A\,S + B\,L)}$$

where D = diameter of cylinder in inches or millimetres,
S = length of stroke in inches or millimetres,
L = span of bearing adjacent to a crank measured from centre to centre in inches or millimetres.

The values of A S + B L are as given in the following tables:—

TABLE I.—FOR PETROL OR PARAFFIN OIL ENGINES.

4-Cycle Single-Acting Engines.	2-Cycle Single-Acting Engines.	For Smooth Water Service Values of A S + B L	For Open Sea Service Values of A S + B L
1, 2, 3, or 4 Cylinders	1 or 2 Cylinders	0·0308 S + 0·0143 L	0·0342 S + 0·0159 L
6 ,,	3 ,,	0·0310 S + 0·0143 L	0·0344 S + 0·0159 L
8 ,,	4 ,,	0·0351 S + 0·0136 L	0·0389 S + 0·0151 L
12 ,,	6 ,,	0·0474 S + 0·0120 L	0·0526 S + 0·0133 L

The above table applies to engines in which there are bearings adjacent to each side of each crank. If there are two cranks between consecutive bearings the same rules will apply, but L will be the span between the centres of the bearings adjacent to the two cranks.

TABLE II.—FOR HEAVY OIL ENGINES IN WHICH THE MAXIMUM PRESSURE IN THE CYLINDERS IS 200 LBS. PER SQUARE INCH.

4-Cycle Single-Acting Engines.	2-Cycle Single-Acting Engines.	Values of A S + B L
1 up to 8 Cylinders	1 up to 4 Cylinders	0·0298 S + 0·0144 L
12 ,,	6 ,,	0·0376 S + 0·0118 L

TABLE III.—FOR HEAVY OIL ENGINES IN WHICH THE MAXIMUM PRESSURE IN THE CYLINDERS IS 550 LBS. PER SQUARE INCH.

4-Cycle Single-Acting Engines.	2-Cycle Single-Acting Engines.	Values of A S + B L
1, 2, 3, or 4 Cylinders	1 or 2 Cylinders	0·0643 S + 0·0340 L
6 ,,	3 ,,	0·0673 S + 0·0347 L
8 ,,	4 ,,	0·0643 S + 0·0340 L
12 ,,	6 ,,	0·0673 S + 0·0347 L

2. For heavy oil engines in which the maximum pressure in the cylinders is intermediate between 200 and 300 lbs. per sq. in., or between 300 and 450 lbs. per sq. in., or between 450 and 550 lbs. per sq. in., the coefficients A S + B L are to be interpolated between those given in the above tables.

3. For auxiliary engines of the above-mentioned types the diameters of the crank shafts may be 5 per cent. less than given by the foregoing formulæ applying to main engines for open sea service.

4. In solid forged shafts the breadth of the webs should be not less than 1·33, and the thickness not less than 0·56 times the diameter of the shaft as found above, or if these proportions are departed from, the webs must be of equivalent strength.

5. The diameter of the intermediate shaft must not be less than that given by the following formula:—

$$\text{Diameter of intermediate shaft} = C \times \sqrt[3]{D^2 \times S}$$

where D = diameter of cylinder;

S = stroke of piston;

the values of C being those given in the tables, p. 1929.

TABLE VI.—FOR PETROL OR PARAFFIN OIL ENGINES.

FOR SMOOTH WATER SERVICE.

4-Cycle Single-Acting Engines.	2-Cycle Single-Acting Engines.	Values of the Coefficient C where A = 0·0025.	A = 0·0050.	A = 0·0100.

TABLE VII.—FOR HEAVY OIL ENGINES IN WHICH THE MAXIMUM PRESSURE IS 200 LBS. PER SQUARE INCH.

4-Cycle Single-Acting Engines.	2-Cycle Single-Acting Engines.	Values of the Coefficient C where A = 0·0025.	A = 0·0050.	A = 0·0100.
2 Cylinders	1 Cylinder	0·210	0·220	0·240
3 ,,	—	0·225	0·234	0·252
4 ,,	2 ,,	0·239	0·248	0·263
6 ,,	3 ,,	0·268	0·272	0·284
8 ,,	4 ,,	0·289	0·290	0·298
12 ,,	6 ,,	0·334	0·335	0·338

TABLE X.—FOR HEAVY OIL ENGINES IN WHICH THE MAXIMUM PRESSURE IS 550 LBS. PER SQUARE INCH.

4-Cycle Single-Acting Engines.	2-Cycle Single-Acting Engines.	Values of the Coefficient C where A = 0·0025	A = 0·0050	A = 0·0100
2 Cylinders	1 Cylinder	0·230	0·255	0·305
3 ,,	—	0·245	0·268	0·309
4 ,,	2 ,,	0·260	0·280	0·312
6 ,,	3 ,,	0·283	0·296	0·318
8 ,,	4 ,,	0·310	0·316	0·323
12 ,,	6 ,,	0·360	0·364	0·368

In using the foregoing tables the appropriate value of A is found from

$$A \times W \times d^2 \times R^2 = D^3 \times S$$

where D = diameter of cylinder in inches
S = stroke of piston in inches;
d = diameter of flywheel in feet;
R = revolutions of engines per minute;
W = total weight of flywheel in tons.

6. If a separate flywheel shaft is fitted its diameter must be at least equal to that of the crank shaft.

7. Where ordinary deep collars are used the diameter of the thrust shaft measured under the collars must be at least $\frac{21}{20}$ths of that of the intermediate shaft. The diameter may be tapered off at each end to the same size as that of the intermediate shaft.

8. The diameter of the screw shaft must not be less than the diameter of the intermediate shaft (found as above) multiplied by $\left(0{\cdot}63 + \frac{0{\cdot}03\ P}{T}\right)$, but in no case must it be less than $1{\cdot}07\ T$

where

P = the diameter of the propeller in inches or millimetres,
T = the diameter of the intermediate shaft in inches or millimetres.

This size of screw shaft is intended to apply to shafts fitted with continuous liners the whole length of the stern tube, as provided for in Section 11, Clause 3 (Rules for Engines and Boilers of Steam Vessels). If no liners are used, or if two separate liners are used, the diameter of the shaft should be $\frac{21}{20}$ths that given above.

The diameter of the screw shaft is to be tapered off at the forward end to the size of the thrust shaft.

Fuel Tanks and Connections.

Section 4.—1. All fuel tanks and their fittings are to be in accordance with Section 49 (rules for steel ships).

2. Strong and readily removable metallic gauze diaphragms should be fitted at all openings on petrol tanks.

3. No glass gauges are to be fitted to fuel tanks containing either petrol or paraffin oil.

4. Filling pipes are to be carried through the deck so that the gas displaced from the tanks has free escape to the atmosphere.

5. Separate fuel tanks should be provided with metal-lined trays to prevent any possible leakage from them flowing into the bilges or saturating woodwork. Arrangements are to be provided for emptying the tanks and draining the trays beneath them. For petrol tanks the trays must have drains leading overboard where possible, or they should be gauze-covered trays with means for draining them.

6. All petrol or paraffin oil pipes are to be of annealed seamless copper with flexible bends. Their joints are to be conical, metal to metal. A cock or valve is to be fitted at each end of the pipe conveying the fuel from the tank to the carburettor or vaporiser. The fuel pipes should be led in positions where they are protected from mechanical injury and can be exposed to view throughout their whole length.

7. The engine-room and the compartment in which the fuel tanks are situated are to be efficiently ventilated.

8. An approved fire-extinguishing apparatus must be supplied.

Periodical Surveys.

Section 5.—1. The machinery is to be submitted to survey annually. At these surveys the cylinders, pistons, connecting-rods, crank and other shafts, inlet and exhaust valves and gear, clutches, reversing gear, propeller, sea connections, and pumps are to be examined. The electric ignition is to be examined and the electric leads tested. The fuel tanks and all connections are to be examined and, if deemed necessary by the surveyor, to be tested to the same pressure as required when new. If practicable, the engines should be tested under working conditions.

2. The screw shaft is to be examined annually and drawn at intervals of not more than three years in the cases of shafts fitted with continuous liners, and of shafts fitted with approved glands, or other approved appliances, at their after ends to permit of them being efficiently lubricated. In the cases of other shafts, they should be drawn at intervals of not more than two years. (On the application of owners the Committee will be prepared to give consideration to the circumstances of any special case.)

High Compression Oil Engines.

Rules for the Construction and Survey of Diesel engines and their auxiliaries have been adopted by the General Committee of Lloyd's Register, and can be obtained on application to Registrary, 71 Fenchurch Street, London, E.C. 3.

Hot-Air Engines.

Hot-Air engines are now but very rarely used; in the best construction a consumption of 1·8 lb. of gas coke has yielded 1 indicated horse-power, or 2·54 lbs. of coke per b.h.p., the h.p. being calculated after deducting the work required to compress the air. The absolute efficiency is therefore only about 7·9 per cent. referred to b.h.p. In the smaller sizes of hot-air engine the consumption of fuel is usually very much higher than this, and is often 20 lbs. or more per b.h.p. hour.

It is practically impossible to construct an air-engine of any great power, as air, like all other gases, expands but one volume for each 493° of temperature through which it is raised; and, in order to double its volume, we must raise it 493° more, that is, to 986° F., which is much too high for practical purposes. Even if air could be worked at this temperature, it would be necessary to have a feed-pump of nearly the capacity of the engine, and the engine itself would have to be more than twice the size of a steam-engine of the same power.

The Gleniffer Cold Starting Oil Engine.

(*Gleniffer Engines Ltd., Anniesland, Glasgow.*)

The Gleniffer heavy oil engine is of the relatively fast-running type, and is made in units having three, four, and six cylinders. As will be seen from the cross-section (fig. 24), the valves

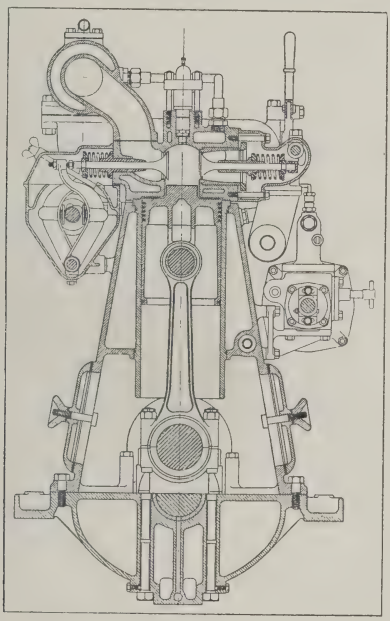

FIG. 24.

are placed horizontally facing each other in the cylinder head, and are operated by the camshaft through levers and pull rods for the admission valves. The engine is of the solid injection type, having the sprayer central over the top of the combustion chamber proper. A projection on the top of the piston increases the turbulence at the top of the stroke by entering a restricted passage in the head. The makers guarantee a fuel consumption of Diesel oil not exceeding 0·44 lb. per b.h.p. per hour. Starting is effected by a compressed air motor, which is mounted over the flywheel, and engages, through a self-disengaging pinion, a gear ring on the flywheel. As soon as the engine starts the air motor is stopped. Compressed air is obtained by employing one of the main engine cylinders as a compressor whilst its fuel pump is cut out of action.

Though solidly constructed the weight is moderate for the power developed, being, in the case of the 4-cylinder 80-h.p. unit, 27 cwts. or 38 lbs. per h.p., and in the case of the same engine arranged for marine duty with reducing gear air receivers, &c., 34½ cwts. or 48 lbs. per h.p.

SECTION XXXII

AUTOMOBILES.

(Contributed by Ernest W. Birch, A.M.I.A.E.)

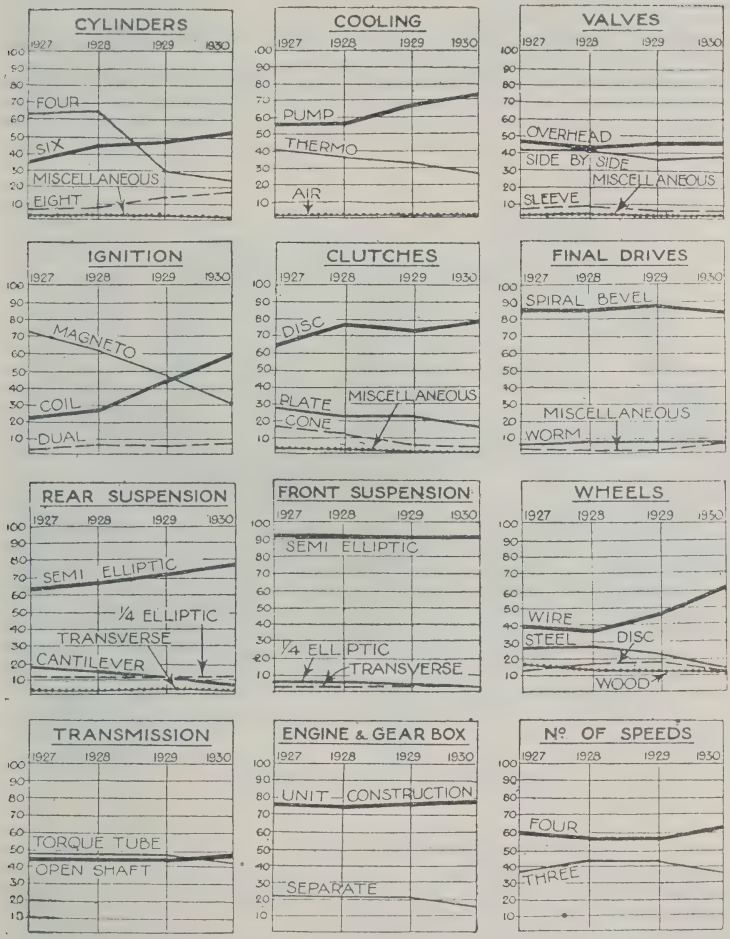

FIG. 1.—Progress in Design, 1927–1930. (*The Autocar.*)

AUTOMOBILES.

Progress in Design.—The four-stroke single-acting, inverted type of engine is in general use. Latest developments show a large increase in the number of six-cylinder engines.

Owing to the horse-power tax it is necessary to make engines of small size, but in America where there are no such restrictions, the eight-cylinder engine is being developed. The progress in design since 1927 is illustrated by the graphs shown in fig. 1. Overhead valves are still the most popular, and bi-metal pistons are coming into use, aluminium alloy being used for the head and gudgeon-pin bosses, and steel or cast-iron sleeves for the skirt. Coil ignition has made great advances, and this is to a great measure due to the increased use of the six-cylinder engine. Further improvements are in the increased size of oil sumps, supply of extra oil to the cylinder walls, and provision for oil cooling.

The single plate (disc) clutch is practically universal, and four-speed gear boxes are increasing in use, and the central gear change is general. Half-elliptic suspension springs are universal in front and are used in the majority of cases for the rear.

Front-wheel drive is receiving considerable attention, and is now standard on several makes.

Other important developments are supercharging, evaporative cooling, thermostatic control of the cooling system, air cleaners, etc., and the improved technique in the manufacture and treatment of the special steels and alloys necessary to meet the exacting requirements of the modern automobile.

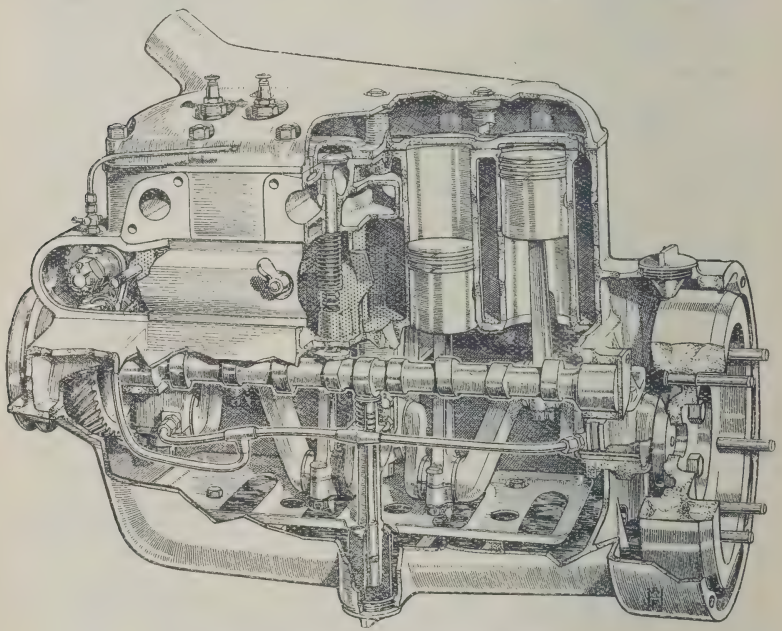

FIG. 2.—Sectional View of the Morris Engine.

THE MORRIS ENGINE.

(Oxford and Cowley Models).

This make represents one of the best examples of 'continuous flow' production in this country. Details of 1929 models are as follows (fig. 2):

Four cylinders cast *en bloc* with the upper half of the crankcase, and fitted with detachable cylinder head. The crankshaft has three white-metal bearings carried upon special bearing blocks attached to the cylinder block.

'*Cowley*' connecting rods 'I' section steel with split small end in which gudgeon pin is clamped by set screw, the gudgeon pin taking its bearing in the piston bosses. '*Oxford*' connecting rods of Duralumin, gudgeon pin fitting the same as for '*Cowley*' model. Piston in both models of aluminium alloy with three rings, the upper one being fitted with special spring centring-ring behind it to reduce liability of piston slap. Side by side valves are used. Camshaft and magneto driven by ekew-gears at forward end of crankshaft. Thermo-syphon cooling assisted by belt-driven fan. Lubrication is by plunger type oil pump driven from an eccentric in the centre of camshaft.

The '*Cowley*' engine develops 22·3 h.p. at 2,800 r.p.m. and the '*Oxford*' 30 h.p. at 2,250 r.p.m.

The six-cylinder model is rated at 17·7 h.p. with a bore of 69 mm. and stroke of 110 mm.

The engine is fitted with an overhead camshaft which operates the overhead valves. The crankshaft is carried in four main bearings, and special attention has been directed in the design of the engine to accessibility.

The 'Morris Minor' has a bore 57 mm., stroke 83 mm., rated at 7·9 h.p. Overhead camshaft and valves. Cylinders cast *en bloc* with detachable head.

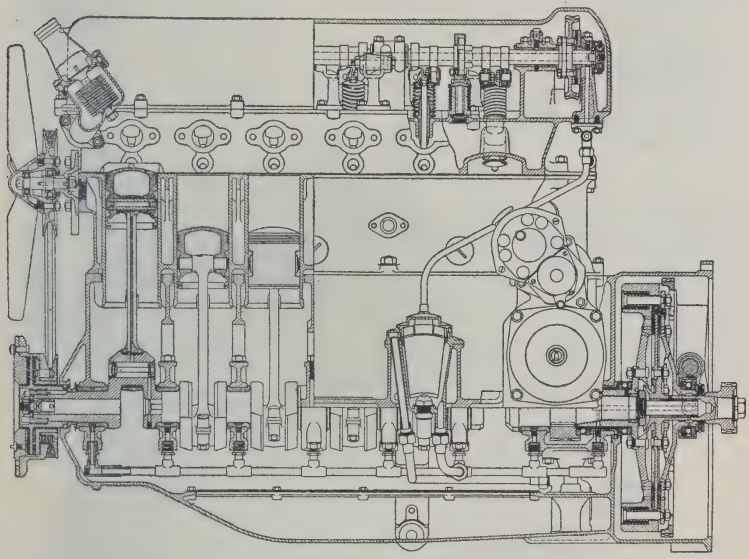

FIG. 3.—Lanchester Engine.

THE LANCHESTER ENGINE.]

Six cylinders 3·1 ins. bore by 4·5 ins. stroke. Treasury rating 23·1 h.p. Swept vloume 203·8 cub. ins. (3,327 c.c.). Power developed at 2,800 r.p.m. is 57 h.p., the brake m.e.p. being 79 lbs. sq. in.

Cylinders cast *en bloc* with detachable head carrying the valves. *Domed* aluminium piston fitted with three light pressure rings and a scraper ring. Hollow floating gudgeon pins with end buttons to prevent scoring of cylinder.

Connecting rods 'I' section with bronze small end bushes and white metal liners for big ends. Crank pin bearings $1\frac{7}{8}$ in. diam. by $1\frac{5}{16}$ in. long. Overhead hollow central camshaft with inclined valves. Camshaft carried on five plain bearings. Damping device provided for damping torsional irregularities. Hollow crankshaft $1\frac{7}{8}$ in. diam. (except for end bearing, which is $2\frac{1}{4}$ in.) carried on seven main bearings of die-cast white metal. Front, middle, and rear bearings $1\frac{7}{8}$ in. long, intermediate journals, $1\frac{3}{4}$ in. long.

Beyond the crankcase proper there is an extension enclosing a vertical shaft and a cross shaft with the gears for driving the overhead camshaft and auxiliaries. An eighth bearing $2\frac{1}{4}$ ins. diam. by $1\frac{5}{8}$ in. long, with white-metal-lined bronze shell, takes the weight of the flywheel.

Daimler Double Sleeve Valve Engine.

This engine operates on the four-stroke, single-acting cycle, but the poppet valves are replaced by cylindrical sliding valves. The piston is enveloped by two open-ended shells which are in turn

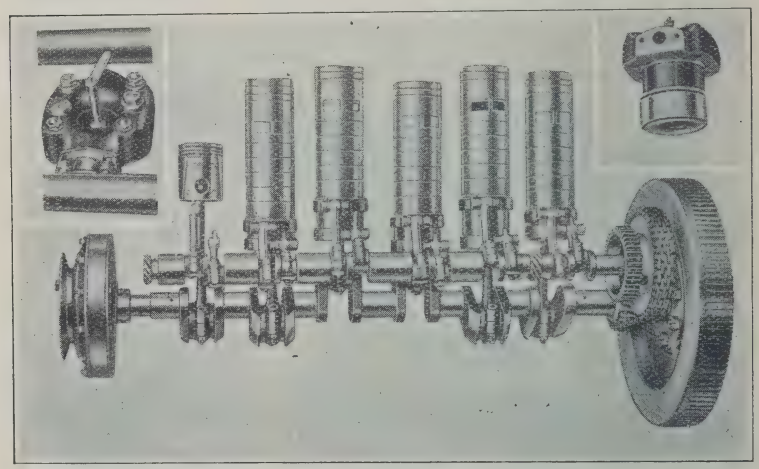

FIG. 4.—Daimler Engine. Sleeve-valve assembly.

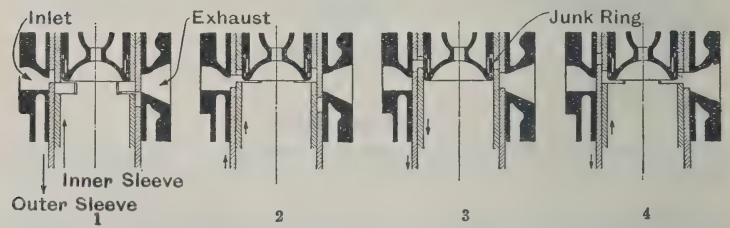

FIG. 5.—Daimler Engine. Valve cycle.

contained within the cylinder casting. These shells are reciprocated in a vertical direction by short links or connecting rods mounted on an independent shaft (fig. 4).

Cycle of Operations.

Diagram 1 (fig. 5) shows the inlet port opening and the exhaust port closing at the beginning of the suction stroke. The inner sleeve is rising and the outer sleeve is descending.

Diagram 2 shows the exhaust closed and the inlet closing at the beginning of the compression stroke. The ports in the inner sleeve are passing up into the cylinder head, where they are sealed by the junk ring during the period of maximum pressure and temperature at the beginning of the firing stroke (*see diagram* 3).

Diagram 4 shows the exhaust already well opened at the beginning of the exhaust stroke. The sleeves are now again moving to the position shown in *diagram* 1.

The complete cycle of operations—suction, compression, firing, and exhaust—occupies two revolutions of the crankshaft.

The latest development is the use of steel sleeves made of seamless drawn tubing in place of cast iron, which, owing to their lightness and great port area, enable the engine to sustain high power with perfect balance at high speeds.

Franklin 26 H.P. Air-cooled Engine.

(American.)

Six cylinders $3\frac{1}{2}$-in. bore by $4\frac{3}{4}$-in. stroke. A special feature of this engine is the system of air cooling. A Sirocco fan directly connected to the front end of the crankshaft supplies air through

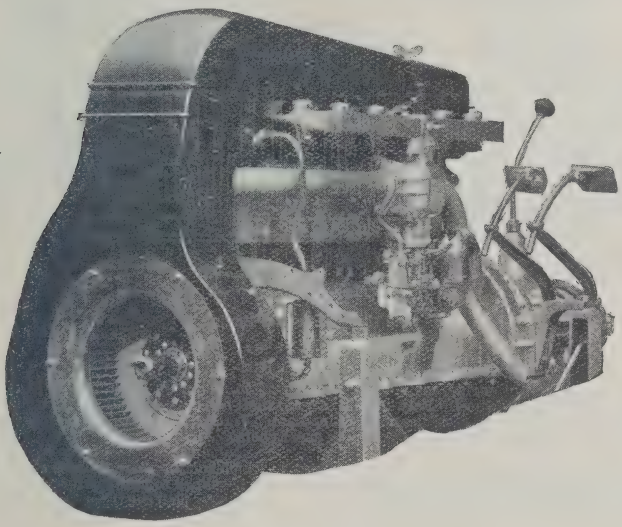

Fig. 6.—Franklin Air-cooled Engine.

a duct over the top of the cylinders, thence through self-enclosing jackets surrounding the cylinders. Deflectors are used to direct the air current in order to secure uniform cooling. At a car speed of 20 m.p.h. the fan absorbs 0·32 h.p. and delivers 1,350 cu. ft. of air.

Crankshaft case-hardened at the seven main bearings. Camshaft has four plain bearings, with cams forged integral with shaft. Timing gear, oil pumps, and ignition driven off camshaft by silent chain. Connecting rods 'I' section of Duralumin, drilled for lubrication of cylinder walls and piston. Aluminium alloy piston with four rings. Gudgeon pin clamped in small end of rod and chromium plated. Cylinders, unit castings of nickel cast iron with copper-cooling flanges cast into cylinder walls.

Packard Engine.

(American.)

Eight cylinders cast *en bloc* with detachable head, 3½-in. bore by 5-in. stroke, swept volume 385 cu. ins. or 6,300 c.c. 106 b.h.p. at 3,200 r.p.m. (*normal speed*), brake m.e.p. 62 lbs. sq. in. Compression ratio, 4·5 : 1.

Side valves of silicon-chrome steel. Aluminium alloy pistons with four rings, weight 24 ozs. Gudgeon pins, hand push fit-in piston boss. Connecting rods of 'I' section, bronze bushed at small end, white-metalled at big end (2 3/16 in. diam. by 1⅜ in. long). Firing order: 1, 3, 2, 5, 8, 6, 7,

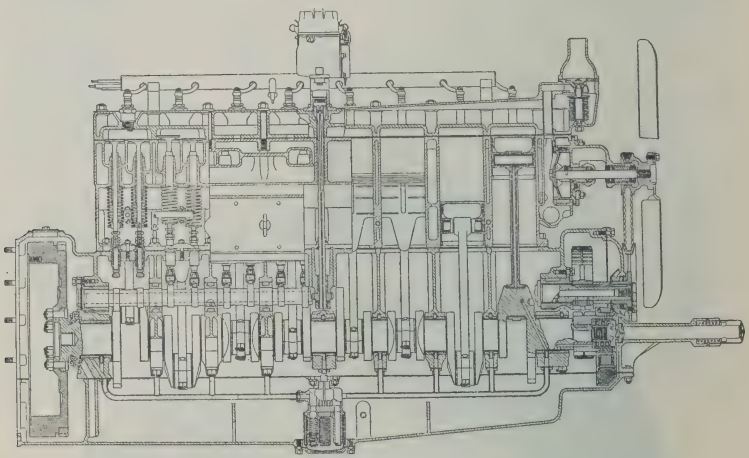

Fig. 7.—Packard Engine.

4, from forward end of engine, main crank bearings 2⅜ in. diam. by 1⅜ in. long. Rear bearing 2½ in. long to support flywheel. Forward end of crankshaft fitted with torsional vibration damper. Hollow camshaft with eight plain bearings, 1⅜ in. diam. Vertical oil pump driven off camshaft by spiral gears. Camshaft and dynamo driven by silent chain.

Water-pump mounted on end of cylinder block in which suction passages are cored. Pump impeller fixed by screw to spindle, the other end of which is splined to take fan boss.

Thermostatic control is fitted to cooling system. Ignition by coil, the timer being driven by a vertical extension of oil-pump shaft.

Analysis of English, American, and Continental Passenger Automobile Practice, 1929–1930.

The figures are the result of an analysis of 100 English cars, 100 American, and 260 Continental. (Figures are in percentages unless otherwise mentioned.)

Main Features of Representative British and Foreign Cars.

Supercharging.

The object of supercharging is to inject a greater quantity of fuel mixture in the period allotted by the timing diagram, thus maintaining the volumetric efficiency at higher engine speeds and increasing the power output.

To supply the required quantity of mixture at the necessary pressure, a pump is provided. There are four types in use : (*a*) Roots blower, (*b*) piston pump, (*c*) vane pump, (*d*) turbo-compressor.

The various methods of supercharging can be classified as (*a*) forced induction, (*b*) supplemented induction, (*c*) scavenging and use of two-stroke cycle.

In system (*a*) the whole of the charge is supplied to the cylinder at a pressure higher than atmospheric, the normal suction of the engine not being utilised.

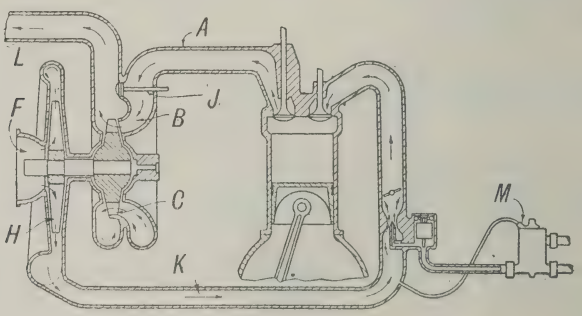

FIG. 8.—Exhaust-turbo Supercharger.

A. Manifold.
B. Nozzle.
C. Turbine wheel.
F. Air intake.
H. Impellor.
K. Air-discharge.

(*b*) The normal suction of the engine is utilised to furnish the greater quantity of the mixture the charge being supplemented by special means.

(*c*) A pump is used that will furnish a volume of air slightly above atmospheric, which is used to free the cylinder and combustion chamber of residual exhaust gases.

Superchargers. Exhaust-driven Turbo-Compressors.—Fig. 8 shows the application of an exhaust-driven supercharger applied to an aero engine. The exhaust gases are collected in manifold A and pass through nozzles B to the turbine wheel C, which is directly coupled to the centrifugal compressor D. In another form the carburettor is connected direct to the suction side of the compressor, and the fuel-air mixture delivered *via* a cooler to the engine.

Positive Displacement Compressors or Eccentric Vane Blowers.—Two general types (*a*) in which the vanes pass through fixed slots in the rotor and the blades are free to fly out under centrifugal action till they make contact with a drum or ring (see fig. 9*a*) ; (*b*) in which the vanes pass through oscillating slots in the rotor and the blades are attached to a lay shaft which coincides with the axis of the casing. The blades do not run out under centrifugal action, but run with a fixed tip clearance inside the casing (see fig. 9*b*).

In the fixed slot type, friction and wear of the blades have been experienced, also the lubrication and friction in the blade guides have proved troublesome.

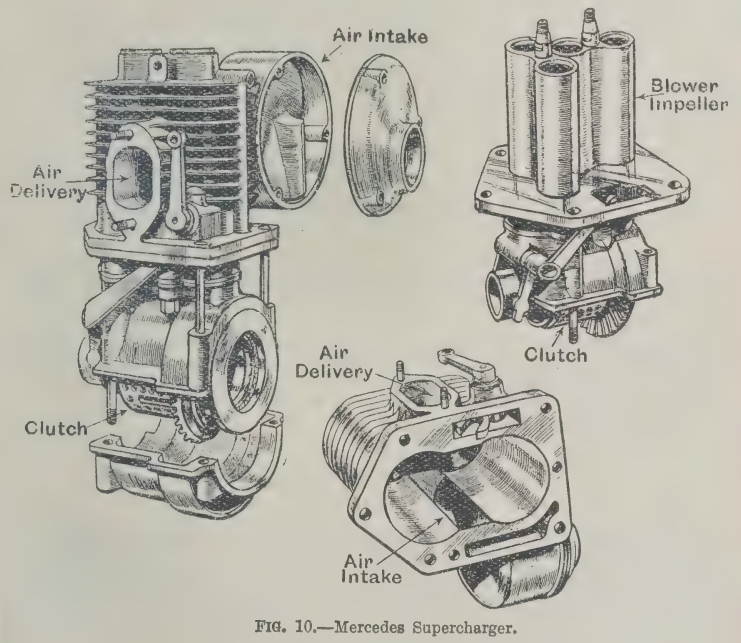

FIG. 10.—Mercedes Supercharger.

Fig. 10 gives details of a Roots' blower type supercharger used on the Mercedes engine. It only becomes operative when the accelerator pedal is depressed past the full open throttle position. This brings into operation a multi-disc clutch that engages a set of bevel gears, and automatically connects the supercharger and closes the normal carburettor intake.

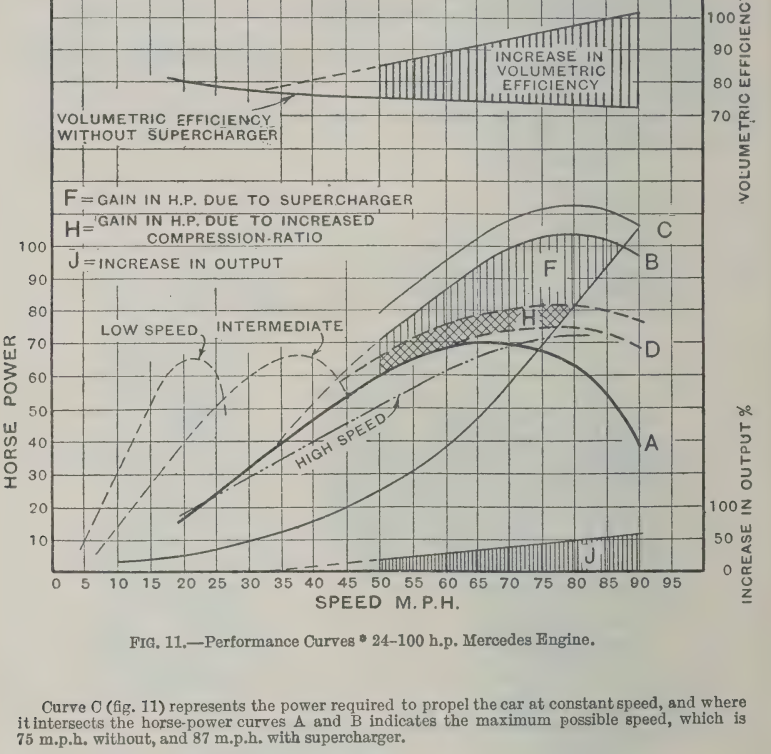

Fig. 11.—Performance Curves * 24–100 h.p. Mercedes Engine.

Curve C (fig. 11) represents the power required to propel the car at constant speed, and where it intersects the horse-power curves A and B indicates the maximum possible speed, which is 75 m.p.h. without, and 87 m.p.h. with supercharger.

Curve A = power output without supercharger.

B = power output with supercharger.

Supercharger Design (Roots' Type).

(*Schwitzer.*)

The mathematically correct cycloidal section is shown at A, fig. 12, in which the diameter of the generating circle is one quarter of the pitch circle. The area included between the housing bore and the sides of the wing section represents the 'bucket' in which the air is carried from the low-pressure to the high-pressure side. The larger this area in relation to the area of the wing section the greater the volumetric efficiency. This area can be increased by using a larger generating circle as at B. The resulting epicycloid will mate with the corresponding hypocycloid in the other

* C. W Iseler, *Proc. S.A.E.*

wing up to the point *a*, which is reached by the generating point when the generating circle has rolled one-eighth of the way round the pitch circle. Beyond this point the curves will not mate at tip and waist, hence the relief shown. The gain in volumetric efficiency over type A is about 7 per cent.

At C the increasing of the size of the bucket is carried to the limit making the diameter of the generating circle one-half that of the pitch circle, the hypocycloid being a straight radial line. These proportions would cut the wing in two if the whole line were used. As at B the curves will not mate beyond *a*, and the gaps can be filled in with circular arcs having their centres on the pitch circle. The gain in efficiency is about 18 per cent. over that at A. The section at D is built up of

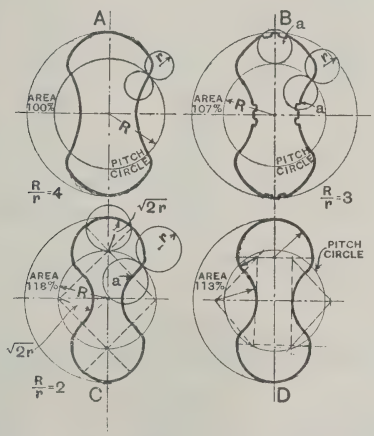

FIG. 12.—Wing Sections for Roots' type Supercharger.

an approximation of circular arcs. It is more efficient by about 13 per cent. than section at A. It is substantially the section used in the latest 'Mercedes' supercharger. This section gives adequate waist strength and the clearance between a pair of wings gradually increases. With this design more backlash can be allowed in the gears than in a mathematically perfect section running with uniform clearance.

The following table shows the effect of the addition of a supercharger to a standard engine:—

R.P.M.	B.H.P.		Power required by Supercharger.	Friction H.P.	
	A.	B.		A.	B.
400	6	7	—	1·0	1·3
800	16	20	0·6	3·0	3·6
1,200	24	32	1·7	4·5	6·2
1,600	31	45	2·7	7·3	10·0
2,000	37	56	4·0	10·0	14·0
2,400	41·5	64	5·8	13·5	19·3
2,800	43·5	68·5	8·3	17·7	26·0
3,000	43	70·0	10·4	20·5	31·0

A. Without Supercharger. B. With Supercharger.

Fuel Distribution to Cylinders.

Tests made on a standard four cylinder 22·5 h.p. car, showed the following values, the latter being determined from gas analysis.

Cylinder No.		CO_2 in Exhaust. Per Cent.	Air Fuel Ratio.	Distribution. Per Cent.	Excess or Deficiency. Per Cent.
A.	1	8·1	10·9	28·5	+ 14·0
	2	8·4	11·1	27·4	+ 9·6
	3	12·0	13·5	21·8	— 12·8
	4	11·6	13·3	22·3	— 10·8
B.	1	9·0	11·5	27·2	+ 8·8
	2	9·5	11·9	26·6	+ 6·4
	3	11·4	13·1	23·2	— 7·2
	4	11·9	13·4	23·0	— 8·0

A = tested at 15 m.p.h. up a 4 per cent. gradient. B = tested at 30 m.p.h. up a 4 per cent. gradient.

The tests show that the two front cylinders (Nos. 1 and 2) are subject to 'loading-up,' particularly at the lower speed.

Air Filters.

Measurements of engine wear of two identical 6-cylinder engines after running under similar conditions:—

		With Air-filter.	Without Air-filter.
Cylinder walls		0·0011 in.	0·0090 in.
Pistons		0·0005 ,,	0·0036 ,,
Ring groove clearance	Upper	0·0110 ,,	0·0650 ,,
	Middle	0·0040 ,,	0·0660 ,,
	Lower	0·0014 ,,	0·0230 ,,
Percentage of incombustible matter in carbon		6·5	31·0

Carburettors.

Sections of typical carburettors are shown in fig. 13, p. 1950.

Location of Carburettor Intake.

As the result of road tests, the best position appears to be (*a*) on the side of the engine on which the fan blades have a descending motion; (*b*) about mid-way between the radiator and the dash; (*c*) about mid-way between the side of the bonnet and the centre line of engine; (*d*) about one-third of the distance down from the top of the bonnet towards the top of the cylinder head.

Engine Starting.

Within certain limits the richness of the fuel determines the number of revolutions the engine must make before an explosion is obtained. Richness of mixture in the cylinder rather than that of the mixture leaving the carburettor determines whether or not an explosion will occur, and it is suggested that this is a function of delayed vaporisation of fuel left in liquid form in the manifold and cylinder during previous cycles. (*T. O. Eisinger.*)

Detonation and Anti-Knock Substances.*

The phenomenon of detonation appears to be substantially as follows:—When a mixture of hydrocarbon vapour and air is compressed to a high pressure and to a temperature approaching that of its self-ignition temperature, and is then ignited from any one point, the flame at first spreads by the normal process of combustion, compressing before it the unburnt portion of the charge. When the rise in temperature of the unburnt portion due to compression by the burning gases exceeds the rate of heat dissipation by a certain margin, spontaneous ignition of the former takes place, and an explosion wave is set up which strikes the cylinder walls with a hammer-like blow, thus causing the metallic ring, known as 'pinking' on detonating.

A number substances will suppress detonation (*anti-knock*), whilst others will induce it.

Element.	Form in which Used.	Effect on Detonation.
Iodine	Element.	Suppresses.
Bromine	Element.	Induces.
Oxygen	Element.	Induces.
Oxygen	Ethyl nitrite or nitrate	Induces.
Nitrogen	Aniline.	Suppresses.
Selenium Tellurium Tin	Di-ethyl compounds	Suppresses.
Lead	Tetra-ethyl compounds.	Suppresses.

'*Anti-knock* substances are efficient when present in minute proportions, and in the case of lead-tetra-ethyl, one molecule in 200,000 molecules of air-fuel mixture is sufficient.

Element.	Compound.	Corresponding Per Cent. by Volume.	Corresponding Number of Molecules of Theoretical Air-Fuel Mixture to one Molecule of Anti-Knock.
—	Benzene	25·0	150
Iodine	Ethyl-iodide	1·6	2,150
Nitrogen	Xylidine	2·0	2,600
Tin	Tin-tetra-ethyl.	1·2	7,100
Selenium	Di-ethyl-selenide.	0·4	11,750
Tellurium	Di-ethyl-telluride	0·1	50,000
Lead	Lead-tetra-ethyl.	0·04	215,000

In using lead-tetra-ethyl it is necessary to add some halogen-containing compound to counteract the harmful action on the sparkling plug electrodes. Carbon tetra-chloride, or ethylene dibromide can be used, the function of these compounds being to convert the lead into lead halides immediately after combustion. Lead-tetra-ethyl is a colourless liquid. S.G. 1·62, boiling point 152° C., miscible with petrol in all proportions and poisonous.

Approximate composition of ethyl fluid: Lead ethyl, 54 per cent.; ethylene dibromide, 36 per cent.; monochlornaphthalene, 9 per cent.†

A usual proportion is 5 c.c. of above mixture to 1 gal. of fuel.

Mechanical Losses in Engines.*

The mechanical losses remain practically constant, irrespective of the torque, for though the friction increases slightly with an increase of load, the work done in filling the cylinder increases as the throttle is closed, and the two practically balance. An 80 per cent. mechanical efficiency at full load becomes only 55 per cent. at 30 per cent. of full torque, while a 90 per cent. efficiency becomes 73 per cent., so that the difference that has to be taken into account is not that between 80 per cent. and 90 per cent., but between 55 per cent. and 73 per cent.

Of the gross mechanical losses, piston friction in a well-designed engine accounts for about 60 per cent. of the total. Pumping losses account for about 25 per cent., while the friction of the bearings and all the auxiliary gear amounts to about 15 per cent. Piston friction can best be reduced by keeping both the weight and bearing surface of the piston down to the minimum. Pumping losses are not susceptible of much reduction. A little can be done by the use of large valves and the most suitable timing, but on reduced loads the losses are mainly due to the restriction through partially closed throttle. These losses are therefore more or less inevitable unless means can be found to work with a weakened instead of a throttling mixture. Unless means be adopted to augment turbulence during the compression the valves must be kept fairly

* H. R. Ricardo, *Proc. I.A.E.*

small and the velocity through them high, or slow and incomplete combustion, with loss of power, efficiency, and excessive heat flow will result. The friction of the bearings is relatively small.

It is almost impossible to assess the losses due to general vibration. However, an engine cannot vibrate without absorbing a considerable amount of energy. Every effort should be made to ensure the best possible balance.

Excessive turbulence gives rise to excessive heat losses and a narrowing of the mixture range.

It gives rise also to excessive roughness of running. The optimum degree of turbulence from the point of view of efficiency corresponds to a rate of pressure rise of 30 to 40 lbs. per sq. in. per degree of crankshaft travel. It is the rate of pressure rise, and not the maximum pressure which gives rise to harshness. A high compression engine, so long as it is not detonating, will be as sweet running as a low compression one, provided its rate of pressure rise is the same or less.

Heat Losses in Engines.

Heat Flow through Cylinder Walls.

Average Heat Flow. B.Th.U.'s per sq. in. per minute.

Water-Jacketed Engines.	6-Cylinder Passenger Car.	6-Cylinder Motor Coach.	12-Cylinder Aircraft.

Surface, sq. ins.	540	1,150	2,520
Average heat flow B.Th.U.'s per sq. in. per min.	4·6	6·4	4·3

Heat Losses to the Cylinder Jackets.

Type of Cylinder.	Heat Loss. B.Th.U.'s./min/B.H.P.	Water evaporated. Lbs./min./B.H.P.
Aviation	30	0·03
Valve in head	50	0·05
L-Head	70	0·07
T-Head	80	0·08

To guarantee that the cylinder block will always be full of water, it is necessary to pump more water than can ever be evaporated. In practice it has been found desirable to pump $2\frac{1}{2}$ times the maximum evaporative requirements. The water pipes should be large enough to carry this quantity of water without undue pressure drop, or at a velocity exceeding 6 ft. per sec.

$$\text{Minimum inside diameter, } d'' = \sqrt{\frac{(4 \times 28{\cdot}8 W_p) \div (60 \times 60 \times 12\pi)}{}} = \sqrt{0{\cdot}0085\, W_p}.$$

W_p = weight of water pumped in pounds per min.;

28·8 = volume in cubic inches of 1 lb. of water at 212° F.

For average conditions in a cylinder jacket, the temperature drop through the water film is approximately 20–25° F. The temperature of cylinder walls will increase approximately with an increase in water temperature until it has reached 185–190° F., when no further rise in the cylinder wall temperature will occur so long as the heated surface is wet with water or foam. The effect of a carbon or lime deposit $\frac{1}{32}$ in. thick may cause an increase of inner wall temperature of some 200° F.

Analysis of Heat Losses.

(*H. R. Ricardo.*)

In the case of a well-designed engine, with a compression ratio of 5 : 1, about 32 per cent. of the total heat of the fuel is converted into useful work on the piston, 28 per cent. is carried away by the cooling water, and the remaining 40 per cent. is lost to radiation, exhaust, etc. Of the total heat carried away by the cooling water, approximately 6 per cent. will be lost to cylinder walls during the combustion period, 7 per cent. will be yielded up during expansion, and 15 per cent. during exhaust stroke.

Of the 6 per cent. lost during the combustion period about 40 per cent. appears as useful work, or 2·4 per cent. of the total heat of the fuel. Of the 7 per cent. lost during expansion, about 20 per cent. will be utilised, or 1·4 per cent. of the total heat of the fuel. Of the 15 per cent. lost during exhaust stroke, no part could be utilised.

Although 28 per cent. of the total heat of the fuel is carried away by the cooling water, only 5·8 per cent. could be converted directly into useful work on the piston, and the efficiency of the engine would be increased from 30 per cent. to 35·8 per cent., a gain of barely 12 per cent.

If all the loss of heat to the cylinder walls be suppressed, the temperature of the working fluid would be corespondingly higher, with a result that the losses due to the increase of specific heat and of dissociation at the higher temperature would be substantially increased, and a net gain from 32 per cent. to about 34·5 per cent.

These figures indicate the relatively small part the loss of heat to the cylinder walls plays in an internal combustion engine, and how misleading it may be to assess that loss of heat by the heat carried away by the cooling water. As a first approximation it is fairly correct to assume that, of all the heat carried away by the cooling water of a cylinder, little more than 10 per cent. would actually be converted directly into useful work.

Water Pump.

(Gear Type.)

Capacity of gear pumps can be calculated from the volume of the space between the teeth of the gears. This space can be assumed to be equal to one-half the volume between the outside cylinder and the root cylinder of the gears. As two gears are working, the theoretical delivery per revolution will be equal to the difference in area between the outside and the root circle of one gear times its width. Tests of pumps running at 1500–2000 r.p.m. with boiling water show that the actual delivery is 20–30 per cent. of this amount.

$$W_p = 0{\cdot}25 \times 0{\cdot}0346 \frac{\pi}{4} (D^2 - d^2)FN = 0{\cdot}0068\ (D^2 - d^2)FN$$

or,
$$\frac{147W_p}{N} = (D^2 - d^2)F$$

where,
d = root diam. of gear-ins.; D = outside diam. of gear-ins.; F = width of gear-ins.; N = r.p.m. of pump gears; W_p = weight of water pumped; lbs. per min.; 0·0346 = weight of 1 cu. in. of water at 212° F.

(*A. G. Herreshoff*, '*Proc. S.A.E.*')

Boilerine Radiator Tablets.

These tablets, invented and manufactured only by Boilerine Limited, are for the purpose of obviating the fur which forms in radiators and water-jackets. There is nothing in the preparation detrimental to the joints or metal parts. Where scale is already in existence 25 tablets per gallon of water take the lime into solution, dissolving the particles, thus leaving the walls of the cylinder-jackets and radiator tubes perfectly clean.

Following this cleaning process all water put in the radiator should be ' Boilerined ' to the extent of 2 tablets per gallon, up to 14 degrees of hardness, and one extra tablet for every 7 degrees beyond; one tablet per gallon for rain water to prevent rust.

When water is poured into the radiator, it amounts to putting in a quantity of lime or chalk, or if soft water, a means of producing rust.

If this is done without ' Boilerine ' tablets, the lime adheres to the walls of the cylinders and radiator tubes until efficiency is choked out of the cooling system.

Boilerine Limited have proved from tests that thirty hours heating of water at 190° F. gives nearly the same amount of deposit as half an hour's boiling, thus, surely, though unseen, the motor is, at the workin gtemperatures, storing up in its cooling system this cause of trouble, consequently the flow of water is reduced, producing overheating, or allowing the impurities in the water to cause rust and corrosion, hence leakages.

These claims are confirmed by the reports given on tests of twelve and six months' duration respectively, made by Thomas Tilling, Ltd., and W. H. Dorman & Co., Ltd., Stafford.

Crankcase Corrosion.

The presence of water in the crankcase is responsible for the corrosion. The quantity of water present in the products of combustion is dependent upon the hydrogen content of the fuel, the mixture ratio, and the humidity of the air that enters the engine. The amount of water that may be condensed on the cylinder walls or in the crankcase depends upon the effectiveness of the piston and piston rings in preventing gas leakage, the temperature of the cylinder walls and crankcase, and the extent of the breather action. Condensation of water from the gases of combustion will start at approximately 130° F. when petrol is used, and at 123° F. when a 50 per cent. mixture of petrol and benzol is used. The relative freedom of some engines from water accumulation is due to their higher operating temperatures, or to the better interchange of air by breather action, which results in dilution of the gases in the crankcase and consequent reduction of the saturation temperature of the gases.

Water alone will cause corrosion, but the action may be accelerated by the formation of weak sulphurous or sulphuric acid.

In order to reduce water accumulation, pistons must reduce blow-by, and in addition means should be provided to reduce the warming-up period and ventilate the crankcase. Either air- or steam-cooling, with provision for controlled heating of the crankcase, is favourable for the solution of the problem.

(*M. A. Thorne*, '*Proc. S.A.E.*')

Chromium plating of the crankcase has proved an effective measure against corrosion (see p. 2704).

Engine Efficiency Constants.*

The following equation for efficiency is recommended by Tizard and Pye, and is based upon a 20 per cent. weak mixture, which corresponds very closely to the conditions under which the maximum observed efficiencies are now obtained.

$$E = 1 - \left(\frac{1}{r}\right)^{0 \cdot 296}.$$

r.	E.	*r.*	E.	*r.*	E.	*r.*	E.	*r.*	E.	*r.*	E.

Firing Order.

From considerations of balance it is necessary to get as uniform a turning-moment as possible. Four-cylinder engines are so arranged that there is a power impulse every stroke or two power impulses every revolution, the one beginning as the other ends. The crank throws are placed all in one plane, the two centre throws being together and at 180° to the two outer throws. With this arrangement two orders of firing are possible, viz. 1–2–4–3 and 1–3–4–2; both are used, but the latter is the more general.

With a six-cylinder engine the throws are divided into three positions or 120° apart. 1 and 6 are always in line, 3 and 4 are always in line, and 2 and 5 are always in line. For a right-hand crank the firing order is 1–5–3–6–2–4 or 1–2–4–6–5–3, and for a left-hand crank 1–4–2–6–3–5 or 1–3–5–6–4–2.

For an eight-cylinder 'V' engine:

$$\left.\begin{matrix}8\text{–}7\text{–}5\text{–}2\\1\text{–}4\text{–}6\text{–}3\end{matrix}\right\} \text{ or } \left\{\begin{matrix}1\text{–}3\text{–}4\text{–}2\\8\text{–}6\text{–}5\text{–}7\end{matrix}\right.$$

For an eight-cylinder 'in-line':

(*a*) 1–5–3–7–4–8–2–6
(*b*) 1–7–3–5–4–2–6–8
(*c*) 1–3–2–5–8–6–7–4
(*d*) 1–5–2–6–4–8–3–7

* I.A.E. Data Sheet No. 205.

Effect of Changes in the Compression Ratio upon Engine Performance.*

With an increase in the compression ratio there is usually an increase in b.h.p. and a decrease in consumption up to a ratio of 14 : 1, provided there is no serious pre-ignition or detonation. The changes in indicated thermal efficiency with changes in compression ratio are in close agreement with those based on the air-cycle efficiencies at the various ratios.

Change in the compression ratio does not produce a consistent change in the friction h.p. volumetric efficiency, or in the range of fuel-air ratios over which the engine can operate. The ratio between the heat loss to the jacket-water and the heat converted into b.h.p. or i.h.p. decreases with an increase in the compression-ratio.

Explosion Pressures in Petrol Engines.

(Research Association of British Motor and Allied Manufacturers.)

The general expression for the explosion pressure is :—

$$P_3 = \frac{0{\cdot}3\,(r-1)}{1-r^{\cdot 3}}\left\{P_i + P_0 \cdot \frac{r}{r-1}\cdot\frac{r^{\gamma'-1}-1}{\gamma'-1}\right\}$$

where

r = compression ratio.
P_3 = explosion pressure, lbs. per sq. in. absolute.
P_0 = pressure at the end of the suction stroke, which is assumed to lie between 12 and 14 lbs. per sq. in. absolute.
P_e = brake mean effective pressure, lbs. per sq. in.
γ = ratio of specific heats; this for the explosion curve is assumed to be 1·3, and for the compression curve, where the ratio is denoted by γ' = 0·64 + 0·05P_0.
P_i = theoretical mean indicated effective pressure, and may be written $P_i = \frac{P_e}{\eta\, K}$ where η is the mechanical efficiency, and K the diagram factor representing the proportion of the actual indicator diagram to the sharp-cornered constant-volume cycle diagram assumed in the calculations.

The above equation may be reduced to the equivalent form :—

$$P_3 = (0{\cdot}72 + 0{\cdot}482r)\left\{\frac{P_e}{\eta\, K} + 5{\cdot}427 + 0{\cdot}780\,P_0 + r\,(0{\cdot}642\,P_0 - 4{\cdot}801)\right\}$$

which agrees with above exact equation to within one part in 400.

Piston Clearance and Compression Ratio.

Analysis of 100 different makes of engines show the average clearance for cast-iron pistons to be 0·013 in. at the top and 0·003 in. at the bottom.

The extreme values were :—Top, max. 0·026 in., min. 0·002 in. Bottom, max. 0·005 in., min. 0·001 in.

Average compression ratio 4·42 : max. value 5·76 ; min. value 3·33. (Compression ratio = Ratio of total cylinder volume to combustion chamber volume.) In general 4·5 may be considered as high compression, 4·0 as medium, and 3·5, or below, as low.

* Report No. 205, National Advisory Committee for Aeronautics, U.S.A.

$$\text{Compression Ratio, } r = \frac{\text{Combustion space + swept volume}}{\text{combustion space}}.$$

$$\text{Air Standard Efficiency, } E = 1 - \left(\frac{1}{r}\right)^{1\cdot4} - 1.$$

Brake M.E.P.

d = diameter of piston.; s = stroke; n = r.p.m. of crankshaft; P = total m.e.p. on piston, lbs. per sq. in.; p = brake m.e.p., lbs. per sq. in.; c = power strokes per revolution of crank.

If d and s are in inches,

$$\text{B.h.p.} = \frac{s.d.^2p.n.c.}{504300}; \quad \text{P} = \frac{396000 \text{ b.h.p.}}{s \times c \times n}; \quad p = \frac{504300 \text{ b.h.p.}}{s.d.^2n.c.}.$$

If d and s are in millimetres,

$$\text{B.h.p.} = \frac{s.d.^2p.n.c.}{8262 \times 10^6}; \quad \text{P} = \frac{\text{b.p.h.} \times 1006 \times 10^6}{s.n.c.}; \quad p = \frac{\text{b.h.p.} \times 8262 \times 10^6}{s.d.^2n.c.}.$$

Pistons.

The material most generally used at present is Cast Iron, but great advances have been made in the use of non-ferrous alloys, and the following, which is an extract from a paper by L. Aitchison, indicates their advantages.

Light alloy pistons are in general use for aero engines and racing car engines. The main advantages in their use are :—

(*a*) Owing to their light weight, friction is reduced, and also the loading on the connecting-rod bearings, due to the reduction of inertia of the reciprocating parts.

(*b*) Owing to the lower temperature of the crown (due to the greater thermal conductivity) little or no carbonisation of the lubricating oil takes place on the under-side.

(*c*) Owing to the lower mean temperature of the oil film between the piston and cylinder walls, less oil may be used without risk of piston seizure.

A disadvantage in their use is due to larger coefficient of expansion, which necessitates increased clearance and is the cause of 'piston-slap.'

The Ricardo Piston.

This piston, fig. 14, is a 'slipper' type and aims at securing increased power by the reduction of friction and weight. The contamination of the lubricating oil due to gas leaking past the rings, which takes place in the ordinary form of piston, is reduced by allowing the leaking gas to escape before reaching the piston skirt. Also the lower ring groove is bevelled and drilled to enable the ring to act as a scraper.

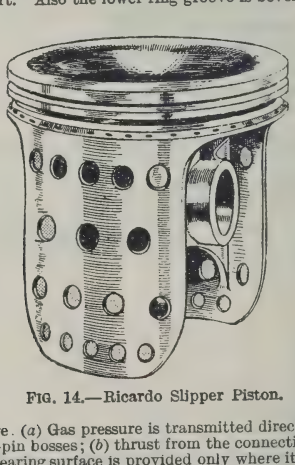

Fig. 14.—Ricardo Slipper Piston.

Features of this piston are. (*a*) Gas pressure is transmitted direct from the crown of the piston to the centre of the gudgeon-pin bosses; (*b*) thrust from the connecting rod is transmitted directly to the bearing surfaces; (*c*) bearing surface is provided only where it is needed; (*d*) gases that pass the piston-rings may escape freely into the crank case; (*e*) no wad is transmitted through the side-

walls, or past the piston-ring grooves; (*f*) the lower piston-ring acts as a scraper, so that oil that has worked up past the slippers can be returned through the small holes beneath. Tests made with this piston showed a reduction in oil consumption from 0·06 lbs. per h.p. hour, to 0·035 lbs. At the same time fuel consumption dropped 4 per cent. with about 4 per cent. increase in b.h.p. For cylinder bores ranging from 3½ ins. to 5 ins. the weight of the piston, complete with gudgeon pin and piston rings, can be reduced to 0·1 lb. per sq. in. of piston area.

Tolerances on Weights of Pistons and Connecting Rods.

(S.M.M. & T. Provisional Standard No. 53, 1928.)

TOLERANCES ON WEIGHTS OF PISTONS.

Diameter of Piston.	Maximum tolerance. Aluminium Pistons. oz.	Cast-iron Pistons. oz.
Up to 70 mm. inclusive	±¼	±½
Over 70 mm. and up to 100 mm. inclusive	±½	±¾
Over 100 mm. and up to 130 mm. inclusive	±¾	±1

TOLERANCES ON WEIGHTS OF CONNECTING RODS.

Weight of Connecting Rod.	Max. Tolerance. oz.
Up to 50 oz. inclusive	±¼
Over 50 oz. and up to 100 oz. inclusive	±⅜
Over 100 oz. and up to 150 oz. inclusive	±½

The weight of a connecting rod shall be that of an assembled rod, the tolerance being on the gross weight. Not more than half the tolerance shall be taken on the small end of a connecting rod.

DESIGN OF PISTON RINGS.

The practice of making eccentric piston rings with the idea of obtaining equal distribution of radial pressure is now being replaced by the use of concentric rings which have been subjected to hammering or peening. The effect of peening is to reduce the nominal modulus of elasticity, E_n, by about 10-15 per cent. (There is no definite elastic modulus for cast iron, as no part of the stress-strain diagram is straight.) The minimum value for the modulus is given in B.E.S.A. specification, No. 5003/1927, as $13 \cdot 5 \times 10^6$ lbs. per sq. in., and the maximum value as $15 \cdot 5 \times 10^6$ lbs. per sq. in. According to the British Piston Ring Co., Ltd., the value of E_n for good piston ring iron varies from approximately $15–17 \times 10^6$ lbs. per sq. in., but the effect of hammering is to reduce this by about $1 \cdot 5 \times 10^6$, so that the value of E_n for the finished rings should be between $13 \cdot 5–15 \cdot 5 \times 10^6$ lbs. per sq. in.

If

d = diameter of cylinder bore, ins.;

t = radial thickness of ring, ins.;

b = width of ring measured parallel to cylinder axis, ins.;

δ = Free gap in ins. (measured in a straight line tangential to the circumference of ring and parallel to the plane of the ring);

p = pressure between ring and cylinder wall per sq. in. of contact area;

f = calculated maximum stress in tons per sq. in., assuming the material to be truly elastic, and of modulus E_n;

E_n = nominal Young's Modulus;

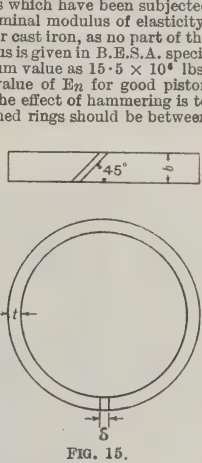

FIG. 15.

Q = diametral load in lbs. applied along diameter of ring corresponding to a change of gap of δ_1 ins.;

then

$$E_n = \frac{5 \cdot 37 \left(\frac{d}{t} - 1\right)^3 Q_1}{b \cdot \delta_1}$$

Minimum thickness of ring $= \frac{d}{30}$.

Maximum thickness of ring $= \frac{d}{30} + 0{\cdot}008$ in.

Width of ring varies in steps from $\frac{d}{16}$ for 2-in. size to $\frac{d}{24}$ for the 6-in. size.

Tolerance $= \begin{matrix} -0{\cdot}001 \text{ in.} \\ +0{\cdot}000 \text{ in.} \end{matrix}$

Maximum free gap $= \frac{d}{7{\cdot}5}$. Such a gap produces approximately the same stress in the ring during the operation of placing it over the piston as it has when in its closed position in the cylinder, but since the ring is continuously closed in the cylinder it is desirable to use a smaller free gap so as to reduce the stress in the ring under working conditions. A free gap of $3\frac{1}{2}$ times the minimum thickness is more satisfactory in practice.

A ring with a free gap of $3{\cdot}5 \times \frac{d}{30}$ gives a minimum pressure of 9·15 lbs. per sq. in. (taking $E_n = 13{\cdot}5 \times 10^6$ lbs. per sq. in.).

$$\text{Cylinder wall pressure } p = \frac{\left(\frac{\delta_1}{t}\right) E_n}{7{\cdot}08 \left(\frac{d}{t}\right) \left(\frac{d}{t} - 1\right)^3},$$

where δ_1 is the difference in inches between the free gap and the gap when in the cylinder measured in the same manner as δ.

$$\text{Maximum stress } f = \frac{\left(\frac{\delta_1}{t}\right) E_n}{5280 \left(\frac{d}{t} - 1\right)^2} \text{ tons per sq. in.}$$

In a ring having a free gap of $3\frac{1}{2} \times t$, the change of gap (δ_1) is approximately equal to $4\frac{1}{2} \times t$ when putting the ring over the piston, and $3\frac{1}{2} \times t$ when putting it into the cylinder.

The load Q is calculated from $Q = \left(\frac{3\pi}{\pi + 4}\right) p.b.d.$,

where b and d are in inch units, p is expressed in lbs. per sq. in., and Q in lbs.

Ignition.

Two systems are in general use (*a*) magneto, (*b*) coil. The magneto may have either a rotating armature or a stationary one, in which case it is known as ' Polar Inductor Type.'

With a stationary armature the current reaches a maximum four times during each revolution of the rotating member or rotor, thus it is possible to produce two or four sparks per revolution of the magneto shaft. In the B.T.H. magneto of this type there are two cobalt-steel magnets fitted on the sides of the main body casting, making intimate contact with two laminated annular poles at each end of the body casting. The poles of the magnets are disposed axially so that the two laminated poles at the ends of the body casting are of opposite magnetic polarity. The flux enters the annular ends of the rotating inductors *via* the small air gap, passing through the inductors to the armature core.

The laminated core (fig. 16), is wound with primary and secondary windings, the beginning of the primary winding being earthed to one of the core flanges. The commencement of the secondary winding is connected to the end of the primary winding, and the end to a brass insert in the armature coil moulding. The condenser, which is carried on the core flanges, makes contact with the flange on one side and with the insulated screw, under which the end of the primary winding is located, on the other.

The low-tension lead from the insulated side of the condenser to the insulated contact of the contact breaker completes the primary circuit.

It is necessary to close and open the primary circuit, and this is effected by a cam mounted on the end of the rotor shaft. This cam operates a bell-crank lever, the end of which carries the movable contact.

In operation the primary winding is short-circuited when the contacts are closed and, as the inductors rotate, the current induced in the primary windings builds up until the cam separates the contacts at the instant when this current is a maximum.

The current induced in the primary winding sets up an intense magnetic field which links itself with the secondary winding, and when the primary current is suddenly broken by the action of the contact breaker this field collapses, with the result that a very high voltage is induced in the secondary winding, giving rise to a spark at the plug.

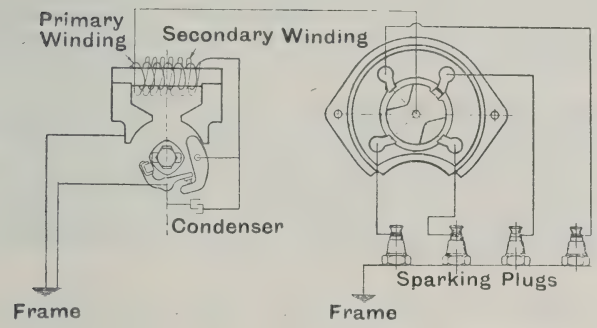

FIG. 16.

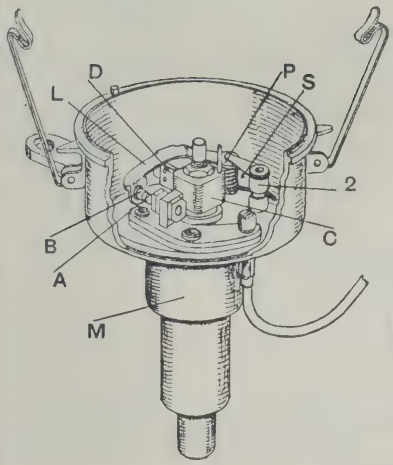

FIG. 17.

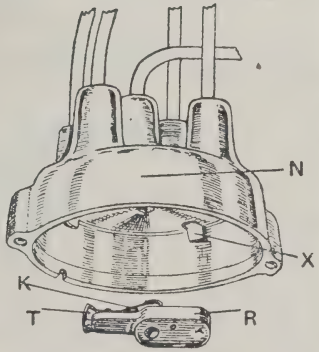

FIG. 18.

The condenser quenches the arc at the contacts, and results in a rapid collapse of the magnetic field linked with the secondary.

In a coil ignition system, such as the Delco-Remy, an intense spark is obtained by converting low voltage current, generated by a dynamo set, into high voltage. For this purpose an ignition coil, combined circuit breaker, and distributing mechanism form a single unit known as the distributor. See figs. 17 and 18.

Low-tension current from the primary coil winding is taken to contact A, which is insulated from the distributor body. Contact B, which is attached to lever L, pivoted at P, is held in contact with A by the spring S. The cam C, which is driven by the engine or dynamo, has as many lobes as there are cylinders to the engine. These lobes press against pad D attached to the lever L. In four-stroke engines the cam rotates at half-engine speed, and in two-stroke engines at engine speed.

The action of the distributor is as follows: The shaft driving the cam C carries an insulating block R, which rotates with it. A metal segment T, to which is attached a light spring K, is mounted on the top of the block R. The block, segment, and spring rotates within the distributor cap N which is made of insulating material and has four metal contacts, X, moulded into it. When the cap is in place the segment T passes very close to or actually touches each of these segments in turn as it rotates. A small carbon brush in the centre of the cap presses on spring K and makes contact with it all the time. This carbon brush is connected to one end of the secondary winding.

The positions of the various parts are arranged so that whenever the cam C separates the contacts A and B the segment T is just opposite one of the metal contacts in the cap N. The high-tension current then jumps across the small air gap between the segment and the contact, and is led away by means of a high-tension wire to the correct plug.

Horse-Power Rating Formulæ of Various Countries.

(S.M.M. & T. and R.A.C. 1928.)

Notation

H = horse-power treasury rating; d = bore of cylinder;
N = number of cylinders; s = stroke;
V = swept volume in one cylinder; r = engine revolutions.

Austria, *Latvia*, *Luxemburg*, *Norway*, *Russia*. $H = 0{\cdot}3Nd^2S$, where d is in cm., S is in metres.

Belgium. $H = KNd^2Sr$,

where

K = S for passenger and light goods cars of less than 6 cylinders;
K = 4·25 for heavy goods vehicles.

d is in mm., S is in metres, and r is in revs. per minute, taken as 1,200 for private cars and 1,000 for heavy goods vehicles and omnibuses.

England, *U.S.A.* $H = \frac{Nd^2}{2{\cdot}5}$, where d is in inches $= \frac{Nd^2}{1613}$, where d is in mm.

Denmark. As Austria for four-stroke engines. Special factory ratings are adopted for two-stroke engines.

France. $H = KNd^2Sr$,

where

K = 0·00020 for 1 cylinder; K = 0·00015 for 4 cylinders;
K = 0·00017 for 2 cylinders; K = 0·0013 for more than 4 cylinders.

d is in cm; s is in metres; r = max. engines revs. per second.

Germany. $H = 0{\cdot}3\ Nd^2S$ for four-stroke engines;
$H = 0{\cdot}45\ Nd^2S$ for two-stroke engines,

where d is in cm., S is in metres.

Hungary. $H = \frac{Na^2}{20}$, where d is in cm.

Irish Free State. $H = \frac{NV}{100}$, where v is in c.c.

Italy. $H = 0{\cdot}0878\ NV^{0{\cdot}654}$ for four-stroke engines;
$H = 1{\cdot}4\ (0{\cdot}0878\ NV^{0{\cdot}654})$ for two-stroke engines,

where V is in c.c.

(*Note*.—Fractions of a horse-power are neglected.)

Japan. $H = \frac{Nd^2}{3}$, where d is in inches.

Spain. $H = 0{\cdot}08\ (0{\cdot}785d^2S)^{0{\cdot}6}\ N$ for four-stroke engines;
$H = 0{\cdot}11\ (0{\cdot}785d^2S)^{0{\cdot}6}\ N$ for two-stroke engines,

where d and S are in cm.

Sweden.

$$H = \frac{Nd^2Sr}{K}$$

where

K = 220,000 for four-stroke engines using benzine;
K = 240,000 for four-stroke engines using petrol;
K = 180,000 for two-stroke engines.

d and S are in cm.; r = normal revs. per minute.

Switzerland.

$$H = 0{\cdot}4\ Nd^2S,$$

where d is in cm.; S is in metres.

Horse Power from Given Working Volume and M.E.P.

$$\text{Horse-power} = \frac{P_m \times Q \times N}{396000},$$

where

P_m = m.e.p. lbs. per sq. in. Q = working volume in cub. ins.; N = r.p.m.

Valve Area for Given Volume, Revolutions and Gas Velocity.

$$Vg = \frac{VcN}{360\ \Delta},$$

where

Vg = gas velocity, ft. per sec.; Vc = volume swept out per cylinder; cub. ins.
Δ = valve area in sq. ins.; N = r.p.m.

Inlet Pipe Diameter.

$$Vg = \frac{QN}{180\pi D_1^2},$$

where

Vg = gas velocity, feet per sec.; Q = working volume per rev.; cub. ins.
D_1 = diameter of inlet pipe; ins. N = r.p.m.

Compression Pressure.

$$\left(\frac{V_2}{V_1}\right)^n = R^n = \frac{P_2}{P_1},$$

where

V_1 = volume of clearance space; cub. ins. V_2 = volume of piston displacement + V_1 cub. ins.
P_1 = atmospheric pressure; lbs. per sq. inch. P_2 = compression pressure in lbs. per sq. in. (absolute).
$n = 1{\cdot}3$;
R = compression ratio.

Calculating Lift of Poppet Valves.

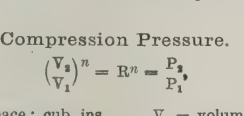

FIG. 19.

The gas passage is the area of the curved surface of the frustrum of the cone *abcd*. V = volume of gas to be discharged in cubic feet, and V_g = mean gas velocity in feet per second through valve opening, and A = area of valve opening, then,

$$A = \frac{144V}{Vg} \text{ (sq. ins.)}.$$

The lift l must be such as to produce this area for the gas to pass through.

$$h^2 = \frac{4A^2}{\pi^2(d_1 + d_2)^2} - \frac{(d_1 - d_2)^2}{4}.$$

Knowing the value of d_1, d_2, A and t, the lift $l = h + t$ (fig. 19).

DIMENSIONS OF POPPET VALVES.
(S.A.E. Standard.)

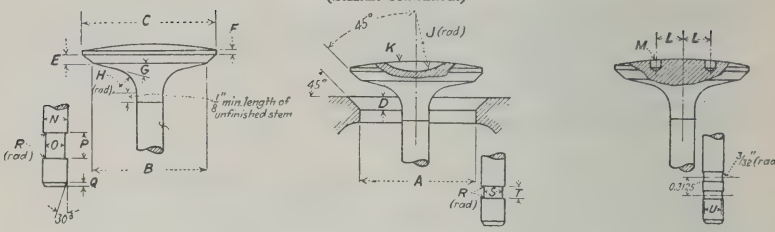

FIG. 20.

DIMENSIONS OF POPPET VALVES.
Heads and Seats.

Radii for Curvature of Crown of Valve-Head.

Nominal size	1–1⅜	1⅜–1⅞	2–2½	2⅜–2⅝	2¾–3
Radius, ins.	5	6	7	8	9

VALVE STEMS AND GROOVES.
(Fig. 20.)

Nom. Size. A.	Dimensions (ins.). N. Max.	O. Max.	P. Max.	Q.	R. Max.	S. Max.	T. Max.	U. Max
1 –1⅜	0·3100	0·250	0·328	1/32	0·012	0·235	0·144	0·250
1⅜–1⅞	0·3725	0·309	0·391	1/32	0·012	0·253	0·144	0·309
2 –2⅜	0·4345	0·312	0·516	3/64	0·015	0·312	0·175	0·372
2½–3	0·5595	0·437	0·578	1/16	0·020	0·405	0·206	0·495

The above dimensions are for steel valves; they are considered equally applicable for cast-iron valves, except that it may be desirable to have slightly more metal in the latter under the heads.

Valve stem tips shall be hardened to give a scleroscope reading of 55–65 after finishing. Recommended that length of tips from end of stems to stem-grooves be not less than finished diameter of stem to prevent undue breakage after hardening.

Tolerance on fractional dimensions = ± 0·010 in.

Valve Springs.

(*Donkin.*)

Load in pounds per inch of deflection or rate R_r

$$R_r = \frac{Gd^4}{8D^3N},$$

where

G = rigidity modulus, lbs. per sq. in.; N = number of active coils;
D = mean diameter of spring, ins.; d = diameter of wire, ins.

The stress in the wire is determined from $S = \frac{8PD}{\pi d^3}$,

where

S = stress in lbs. per sq. in.; D = mean diameter of spring, ins.;
P = load in lbs.; d = diameter of wire, ins.

Experience has set a value of about 60,000 lbs. per sq. in. for the maximum stress, and 25,000 lbs. per sq. in. for the maximum stress range. The stress range is more important than the maximum stress up to the elastic limit. With a high stress range, the material is put through a large angle of twist which tends to fatigue it quickly and open up any discontinuity in the metal, causing early failure, therefore a high maximum stress with low stress range is less destructive.

Common practice is to make valve springs from oil-tempered spring wire. Tests made during a five-year period show that springs made from soft wire, heat-treated after coiling, are far superior to springs coiled from heat-treated wire.

Averages of life tests give the following comparative values:

(*a*) Carbon steel, heat-treated before coiling	1·0
(*b*) Electric furnace, chrome vanadium, heat-treated before coiling . .	0·9
(*c*) Carbon steel, heat-treated after coiling	5·0
(*d*) Electric furnace, chrome vanadium, heat-treated after coiling . .	10·0

Even though extreme care is taken with the material, etc., failures may occur due to the resonance between the natural frequency of the spring and the frequency of the forced vibration of the camshaft. When the forced vibration is of such a frequency that its wave-length is a simple multiple of the free wave-length of the spring a condition of resonance may be created. If the wave-length is long and is such that an integral number of the free wave-lengths of the spring are completed during the cycle of the valve, the application of the force will be in phase, and the resulting wave motion in the spring will be cumulative and resonant. The natural frequency of a spring $N = 531\sqrt{\frac{W}{R}}$ (Ricardo),

where

N = complete number of free vibrations of the spring per minute;
R = rate of spring in lbs. per sq. in
W = weight of the active mass of the spring in lbs.

If the vibration within the spring is excessive it may cause the valve to float open and thus impede the operation of the engine and cause excessive hum and noise. In all cases it causes a building up of stress which is destructive to the life of the spring.

Valve-Spring Pressure required with Tangential Cams.

For round-nosed cams with roller-footed tappets, see fig. 21.

$$\text{Minimum valve-spring force} = \frac{W \times N^2 \times D}{2{\cdot}256 \times 10^6} \left\{ 1 + \frac{D}{R + r} \right\} \text{ lbs.}$$

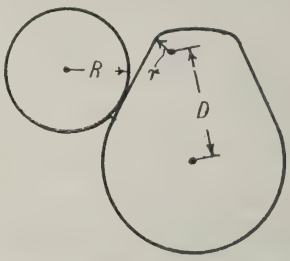

Fig. 21.—Valve Spring Pressure required with Tangential Cams.

where

W = equivalent weight of the valve system in ounces.
N = r.p.m. of engine.
D = distance between the centres of the cam-base circle and the cam-nose circle in inches.
R = radius of the roller on the foot of the tappet in inches.
r = radius of the cam-nose circle in inches.

Valve Timing.

Analysis of one hundred automobile engines (1927) showed the following average timing:

Inlet opens, 10° A.	Exhaust opens, 47° 50′ B.
Inlet closes, 40° A.	Exhaust closes, 7° 30′ A.
A = after T.D.C.	B = before T.D.C.

In 95 per cent. of the engines the inlet and exhaust valves were of the same diameter.

$$\frac{\text{Diameter of inlet valve } (\textit{clear})}{\text{Valve lift}} = 4{\cdot}75. \qquad \frac{\text{Cylinder Bore}}{\text{Valve diameter}} = 2{\cdot}2.$$

Material for Valves.

Valves operate under a tension-impact load, the temperature varying from practically atmospheric at the tappet end to about 1600° F. at the head. The temperature gradient is a function of the guides in which the valve reciprocates, and for any particular design is affected by the material in the guide, the degree in which it shrouds the stem, and the inner surface of the guide. The temperature of the head is affected by the width of valve seat and cross-sectional area of stem. The head and upper part of stem are subjected not only to high temperatures, but also to the corroding action of the mixture, and the corroding and eroding action of the hot gases passing through the valve at a velocity of 150–200 ft./sec.

The scaling of a valve not only reduces the cross-sectional area, but the loose scale may also become attached to the valve seat.

The strength of the valve material at ordinary temperature is important only in so far as it is a function of the hardness. For highly stressed valves the strength at high temperatures is important, and it is necessary to select a material which does not show a decrease in the original strength sufficient to cause distortion or failure.

Camshaft Drives.

(*H. E. Merritt*, '*Proc. I.A.E.*')

With side-by-side valves there are two general types—(*a*) chain; (*b*) spur or helical gear. Silence of operation is important, and the chief obstacle to this centres round the uneven torque of the drive. This may result in a wave motion in a chain drive, introducing considerable stresses and limiting the allowable velocity of the chain. With tooth gear the silence of operation depends largely on the accuracy of manufacture. In many cases helical teeth are used in place of the straight tooth, with improved performance. This introduces, however, an end-thrust on the crankshaft and camshaft, and a transverse torque on the intermediate gear. In correctly designed helical teeth the degree of overlap should not be less than one pitch, and with double helical gear end-thrust is eliminated.

Camshaft brakes may be used to secure uniformity of driving torque, in which case the breaking torque must be at least equal to the maximum forward accelerating torque, due to a closing valve spring.

Another method is to drive an auxiliary, such as the fan, water, or oil pump from the free end of the camshaft, thereby providing the necessary constant resistance.

The majority of camshaft drives are taken from the front end of the crankshaft with the object of accessibility, but in this position crankshaft torsional vibrations may produce severe fluctuations in tooth pressure. For minimising gear noise, the use of non-metallic gears is very common. Due to their resilience and high inter-molecular friction, the energy of tooth impact is absorbed, which prevents the bounce of the teeth.

Owing to the greater centre distance between an overhead camshaft and the crankshaft a variety of drives is possible, and representative arrangements are shown in fig. 22.

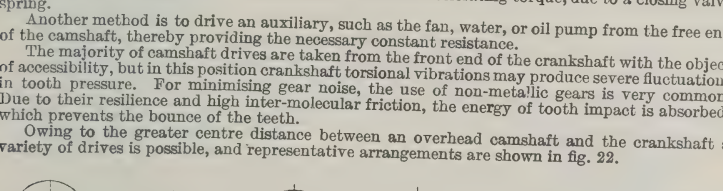

Fig. 22.—Types of Overhead Camshaft Drive.

A. Chain.
B. Spur Gear.
C. Bevel.
D. Chain-bevel.
E. Helical gear.
F. Bevel worm.

The train of spur gears (B) has a large number of points at which wear may occur, and is liable to be noisy. The bevel drive demands care in layout. Bevel gears require very accurate location in every direction, means for axial adjustment, and thrust bearings. Straight-tooth bevel gears are the most difficult of all gears to get to run quietly, and the tendency is to use spiral bevels, but this type calls for the greatest accuracy in cutting and assembly.

The unequal expansion of the cylinder block and the vertical shaft has an important effect on gear mesh and tappet clearance, and this can be provided for by the use of a telescopic vertical shaft. With the spiral and worm drives a wide range of gear diameters is possible. Another advantage is that there is no necessity for precise adjustment for end float on either crankshaft or camshaft, or expansion of the vertical shaft. On the other hand, the contact between spiral gears is only point contact and the intensity of tooth pressure is very high.

Bearings.

Crankshaft and big-end bearings are usually white-metal lined; gudgeon bushes of bronze.

Corresponding to a maximum explosion pressure of 300 lbs. per sq. in., the bearing pressure in lbs. per sq. in. of projected area is as follows:—

For 'big-end' bearings: 800–1,100 lbs. per sq. in.; more usually the latter.

For 'gudgeon' bearings: 1,500–2,700 lbs. per sq. in.; average about 2,000 lbs. per sq. in.

Strength of Splined Shafts.

From tests carried out on actual shafts, the elastic limit for a splined shaft is substantially less than for a plain round shaft of a diameter equal to the base diameter of the spline. On the other hand, the ultimate strength of the splined shaft is materially greater than that of the round shaft. It would appear that the reason the elastic limit is lower in the splined shaft is that the material in the splines adds very little to the torsional strength, but the strain on the fibres at the outside of the splines will be about the same as if the shaft were of solid round section and equal in diameter to the outside diameter of the splines. With fairly elastic material, if the distortion is continued beyond the elastic limit, the splines assume a helical form and gradually come into tension, thereby adding to the resistance of the shaft to further deformation. If the splines are supported, as in the case of the permanent fitting so that they are in more nearly direct shear from the beginning of the load application, their shearing strength is added to that of the body of the shaft.

Design of Gear-box Gears.

(*H. E. Merritt*, '*Proc. I.A.E.*').

To determine the surface stress and bending stress.

If

T = torque in lb.-in. units;
t = number of teeth;
M = module;
f = face width, ins.;
Y = strength factor;
Z = zone factor;
F_i = load (lbs.) per in. of face;
C = cone distance;
S_b = bending stress, lbs. per sq. in.;
S_c = surface stress, lbs. per sq. in.

For a spur gear

$F_i = 2\,T/M.t.f$;
$S^b = F_i/M.Y$;
$S_c = F_i/M.Z$.

For a straight bevel $F_i = 2\,T.C./[M.t.f(c - f)]$.

Surface stress S_c = load per in. of face per in. of relative radius of curvature

$$= \frac{\text{Tooth load}}{(\text{Length of line of contact}) \times (\text{Relative radius of curvature})}.$$

Values of S_b and S_c obtained in practice.

No.	Car.*	Constant Mesh Gears.		First-speed Gears.		Differential.		Spiral.

CHCN = nickel-chrome case-hardening steel;
OHNC = oil-hardened nickel-chrome steel.

Advantages.—(*a*) Relatively unencumbered space for a body of any design, floor, height, and dimensions; (*b*) elimination of the rear axle; (*c*) driving force always applied to the wheels in the direction of their motion; (*d*) elimination of long propeller shaft and substitution of shafts having lower speed and less tendency to vibrate; (*e*) greater quietness and freedom from body rumble; (*f*) ability to provide front-wheel braking without carrying brake drums and operating mechanism on wheels or axle; (*g*) a less expensive rear axle and a simplified frame construction; (*h*) decrease in the total weight of vehicle; (*i*) decreased thrust on front-wheel bearings; (*j*) front axle and spring can be relieved of all braking torque, and all springs can be relieved of driving torque reaction.

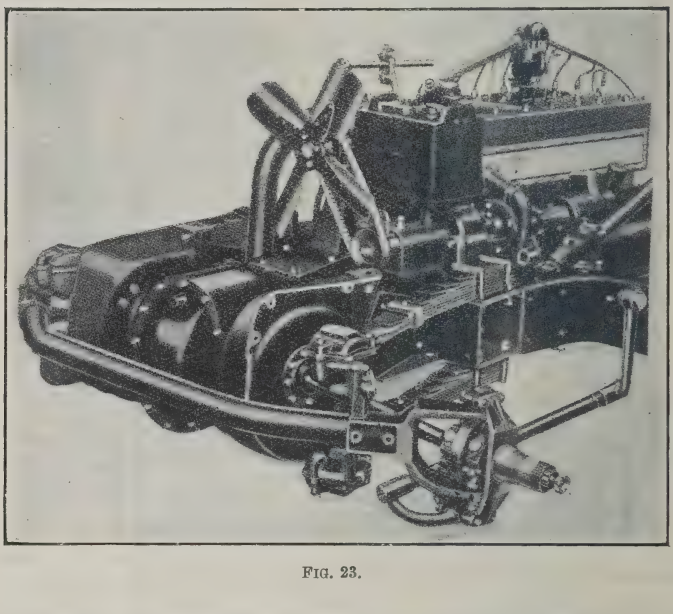

FIG. 23.

Disadvantages.—(*a*) Decreased traction, notably when hill-climbing and accelerating; (*b*) liability of greater damage to driving mechanism in the event of collision; (*c*) difficulty of obtaining satisfactory weight distribution, especially in trucks and coaches; (*d*) increased complication in the driving mechanism; (*e*) decreased space for radiator; (*f*) difficulty in obtaining a quiet drive, especially with a bevel drive mounted on the frame; (*g*) harder steering, due to increased load on front axle and steering pivots; (*h*) difficulty of obtaining an adequate steering angle.

A typical example of a front-wheel drive is shown in fig. 23.

Steering-Wheel Position.

The following formulæ (*W. Ferrier Brown*) are for the calculation of the steering-wheel position, a, b, and d, being known factors.

Given m and θ—to find c and e.

$$\phi = \tan^{-1}\frac{b-a}{m}; \quad n = \frac{m}{\cos\phi} = m\sec\phi;$$

$$\beta = \theta - \phi = \sin^{-1}\frac{c+d}{n}; \quad e = n\cos\beta;$$

Given c and e—to find m and θ.

$$\beta = \tan^{-1}\frac{c+d}{e}; \quad n = \frac{e}{\cos\beta} = e\sec\beta;$$

$$\phi = \sin^{-1}\frac{b-a}{n}; \quad m = n\cos\phi;$$

$c = n \sin \beta - d$.

To find h and l.

$h = m \sin \theta + a \cos \theta - d$; $l = \cos \theta (m - a \tan \theta)$.

$\theta = \phi + \beta$ = rake of column.

To find h and l.

$h = c + b \cos \theta$; $l = e - b \sin \theta$.

To find k (which may be + or −)

$$k = \frac{a}{\sin \theta} - \frac{d}{\tan \theta}.$$

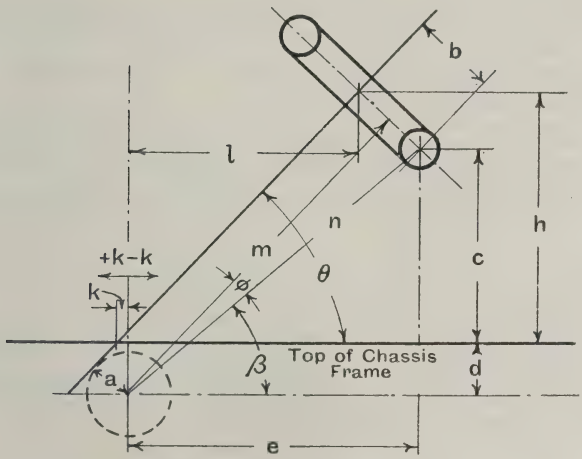

FIG. 24.—Steering-Wheel Position.

Lubrication.*

Carbon Formation.—The tendency towards carbon formation is due to an excess of oil working past the piston rings into the combustion chamber. Special means are used to limit the amount of oil reaching the combustion chamber, such as (*a*) baffle plates between the crank case and cylinder casting, (*b*) scraper ring on the piston, (*c*) effective oil relief groove on the piston or oil relief holes, (*d*) adequate control of the oil supply to meet the engine's requirements.

Sealing the Piston Rings.—The clearance between the piston and the cylinder wall controls the lubricant to seal the piston rings. When this is small, a light or medium bodied oil is sufficient. Larger clearances require a heavier-bodied oil.

Piston clearance must be considered in conjunction with the cylinder bore. A clearance of 0·005 in. on a small-diameter piston is relatively large compared with the same clearance on a piston of double the size.

Piston material affects the clearance allowed; thus heavier-bodied oils are necessary for aluminium pistons compared to cast iron. Other factors are: the number of piston rings and their position on the piston, the presence of oil grooves on the piston to assist in oil distribution, method of finishing cylinder bore.

Lubrication of Transmission and Differential.

The following characteristics of the lubricant are necessary:—

(*a*) Must be of a character and consistency to coat, follow, cushion, and adequately lubricate the gear mesh.

(*b*) Must be capable of thorough distribution to any ball, roller, or plain bearing, and must have no corroding effect on the balls, rollers, or raceways.

(*c*) Should be of a body and character to minimise resistance and power loss due to the churning action of the gears. In the case of transmission, it should offer the minimum of resistance to the manual act of gear changing.

(*d*) Should be capable of carrying off the greatest amount of heat, and of exerting a washing action on the gear teeth and bearing surfaces.

(*e*) Should be a body to prevent leakage from the gear-box or back axle under all normal operating conditions.

* See also Handbook published by the Vacuum Oil Co., Ltd.

Chassis Lubrication.

Advantages of Oil for Lubrication.

(O. T. Myers.)

(1) Sustains as heavy a bearing load as grease with less friction.

(2) Fed to one properly located point in a bearing will quickly spread over the entire surface.

(3) Will flow through a very small hole, and can be conducted a considerable distance by capillary attraction and surface tension.

(4) Carries much less dust than grease, can be filtered, and not so much exposed to dirt as grease, when in bulk or when being applied.

(5) Contains no inert matter to clog holes or channels.

(6) Engine oil can be used.

(7) Easier to apply automatically than grease.

(8) A flow of clean oil tends to clean a bearing, and bearings arranged for oil lubrication can be cleaned with petrol or paraffin.

(9) When oil is used on spring bolts, the seepage works down into the spring leaves, preventing rust.

Weight of Passenger Cars.

(*W. Ferrier Brown*, '*Proc. I.A.E.*')

The total weight of an average car is made up as follows:—
Chassis complete, 65 per. cent.; body complete, 30 per cent.; wings, valances, and step-boards, 5 per cent.

For the complete body in detail, the proportionate weights are:—
Body frame (steel), 14 per cent.; body framing complete with head-fittings, 42 per cent.; panels (steel), 10 per cent.; paint, glass and inside mouldings, 12 per cent.; trimming, including two extra seats complete, etc., 22 per cent.

Percentage Weight of Automobile Parts.

(P. M. Heldt.)

The following table shows the averaged values for the years 1917 and 1929. The percentage change gives an indication of the progress in design.

Component.	Percentage of Total Chassis Weight.		Change. Per cent.
	1917.	1929.	
Frame	9·12	13·0	+ 42·6
Front springs Rear springs	9·12	2·4 4·2	− 27·6

Automobile Brakes.

A common misapprehension is that which assumes that there is no slipping between tyre and road until wheels are locked. Actually slippage occurs immediately upon the sudden application of the brakes, and continues until the car is brought to rest whether the wheels are locked or not. Although the wheels continue to roll, their peripheral speed begins to decrease immediately and is therefore always less than that at which the road surface passes under the car.

The effectiveness of brakes can be determined directly by measuring the breaking force per unit of car weight *i.e.* per lb. per 1000 lbs. or per ton of car weight. The relation between the distance S in feet required to stop, the initial car speed V in m.p.h., and (1) the rate of slowing down in feet per sec.$^2 = a$; (2) the retarding force in lbs. per lb. $= f_1$, (3) the retarding force in lbs. per 1000 lbs. of car weight $= f_2$, is given by

$$(1)\ S = 1{\cdot}08\,\frac{V^2}{a}; \qquad (2)\ S = 0{\cdot}0336\,\frac{V^2}{f_1} \qquad (3)\ S = 33{\cdot}6\,\frac{V^2}{f_2}.$$

STOPPING DISTANCES FOR DIFFERENT TYPES OF BRAKE APPLICATION.

	Type of Brake.		
	Rear External Band Brake.	Four Brakes Internal Shoes.	Four Brakes, External Bands.
Total weight of car lbs.	6,000	6,000	6,000
Total surface of brake lining, sq. ins.	332·4	308·6	600
Weight per sq. in. of lining, lbs.	18·1	19·4	10
Stopping distance in feet at			
20 m.p.h.	35	23	15
30 „	70	45	35
40 „	113	74	60
50 „	175	114	90

STOPPING TESTS OF CAR FITTED WITH HYDRAULIC BRAKES.

Total weight of car with driver = 4,400 lbs.; Weight on front wheels = 2,000 lbs.; Weight on rear wheels = 2,400 lbs.

Tyres, cord, size 35 × 5, pressure 65 lbs. per sq. in.;
Road surface—dry concrete.
Speed, 30 m.p.h.
Stopping distance—brakes applied on rear wheels only = 89·2 feet.
" " " front " " = 67·6 "
" " " rear and front wheels = 36·8 feet.

BRAKES.

Four-wheel brakes have now become standard practice. Typical systems are illustrated in fig. 25.*

(*a*) *Six-brake Systems*, using two cross-shafts, as on Rolls-Royce, Bentley, Morris cars, etc. It is not much used on Continental or American cars. The hand-operated brakes operate a second pair of shoes side by side in each rear-wheel drum. The linkage employed may take several forms, of which the simplest and most popular is shown.

Compensation is effected by the use of swinging levers which interrupt the pull rods or cables near to each brake approximately at the point representing the centre around which the axle moves, as an arc when the springs deflect.

A second six-brake system is shown at B, fig. 25. In this case a single pedal controlled cross-shaft distributes the forces to four-wheel brakes as in (A), but instead of using separate shafts one is

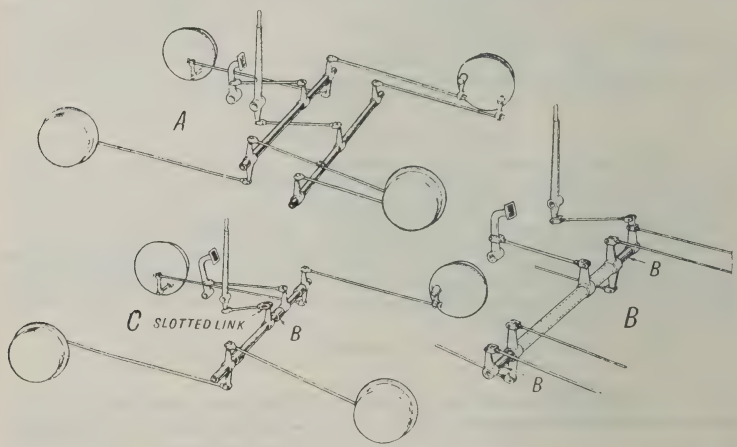

FIG. 25.—Four-Wheel Brake Systems.

placed inside the other. Thus the hand-lever may control a cross-shaft supported by end bearings BB, on which shaft is carried a tube operated by the pedal, and all the brake connections are taken to levers on this shaft and tube.

(*b*) *Five-brake Systems.*— In this system a hand-operated transmission brake is used. The brakes on the four wheels are connected by linkages to the foot pedal. A failure in a rod or pin may make the wheel brakes entirely inoperative.

(*c*) *Four-brake systems*, in which there are four brake units, one applied to each wheel, and all four or a pair of these units can be brought into operation by the use of either the pedal or hand-lever. A dangerous result is, however, obtained if this system is provided with thorough compensation, for the failure of any rod, pin, or cable would leave the brakes useless. The most widely used four-brake system is shown at C, fig. 25. There are two cross-shafts, one coupled to

* *Proc. I.A.E.*

the rear brakes and the other to the front brakes, and these shafts work in unison in virtue of a positive connection one to the other by rods or cables. The pedal operates the front shaft, and the hand-lever is connected to the rear shaft through the medium of a slotted yoke, cable, or chain, so as to be unaffected when the brakes are applied by the pedal.

Design of Brakes.

A retardation of 22·6 ft. sec.^{2} generally accepted as sufficient.
Retarding force F applied at the tyres = weight of car × 0·7.
Total outward force P on shoe lining,

$$P = (F.D)/(\mu.d),$$

where
D = tyre diameter, ins.
d = internal diameter of drum, ins.
μ = coefficient of friction of lining. 0·33 for general conditions.
Common to employ 1 sq. in. of lining on the service brakes per 28 lbs. of car weight.

Mean pressure on lining, 120 lbs. per sq. in. For internal expanding brakes not advisable for the arc of lining material to subtend an angle greater than 120°, 100° is generally sufficient.

Linkage leverage (overall) employed on current chassis varies between 35 to 1 and 45 to 1, made up as follows :—

(*a*) A cam and lever ratio at the brake itself of between 6 to 1 and 8 to 1.
(*b*) A ratio in the cross-shafts levers on other intermediate levers of between 1·2 to 1 and 1·7 to 1, sometimes unity.
(*c*) A pedal leverage of between 4 to 1 and 6 to 1.
For hand-lever, overall leverage 50 to 1.

Power Brakes.

'Servo' braking apparatus may be either 'hydraulic' or 'vacuum.' The Westinghouse vacuum system is shown in fig. 26. This system utilises, as its source of power, pressure of the atmosphere operating against the partial vacuum created by the pistons of the engine on the suction stroke, when the throttle is closed. A section of the 'Servo' motor is shown in fig. 26. The cylinder M contains a piston N with leather packing O, a hollow stem P guided in the end cover Q of the cylinder. Pull rod R has a spherical end to allow for angular motion of lever S. A spring, T, assists the prompt release of the brake.

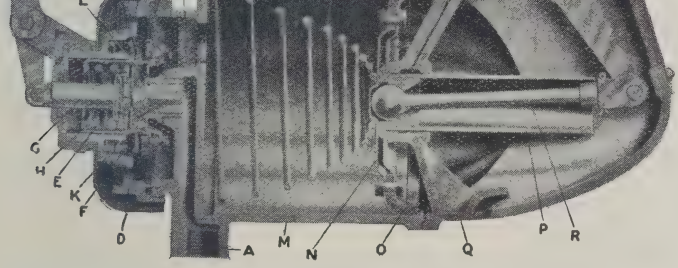

Fig. 26.

Shaft V is extended through the casing Q and carries a double-ended lever, one end of which may be connected to the front brakes and the other to the rear brakes.

The control valve consists of a diaphragm C open on one side to the atmosphere by orifices D, and on the other side with the brake cylinder by orifice B.

The hollow guide E, of which the interior always communicates with the atmosphere by orifices F and D, is fixed to diaphragm C. Valve K controls the passage between the induction pipe and the brake cylinder, and valve L controls the passage from brake cylinder to atmosphere.

In the normal or release position K is on its seat KS, while L is off its seat LS, the brake cylinder being open to the atmosphere by valve L and orifices F and D.

The pull exercised by the brake pedal on G is transmitted through spring H to guide E and diaphragm C which lifts seat LS against valve L thus closing communication between brake cylinder and atmosphere. Guide E continuing its upward movement, valve K is raised off its seat KS, and the end of brake cylinder connected to orifice B is put in communication with the induction pipe of the engine, and thereby subjected to a reduction of pressure, the degree of which determines the amount of pull on the brake rigging.

Laminated Springs.

Size and Number of Plates.

$$\text{Total load on spring W in cwts.} = \frac{sbt^2n}{L},$$

where,

s = maximum stress in plates = 460 cwts. per sq. in.; t = thickness of plates in ins.; b = breadth of plates in ins.; L = length of spring between eyes in ins.; n = number of plates.

Given W and L, and assuming n, values for b and t can be calculated. These must be checked against the rate of deflection, which is determined by :

$$\text{Deflection per ton of load} = \frac{L^3}{40{,}000bnt^2}.$$

From experimental data it appears desirable to so design leaf springs that the plate lengths are proportional to the second moment of area (moment of inertia) of the plate sections, except for strengthening near the eyes to take care of rebound.

Friction in Laminated Springs.

Friction tests show that the friction is a minimum with a lubricant consisting of equal volumes of cylinder oil and powdered graphite. The close proximity of the curve for static and sliding friction with this lubricant are of special note. An important conclusion drawn from the tests is that with graphite μ is substantially constant.

Values of μ under similar loading conditions.

	Light Oil.	Excess Oil wiped off.	Graphite.
Static . . .	0·24	0·34	0·08
Sliding . . .	0·10	0·18	0·06

Effect of End Taper.

Fig. 27 is a diagram showing the relative liability to fracture of various plates in springs as deduced from more than 500 fractures.

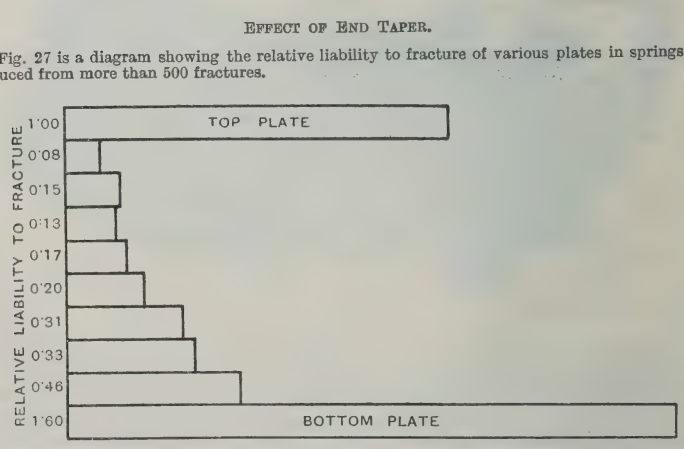

Fig. 27. Diagram showing the relative liability to fracture of spring plates. (*H. S. Rowell.*)

Plates which are reduced in width only are not appreciably different from square-ended plates, such tapering having no practical effect on the strengths, reactions, stresses, or flexibilities of the spring. On the other hand, taper in the thickness has an enormous effect. A combination of the two tapers—in the width and in the thickness—is sometimes of much importance, but generally the effect of tapering the width is very much less than of a taper in the thickness.

The life or fatigue of a spring is to a considerable extent governed by the stress reversal which occurs on account of nip and flick.

NOTE.—For a very complete survey of the subject, papers by Landau and Parr (*Journal Franklin Institute*, U.S.A.) and Rowell (*Proc. Institution of Automobile Engineers*) should be consulted.

Power Required by Motor Vehicles to Negotiate Gradients.

It is first necessary to determine the maximum engine torque T. If d = engine bore in ins., n = number of cylinders, s = stroke in ins., then $T = 5 \cdot 66 d^2 sn$ (approx.). Let S_R = total speed reduction ratio between engine and driving wheels and e = efficiency of driving mechanism, then the torque T_1 transmitted to the driving wheels is given by $T_1 = TS_R e$ (e may be taken as 0·9 for top gear and 0·75 to 0·85 for intermediate and low gears).

Total tractive force F in lbs. $= \frac{2TS_R e}{D}$, where D = diameter of driving wheels in ins.

This tractive force is available to overcome (*a*) resistance due to acceleration or gradients, (*b*) road resistance and wind resistance.

AVERAGE VALUES IN POUNDS PER TON FOR ROLLING PLUS AIR RESISTANCE FOR DIFFERENT CLASSES OF VEHICLES ON VARIOUS ROAD SURFACES.*

Road Surface.	Motor Buses and † Passenger Cars.	Commercial ‡ Vehicles.

Best water-bound gravel	55	40
Ordinary gravel	65	50
Best earth roads	65	50
Fair to good earth roads	75	60

The size of tyre appears to affect the rolling resistance very little so long as the tyres conform to good practice as to size and load. Low-pressure cord tyres have somewhat higher rolling resistance than the high-pressure cords, but the difference decreases for the rougher surfaces.

If

G = gradient per cent. and R = rolling plus air resistance in lbs. per ton, and W = gross weight of vehicle in lbs.,

then, $\frac{2TS_R e}{D} = \frac{W.G}{100} + \frac{W.R}{2240}$; or, $\frac{4480TS_R e}{D} = W(24G + R)$;

from which the engine torque required to drive a vehicle up a given gradient can be determined; or knowing the engine torque, the maximum gradient that the vehicle can negotiate.

---

* Report of Committee on the Economic Theory of Highway Improvements, S.A.E. Highway Research Board, 1925.

† Speed 35 m.p.h., high-pressure cord tyres. For low-pressure cord tyres add 10 lbs. per ton.

‡ Speed 15 m.p.h., pneumatic tyres.

The following values of road resistances are given by G. W. Watson (*Proc. I.A.E.*):

Nature of Road.	Resistance, lbs. per Ton.	Nature of Road.	Resistance, lbs. per Ton.
Good asphalt	15	Soft macadam	97
Poor asphalt	29	Small cobbles	60
Good wood paving	30	Medium cobbles	130
Good granite sets	35	Large cobbles	240
Best macadam	43–46	Sand road	360
Ordinary macadam	50–60	Loose sand	560

Tyres.

Comparison of Tyre Sizes.

Range of wheel load, lbs.	675–1,120	1,000–1,500	1,400–1,900
High-pressure Tyres, ins.	4	4½	5
Inflation pressure, lbs. per sq. in.	45–60	45–60	45–65
Medium-pressure Tyres, ins.	4½	5½	6
Inflation-pressure, lbs. per sq. in.	30–50	38–54	42–58
Balloon Tyres, ins.	5½	6	6½
Inflation pressure, lbs. per sq. in.	27–35	26–38	30–40

Ideal Load and Inflation Pressure.

The following formulæ are based on the Goodyear Company's tables:

If d = section diameter ins. and P = inflation pressure lbs. per sq. in.:

For cord tyres $P = 12 \cdot 5 + 10d$; For canvas tyres $P = 17 \cdot 5 + 10d$.

The ideal load (W) per tyre is, $W = 32 \cdot 4d^{2 \cdot 24}$ lbs.

For any given inflation pressure the variation of permissible load with diameter is given by $W = cpd^{1 \cdot 8}$, where c = 1·81 for cord tyres and 1·63 for canvas tyres.

*Wear of Tyres.**

For high-pressure tyres, road tests show:

(1) Wear increases with speed.
(2) Increased wear with higher temperatures (high temperatures are very destructive to tyres).
(3) Relative wear of rear tyres to front varies from 200 to 118, probable average 150.

For balloon tyres:

(1) Wear is less affected by differences in road surfaces than for high-pressure tyres.
(2) Firm-surfaced roads (*i.e.* asphalt, cement) all have approximately the same effect on tread wear.
(3) Surfaces such as gravel, earth, dry and in good surface condition, cause less tread wear than firm-surfaced roads.
(4) Front tyre wear is greater than rear tyre wear on firm-surfaced roads, and is less than rear tread wear on loose-surfaced roads.

Power Losses in Tyres.

(W. H. Paull.)

The balloon tyre, due to its bigger running deflection, consumes slightly more power than the high-pressure tyre, which it replaces. At 25 m.p.h. the four tyres of a light car will consume about 1·8 h.p. if 3½-in. high-pressure tyres are used at 40 lbs. per sq. in., or 2·4 h.p. if 4·40-in. balloon tyres are used at 25 lbs. per sq. in. A 20 per cent. decrease in inflation pressure would cause these losses to be increased to 2·5 h.p. and 3·0 h.p. respectively. Four 5-in. high-pressure tyres fitted to a large car and running at 50 m.p.h. will consume 7·2 h.p.—6·75-in. balloon tyres on the same car will consume 11·9 h.p. under the same conditions.

130 × 850	15	17	13
140 × 850	18	22	12
160 × 850	13	16	10
180 × 850	11	13	9
8″ × 850	11	13	10
10″ × 850	7	9	6
12″ × 850	6	7	5

THE MACINTOSH N.A.P. UNPUNCTURABLE TYRE.

This tyre, fig. 28, is so constructed that it possesses a large hermetically sealed core containing uncompressed air. It has a broad and flat base similar to that of the ordinary solid tyre, thick, strong, and abnormally flexible walls, and a narrow tread having a central row of triangular cavities about half an inch deep, which give definite non-skidding and side-slipping properties on slippery surfaces. This form of construction is such that it is claimed to need no attention whatever during the whole life of the tyre, which is guaranteed in the United Kingdom to be a minimum of 10,000 miles or twelve months, whichever expires the sooner. Another important feature is that the walls are entirely of rubber and contain no fabric, with the result that exceptionally cool running is obtained. This tyre seems to combine in a remarkably efficient manner the advantages both of the pneumatic and the solid variety. For such vehicles as Ford one-ton trucks it is particularly well adapted.

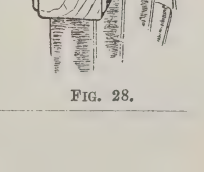

FIG. 28.

Torque tube	—	3N	3N
Universal joint pin	—	5NCHS	5NCHS

Abbreviations used :—

AHRS = austenitic heat-resisting steel.
AHNC = air-hardening nickel-chrome steel.
ANC = austenitic high nickel-chrome steel.
Al = aluminium alloy.
CI = cast iron.
CHC = case-hardening carbon steel.
CMS = chrome-molybdenum steel.
CVS = chrome-vanadium steel.
HCS = high-carbon steel.
HCr = high-chrome steel.
MCI = malleable cast iron.
MS = mild carbon steel.
MCS = medium carbon steel.
3N = 3 per cent. nickel steel.
NCH = 3 per cent. nickel case-hardening steel.
5NCH = 5 per cent. nickel case-hardening steel.
NCCH = nickel-chrome case-hardening steel.
NCM = nickel-chrome-molybdenum steel.
NCV = nickel-chrome-vanadium steel.
NCMV = nickel-chrome-molybdenum-vanadium steel.
3NCS = 3 per cent. nickel-chrome steel.
Nit. = Nitralloy.
SMS = silicon-manganese steel.
THS = tungsten high-speed steel.

ADDENDUM.

Automobiles.

No radical change in general design is to be noted. Minor improvements have been incorporated from time to time. Front wheel drive has met with a certain degree of success in one or two instances; the adoption of this form of drive admits of a lower chassis and consequent overall height of body. These advantages can be obtained by placing the engine at the rear, which removes the objection of taking the drive through the steering swivels. Further, better

tractive adhesion is obtained by taking the drive through the rear wheels than through the front wheels. This is especially noticeable when getting away from rest or climbing a hill. In commercial vehicles the combination of rear and front wheel drive has proved very successful.

The 6-cylinder engine, except for small sizes, is predominant, owing to the smoother running that can be obtained than with a 4-cylinder engine. The 8-cylinder engine is only used on the more expensive cars owing to the added complications and cost.

Side-by-side valves (L-head) construction is again showing increased use, partly owing to the advantages it offers in manufacture, and generally speaking it provides quieter running.

The gear-box has been improved by the introduction of silent seconds and thirds. Central gear change is practically universal; automatic gear-changing devices have been introduced but are not likely to become general, at least in their present form. Free-wheel devices have extending application.

The trend in design as given on page 1935 may still be taken as representative.

The compression-ignition oil engine is receiving great attention, and although there is little prospects of its immediate adaptation to automobiles, it has been used in increasing number of commercial vehicles with definite success.

The advantages of this type of engine are: (*a*) higher thermal efficiency, (*b*) saving in fuel costs. Tests show a saving of over 70 per cent., (*c*) practical elimination of fire risks, (*d*) heavy fuel oil occupies about 16 per cent. less volume than an equal weight of petrol, a consideration where radius of action is concerned.

In comparing the relative merits of the heavy oil engine and the petrol engine, the following must also be taken into account: (*a*) m.e.p., (*b*) maximum fluid pressure in cylinders, (*c*) weight per h.p., (*d*) maintenance costs, (*e*) initial cost, (*f*) fuel consumption at reduced output.

With present practice the advantages as far as (*a*), (*b*) and (*c*) lies with the petrol engine. With regard to (*c*) the A.E.C. engine, which is rated at 95 h.p., weighs complete with all accessories and flywheel, 1,350 lbs., or 14 lbs. per h.p., which is claimed to be no more than a petrol engine of the corresponding size. Regarding maintenance, available information shows that it is no greater than for the petrol engine. The initial cost is at present much higher owing to the limited production, but given equal volumes of production the difference may prove slight.

The fuel consumption at reduced loads with the heavy oil engine is greatly superior to that of the petrol engine. Further, combustion is less affected by variations in r.p.m., so that the variation in m.e.p. or torque and fuel consumption with change of speed is relatively small. The heavy oil engine is more flexible than the petrol engine; sustaining its torque better at low speeds and assuming equal flywheel conditions, has a better acceleration.

The design of the combustion chamber is of great importance. With the petrol engine only sufficient air is taken into the working cylinder to deal with the fuel charge, whereas the oil engine always takes in a full charge of air. Four general types of combustion chamber design are in use: (*a*) open or non-turbulent type, in which the air is compressed into a relatively small space and the fuel introduced in a number of small finely atomised jets; (*b*) the combustion chamber is separated from the working cylinder by a neck or restriction; (*c*) pre-combustion type, in which a small auxiliary chamber is separated from the main combustion space by a number of small holes, and into this the fuel charge is introduced at a comparatively low pressure; (*d*) the rotational swirl, best used with a sleeve valve. In all systems a separate fuel pump is necessary to meter and time the charge to each cylinder, and in general there are two distinct types: (*a*) the ported type where the start and finish of injection are controlled by the pump plunger, (*b*) the valve type, where the operations are controlled by poppet valves. There appears to be little to choose between them as regards performance. There are two main types of injectors: the open type and the closed or differential area type.

The recommended fuel for this type of engine is gas oil, which distils after paraffin (between 200° and 350° C.), the remainder being known as fuel oil. A mixture of gas and fuel oil, known as Diesel oil, is obtainable, and is much cheaper than gas oil. The oil used should be free from solid matter and contain no asphalt. The following variations in properties appear to have little influence on the efficiency of operations: *

Specific gravity	0·84 to 0·91
Carbon content	up to 2·5 per cent.
Sulphur	up to 2 per cent.
Water and sediment content	up to 0·1 per cent.
Flash point	160° to 225° F.

TYPES OF AIRCRAFT—AERODYNAMICS—AIRSCREWS—SCALE EFFECT AND DYNAMIC SIMILARITY—PERFORMANCE—DESIGN.

(Contributed by J. D. Frier, A.R.C.Sc., D.I.C., F.R.Aë.S.)

A.—TYPES OF AIRCRAFT.

Aircraft fall naturally into two groups, viz. (*a*) Heavier- or (*b*) Lighter-than-air, craft.

The Aeroplane and Seaplane.

The type under group (*a*) is commonly known as the 'Aeroplane' when used for land purposes, or the 'Seaplane' or flying-boat when used for maritime purposes. Machines of this type are initially able to leave the ground or water and subsequently maintain themselves in flight by virtue of their forward motion relative to the surrounding air.

An aeroplane consists essentially of five components:—

1. The main planes, by means of which the aeroplane is sustained in flight.

2. The fuselage or hull, in which the pilot, passengers, and/or other load, such as cargo, petrol, and oil, are carried.

3. The tail, which is rigidly attached to the rear of the fuselage or hull and comprises a tail plane and elevators in a horizontal plane, and fins and rudders in a vertical plane. This component is mainly responsible for the control of the aircraft.

4. The undercarriage, which, in the case of land planes, consists of a braced structure connected to the underside of the fuselage near its front end, supporting an axle carrying wheels, by the aid of which the machine leaves or alights on the ground.

In the case of twin- or multi-engined aeroplanes, this component may be in duplicate.

In getting off and landing, the tail is protected by a small skid attached to the rear end of the fuselage.

In Arctic regions, the wheels are replaced satisfactorily by long skids, while some aeroplanes are convertible into seaplanes by replacing the undercarriage structure by a similar one having two floats instead of wheels.

In the case of flying-boats, the hull serves the dual purpose of the fuselage and the undercarriage. Present-day hulls are manufactured in duralumin, which have a very important advantage over wooden hulls owing to the absence of water soakage; which in the latter hulls may amount to several cubic feet; this equivalent weight is thus available for useful load.

5. The engine, being the unit controlling the height to which a machine may attain. In single-engined aeroplanes it is placed in the nose of the fuselage, so that the airscrew operates as a tractor; installations employing a pusher airscrew, with the exception of the Hill Pterodactyl, are now rarely seen, it being well known that the latter arrangement is less efficient than the former.

In the case of single-engined flying-boats the pusher airscrew is employed because of the necessity of keeping the airscrew well clear of both pilot and water.

When outboard engines are used, the mountings generally form part of the main plane structure.

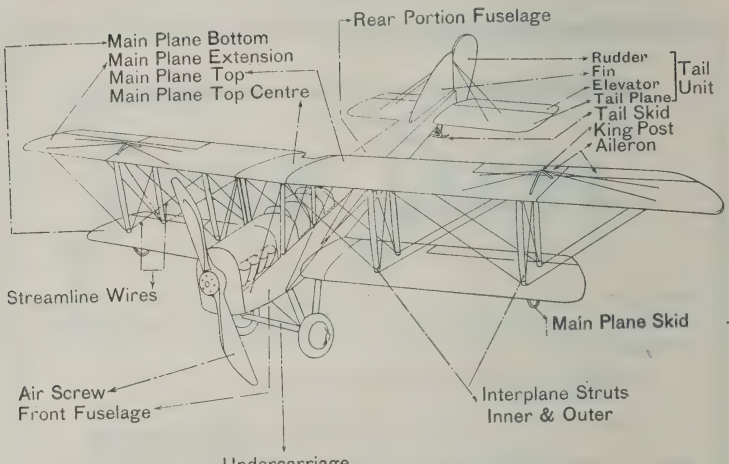

FIG. 1.—Aeroplane Components.

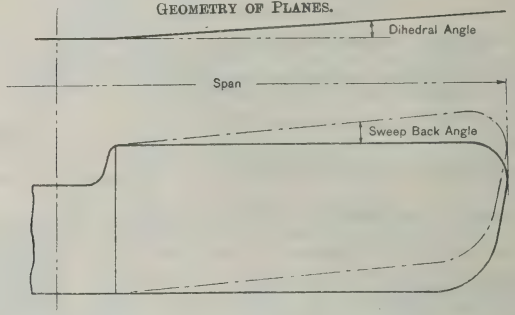

FIG. 2.

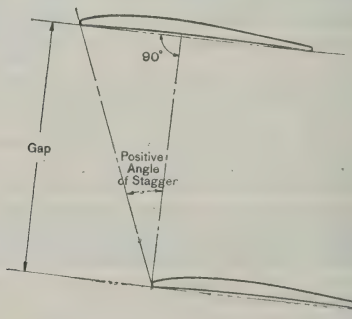

FIG. 3.

The several components are indicated in fig. 1, while the geometry of main planes is indicated in figs. 2 and 3.

Airships and Balloons.

Under group (*b*) aircrafts are classified either as Airships or Balloons, of which the former class is, of course, by far the most important.

Airships have experienced three stages of development, commencing with the non-rigid type, passing to the semi-rigid, and thence to the rigid type.

Both airships and balloons derive their total lift from two sources—viz. buoyancy and dynamic lift. The former is due to the difference in density of the gas in the envelope and the external air, while the latter is due to the relative air speed, and is also affected by the geometrical shape of the envelope.

Kite Balloons.

The free spherical balloon is now practically extinct. Balloons, however, of a certain kind, known as 'kite balloons,' are used for observation purposes. As their name would imply, they are either let up into the air from a fixed point on the ground by means of a cable, or towed behind a ship (as in the late war) for submarine spotting.

The height to which a balloon of this kind may be flown is determined largely by the weight of the cable to which it is attached; thus the balloon ceases to rise when its weight together with the weight of cable is equal to the total lift. Heights between 2000–3000 ft. may be reached.

The shape is maintained by means of the pressure of the gas it contains. When fully inflated, the fabric assumes a streamline shape. One or three fins are fitted, but these are inflated by air pressure, for which purpose a fabric pipe or scoop is directed into the wind.

Non-Rigid Airships.

As in the case of the kite balloon, the shape of a non-rigid airship is maintained solely by the internal gas pressure.

The relative speed of the ship being generally greater than that of a kite balloon, particular attention must be paid to its dynamic loading. Experiment shows that under flight conditions a very high pressure is exerted on the nose. It is not, therefore, surprising if at high speeds the nose is blown in. Fortunately the region of this high-pressure zone is quite local, the pressure falling off rapidly in a longitudinal direction.

The type of ship which survived others of more simple form was devised by Torres in Spain, and manufactured in France by the Astra Co., and known as the Astra-Torres type.

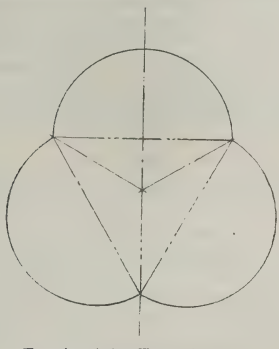

FIG. 4.—Astra-Torres Trefoil Section.

Although in outline the ship has a streamline shape, in cross-section a circular shape is distorted to form a trefoil section having three equal lobes, as in fig. 4. In this way an internal system of triangular bracing is possible, and to this the dead weights of the car and engine are carried by ropes.

The car is slung immediately underneath the envelope somewhat to the front of the ship, provision being made for the engine at the rear of the car, so that a pusher airscrew is employed, or separate engine units may be installed. To guard against any independent pitch or roll of the car, ropes are taken from it fore and aft, as well as port and starboard, to the two lower lobes. In these two lobes small compartments called balloonettes are made with fabric fore and aft, each being fitted with a scoop which may be adjusted to point into the airscrew slip stream. The function of these air balloonettes is to maintain the shape of the envelope when the internal gas pressure is varied. Thus air may be withdrawn or delivered to the balloonettes at the pilot's will. Should the nose be blown in for reasons already stated, the shape is regained by delivering air to

the forward balloonette. To assist the retention of the airship's shape, ribs are usually fitted at the nose in radial directions and taken back several feet behind the plane of the nose.

As is general, automatic gas valves are supplied apart from the pilot's control. The ship is fitted with relatively large rudder and elevator planes, to the rear of which the rudder and elevators are respectively attached.

Semi-Rigid Airships.

In order to relieve the envelope of a non-rigid airship from some of its strains arising from the connection of cabins, power cars, etc., this type of ship has been introduced permitting an envelope of circular cross-section to be used. For this purpose a keel consisting of a braced structure, usually triangular or rectangular in section, is suspended immediately under the envelope, and to this in turn the dead weights of the car and engine are transmitted.

In modern designs, as for instance the "Norge," the keel is practically enclosed in the envelope, in order to produce a good streamline form of low head resistance. In this way very little external rigging is therefore necessary.

Recently, it was suggested, in a proposed design,* to employ a form of twin keel, the two independent structures being manufactured in duralumin and braced together at intervals. The control cabin and a passenger saloon was arranged to be built between the two keels, and the wing power cars mounted on a transverse girder made integral with the twin keel.

Apart from the employment of a keel, a semi-rigid is in other respects similar to a non-rigid airship. The particular advantage of this type of ship over the rigid type is that in case of necessity the envelope may be deflated, the keel dismantled, and the whole transported without much difficulty.

Rigid Airships.

This type was developed in Germany by Count Zeppelin; it consists of a framework of girders whose external form corresponds with the shape of the airship, the covering being directly attached to them.

The early rigids were made with a comparatively long central parallel portion with a short head and tail; the parallel portion underwent successive shortening until the modern perfect streamline shape was evolved. Thus the fineness ratio was reduced from something in excess of 10 to about 8·5 in the case of R33, whose form is shown in fig. 5, while future ships may have this figure reduced further to about 5. In order to obtain minimum resistance, the actual lines of the hull are determined from a consideration of the rates of change of curvature.† The early shape had certain manufacturing advantages owing to its parallel centre portion, but with the new streamline form these advantages disappear.

Structurally, the framework consists of a series of transverse hoops or rings connected to a series of longitudinals. Both the rings and the longitudinals are similarly constructed, frequently

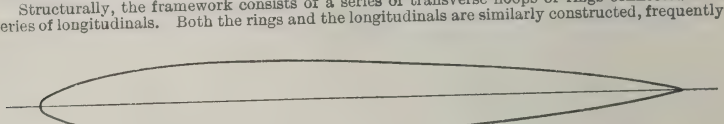

FIG. 5.—Envelope form of R33. Fineness ratio, 8·5.

being triangular in section. The rings are polygonal, having approximately twenty-five sides. Special provision is made for the efficient connection between the rings and longitudinals, while the whole structure is made rigid by a system of wire bracing. A central wire runs from nose to stern, and there are radial wires in the plane of each ring, which pick up the central cable. The space between two rings is occupied by a balloonette; there may be twenty of these balloonettes in all. About half the bags are fitted with a manœuvring valve on top, but each is supplied with an automatic valve, which maintains the hydrogen pressure at some predetermined amount, usually opening when the ship has reached a height of about 20,000 ft.

The navigation car is suspended near the nose of the ship, and is fitted with the usual controls and instruments. Another car placed aft is generally fitted up as an auxiliary control car in case of necessity. Engines may be installed in the rear of these cars. Other cars or gondolas may be employed to carry power units only. Such are suspended out of the plane of symmetry, in order that their airscrews may not operate in the slip stream of those attached to the navigating or after car.

---

* *Flight*, November 17, 1927, p. 790.

† 'Some Modern Developments in Rigid Airship Construction.' By V. C. Richmond, Inst.N.A., March 30, 1928.

Bumpers are generally provided under all cars.

Elevators and rudders are connected to large fin surfaces, which are, of course, fabric covered. The structure of these latter is integral with the hull, in order that the considerable lateral forces, due to the control surfaces, may be sustained and transmitted to it. In the past the control surfaces have been hand-controlled through suitable gearing.

RIGID AIRSHIP R101.*

This airship, intended for Empire communication on a passenger-carrying and commercial basis, embodies a number of features which are entirely new in airship construction.

The ship is capable of non-stop flights of about 3 days, the passengers being accommodated on two decks inside the hull near the centre of the ship.

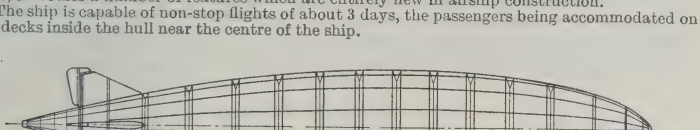

FIG. 6.

A skeleton diagram of the structure is given in fig. 6, brief particulars of the design and construction being as under :—

SHAPE OF ENVELOPE.

This is of streamline form of fineness ratio 5·5, the lowest on record. There is no parallel portion of the envelope as in previous designs.

The shape of the envelope was evolved to give a very low drag coefficient, the latter being very little more (about 2 per cent.) than that of a circular plate of diameter equal to the maximum diameter of the ship. The equation to the profile is :—

$$y = \left[0{\cdot}05549 \left\{ 400 - 0{\cdot}00076x^2 \right\}^{\frac{1}{2}} + 0{\cdot}09968 \right] \left[x \left\{ 20 - 0{\cdot}02762x \right\} \right]^{\frac{1}{2}}$$

where x = distance from bow in feet;
y = ordinate or radius in feet; from the longitudinal axis.

The total length of the ship is 732 ft., and the maximum diameter 132 ft. After initial trials the length was increased to 777 ft.

GAS BAGS.

Including one in the tail there are 16 gas bags, having a total capacity of 5×10^6 cu. ft. A gross lift of 150 tons is obtained.

FRAMES.

In the main, the structure has been manufactured by Messrs. Boulton and Paul, Ltd., Norwich. The frames are of the rigid 'ring' type, requiring no radial bracing in their own plane. The structure of each ring is triangular, there being two outer ridge girders and one inner, all braced together. Again, each girder is, in itself, of triangular form, whose booms and webs are made from stainless strip steel and suitably lightened duralumin respectively.

There are 15 frames, apart from the light conical structure ending with the tail cockpit.

LONGITUDINALS.

There are 15 main longitudinal members bolted to the frames, so as to be entirely outside them. By the introduction of 15 intermediate longitudinals the airship section is a polygon of 30 sides. The intermediate members are intended to assist in taking the lateral load from the envelope, reduce the tension in the latter, and thus help to keep a better shape of envelope.

The longitudinals are braced triangular structures, consisting of Boulton and Paul closed joint tubes of rolled stainless steel strip.

FINS.

The horizontal and vertical fins are built on continuous girders at two frames. To facilitate the fitting of the fins, the section of the ship changes between frames Nos. 12 and 13 (*i.e.* immediately in front of the leading edge of the tail fins) from 30 to 32 sides. To do this the top longitudinal is forked and the others skewed.

* Destroyed by fire at Beauvais in France, October 5, 1930. Official Report, April 1931.

Power Installation.

There are five identical power units, each housed in a car, which are quickly and easily detachable. The engines are of the Beardmore heavy fuel oil type, giving 585 h.p. (normal) and 650 h.p. (max.), at about 1,000 r.p.m.

The main engine is started by an auxiliary petrol engine through a Bendix drive.

There is room for an engineer in each car, and certain repairs may be effected during flight.

Evaporative cooling is employed.

The airscrews are required to be about 16 ft. diameter. Variable pitch hollow steel airscrews have suffered on test under torque variation, and solid, light alloy ones are being developed.

A windmill absorbing 15 h.p. drives an auxiliary generator and air-compressor. The latter is used for trimming the water-ballast and also to pump fuel from the main tanks to the engines, or to shift it from tank to tank to give trim.

About 30 tons of fuel is carried in all, being sufficient for about 50 hours' flight at 75 m.p.h.

Prevention of Corrosion.

All duralumin is treated by the anodic process, and the Boulton and Paul rust-proofing process is applied to steel parts.

B.—AERODYNAMICS.

Wind Channels.

Practically all aerodynamic research is performed with a wind channel, the forces and moments on a model suspended in an air stream being measured. Invariably it is impossible to apply the data thus obtained to the full-scale machine or component (as distinct from a detail such as a wheel or strut) without certain corrections, due to what is known as 'scale effect,' which is dealt with in Part D, p. 2011.

Up to 1923 two principal types of channel had been developed. At Göttingen, Professor Prandtl uses a channel of the 'racecourse' type, *i.e.* one in which the same air is caused by means of a fan to move along a closed circuit of rectangular plan form. The working portion occurs at one of the longer sides. A particular advantage of this type of channel is that it is independent of the size and shape of the room in which it is installed.

N.P.L. Type Channel.

In this country the staff of the National Physical Laboratory has been responsible for the development (since 1910) of the English type of channel. Fig. 7 shows in outline the general layout of a 2 ft. 6 ins. × 2 ft. 0 in. demonstration channel of modified N.P.L. type, constructed at the Northampton Polytechnic Institute, London, for the use of students in the Aeronautical Laboratory.

The N.P.L. type channel is built of wood and supported on a braced steel structure, so that the horizontal centre line is well above the floor. The working portion of the channel is situated towards the end of the front portion of the channel which is fitted with a carefully shaped intake. This part of the channel is generally square in section and about six diameters long. In order to further reduce any possible eddy motion which may have been set up at the intake, and to counteract the tendency of the fan to impart rotation to the air stream, a honeycomb is placed at each end of the channel. This is made of mild steel sheet, and is constructed to give cells 2 ins. to 4 ins. square and 1 ft. to 2 ft. long, according to the size of the channel.

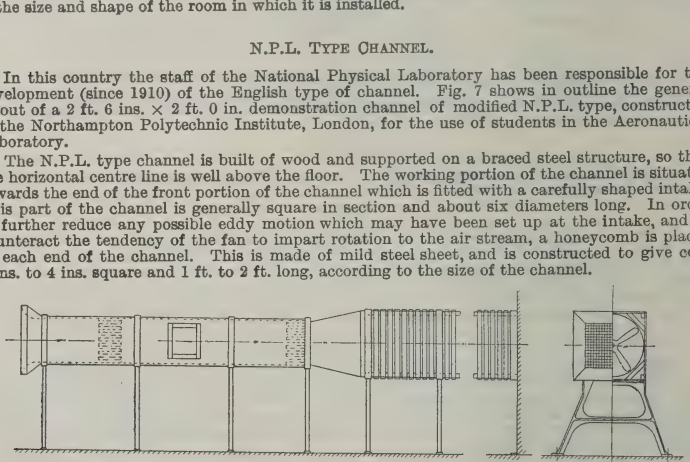

Fig. 7.—Modified N.P.L. Type, 2 ft. 6 ins. Wind Channel. End View of Channel.

The end of the channel at the rear honeycomb is rigidly connected to a metal fan chamber, so constructed that in a distance of a few feet its section changes from that of the channel, viz. square or rectangular, to circular. The four-bladed fan is driven directly by a motor mounted on independent supports, so that no vibration from it shall reach and affect the air stream.

The air thus drawn into the channel is discharged by the fan into another and somewhat larger channel known as the diffuser, which in length is shorter than the channel. It is constructed to have a number of transverse slots in horizontal and vertical planes. The slot widths are adjusted by experiment to give a constant outflow velocity along the length of the diffuser.

This type of wind channel, in which air enters at one end and is discharged through the diffuser at the other, must be installed in a large room free from obstacles which interfere with steady flow.

In the region of the working portion, glazed air-tight doors are fitted for convenient access and visibility.

Under working conditions, the air speed must be maintained as constant as possible. For this purpose the line voltage is regulated to within $\frac{1}{2}$ per cent., while in addition the motor speed is under the complete control of the experimenter. With a carefully shaped intake and a properly adjusted diffuser the velocity of flow in the channel at the working portion will be uniform to within $\pm$ 1 per cent.

Other Types of Channel.

It has long been realised that with the present-day high-speed aircraft, special care must be taken in order to reduce the scale effect corrections which should otherwise be applied to results of model tests. The criterion being that Reynold's number $\frac{vl}{\nu}$ (where v is speed, l some linear dimension, usually the wing chord, and ν the kinematic viscosity of the fluid medium) for the full-scale machine, and the model should be the same, suggests the possible courses:

(*a*) To increase the size of model and/or wind speed of test.

(*b*) To increase the wind speed and decrease the kinematic viscosity of the air by increasing its pressure, *ie.* its density.

The N.P.L. Duplex Channel.

During 1917 the existing 7-ft. wind channels at the N.P.L. were found to be inadequate, and in accordance with (*a*) above the now well-known 'Duplex' channel of section 14 ft. wide and 7 ft. high was designed and built on the lines suggested by experiments on models. In this channel the diffuser takes the special form of a cellular wall across the room. The air speed may be maintained at 120 ft. per sec. by two fans.

The Variable Density Channel.

In America it was decided to work upon the lines indicated in (*b*), and as a result Munk designed a channel to operate with air under a pressure of 20 atmospheres. Fig. 8 shows the form of the

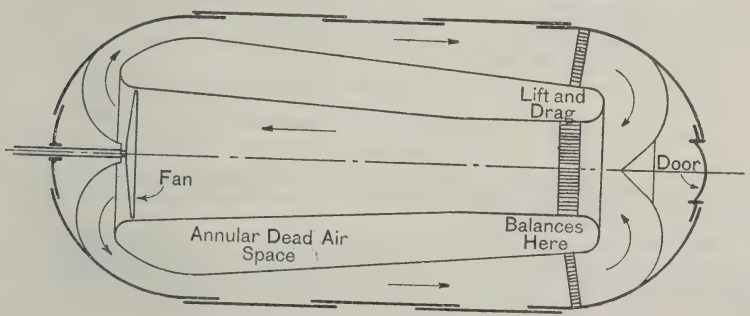

Fig. 8.—N.A.C.A., Variable Density Wind Channel.

channel constructed at Langley Field for the N.A.C.A. (National Advisory Committee for Aeronautics). It consists of a 5 ft. diameter working portion fitted with a honeycomb, the air being delivered by a fan at the 7 ft. diameter intake. Using the 'racecourse' principle, the channel proper is enclosed in a cylindrical steel shell fitted with hemispherical ends. The fan is driven by an externally placed motor, and observation panels are of course provided. Special balances are arranged in a dead air space and controlled from outside the channel. The casing rests on concrete supports. The air-compressor takes about half an hour to raise the channel pressure to the required amount. The channel operates at a Reynold's number of 5×10^6, which corresponds to a vl in free air of about 830. This is in excess of the vl for some full-scale machines.

Wind Channel Constraint.

The theory that the wind channel walls restrict the flow past bodies suspended in the channel for test, necessitating certain corrections to be made to the observed data, has been developed by Prandtl.* For an observed k_L the corrections, owing to the deflection of the air stream, involve (in the case of an aerofoil) small increases $\Delta\alpha$ and Δk_D to the observed α and k_D in order that the results may apply to a channel of infinite size—*i.e.* free air conditions.

The corrections take the form,

$$\Delta\alpha = \delta \frac{S}{C} k_L \text{ radians} = 57{\cdot}3\, \delta \frac{S}{C} k_L \text{ degrees} \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

$$\text{and } \Delta k_D = \delta \frac{S}{C} k_L^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where,

S = main plane area of model.
C = cross-sectional area of channel.
δ = a coefficient which depends on the shape of the channel.

Values of δ obtained mathematically are given in Table I.

Table I.

Shape of Channel.	Rectangular.			Circular.
Ratio $\frac{\text{height}}{\text{width}}$	$\frac{1}{2}$	$\frac{1}{\sqrt{2}}$	1	—
δ	0·274	0·238	0·274	0·25

Aerofoils.

When the main planes of an aeroplane are considered apart from the rest of the machine they may be referred to as 'aerofoils,' and the shape of a main plane section given by a plane parallel to the plane of symmetry is spoken of as the 'aerofoil section.'

A typical section is shown in fig. 9.

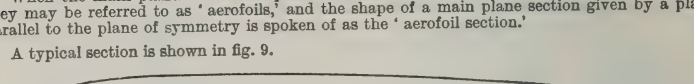

Fig. 9.—Aerofoil R.A.F. 15.

The upper and lower surfaces of an aerofoil are cambered, being arranged to meet in the front to form a blunt nose or leading edge, while at the rear the aerofoil is finished off with a somewhat elongated trailing edge.

The chord of an aerofoil is generally defined as the length of the common tangent to the lower cambered surface cut off by projectors from the leading and trailing edges. In the case of a 'thick' aerofoil section in which the lower camber is convex like the upper, the chord may then be defined as the length of the line passing through the centre of curvature of the leading and trailing edges cut off by the extremities of the aerofoil.

* 'Tragflügeltheorie,' *Göttingen Nachrichten*, 1919.

Fig. 10 shows an aerofoil inclined at an angle of incidence α to the direction of the wind. The resultant force R acting on the aerofoil depends upon α, the wind speed V, and the area of the aerofoil S. Let the line of action of R cut the chord AB in C. The resultant force R may be resolved normal to and along the direction of flight giving a lift force L and a drag force D. The angle between the direction of the resultant force and the lift component is γ. The position of C is determined in the case of model experiments by the measurement of the moment M acting at the point A, the sign of M being reckoned positive when acting in a clockwise direction.

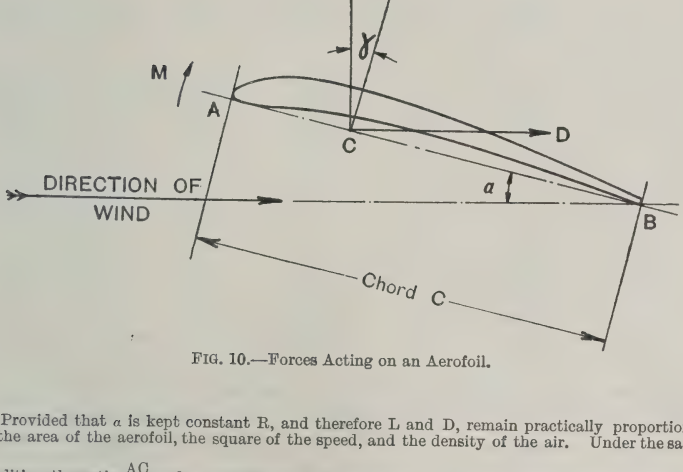

FIG. 10.—Forces Acting on an Aerofoil.

Provided that α is kept constant R, and therefore L and D, remain practically proportional to the area of the aerofoil, the square of the speed, and the density of the air. Under the same condition the ratio $\frac{AC}{AB}$ and γ remain practically constant. If ρ is the mass density * of air, the quantities $\frac{R}{\rho SV^2}$ and $\frac{AC}{AB} \cdot \gamma$ are non-dimensional and also practically independent of the linear dimensions of the model or wind speed during a given test.

The following definitions may now be made :—

$$\text{Lift coefficient } k_L = \frac{L}{\rho S V^2} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

$$\text{Drag coefficient } k_D = \frac{D}{\rho S V^2} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

$$\text{Moment coefficient } k_M = \frac{M}{\rho S c V^2} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

Centre of pressure coefficient—

$$k_{CP} = \frac{AC}{AB} = -\frac{M}{c\,(L \cos \alpha + D \sin \alpha)} = -\frac{k_M}{k_L \cos \alpha + k_D \sin \alpha} = -\frac{k_M}{k_L} \text{ approx.} \quad . \quad (6)$$

* The mass density $= \frac{\text{weight density in lbs./ft.}^3}{g} = 0{\cdot}00237$ slug/ft.^{3} at ground level under standard conditions.

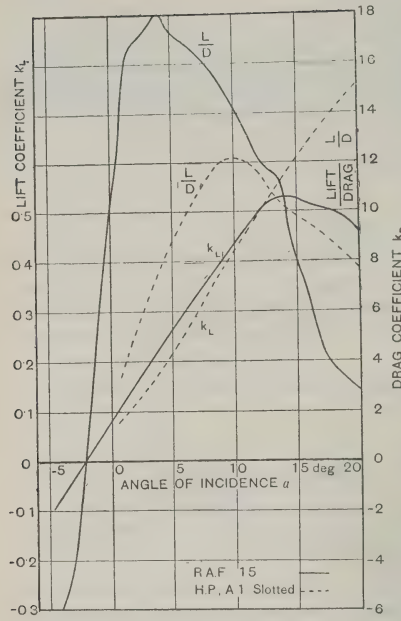

FIG. 11.

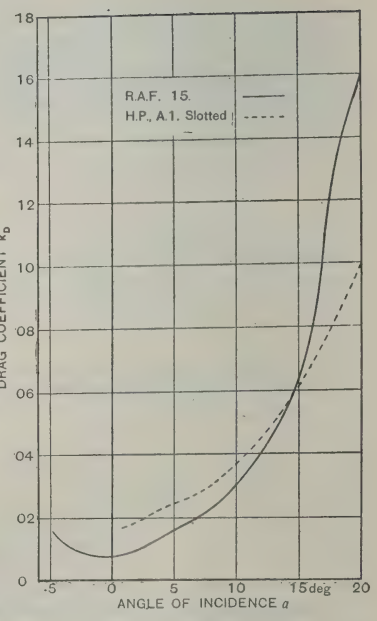

FIG. 12.

It is thus possible to express the aerodynamic characteristics of an aerofoil by plotting, as in figs. 11 and 12, the coefficients in equations (3) and (4) against the independent variable α, the angle of incidence. In experimental work α is given various values between $-5°$ and $+20°$, so that the whole flying range is more than covered.

0·443	20·10	0·1619	0·334	20·31	0·1635	2·71

Correcting factors : $\Delta\alpha° = 0·48k_L$; $\Delta k_D = 0·00838k_L^2$.

Table II. gives the contours of aerofoil R.A.F. 15 and its aerodynamic characteristics, which have been corrected for channel constraint.

The correcting factors are obtained in the following way :—

For N.P.L. 7 ft. channel $h/b = 1$ $\therefore \delta = 0·274$ as given by Table I.

Area of model aerofoil $= \frac{36 \times 6}{144} = 1·5$ sq. ft.

Area of channel $C = 7 \times 7 = 49$ sq. ft.

then

$$\Delta\alpha = \frac{57·3 \times 0·274 \times 1·5}{49} k_L \text{ degrees}$$

$$\Delta\alpha° = 0·480\, k_L$$

and

$$\Delta k_D = \frac{0·274 \times 1·5}{49} k_L^2 = 0·00838\, k_L^2.$$

THE SLOTTED AEROFOIL.

The introduction of the slotted aerofoil has been described as the most important invention of the last decade. It was produced simultaneously by Handley Page in this country, and Lachmann in Germany in 1919, both working independently. At that time the primary object was to produce an aerofoil having a high lift coefficient in order to reduce the landing speed of a given machine.

The main aerofoil, throughout its entire length, was made with an adjustable nose of streamline form called an auxiliary aerofoil, which could be moved to or away from the main aerofoil by

* The abbreviation R. and M. refers to Reports and Memoranda of the Advisory Committee for Aeronautics. Published by H.M.S.O.

a hand-operated link motion. With the slot closed the main aerofoil is of normal section. With the auxiliary aerofoil in its forward position the slot is said to be open.

Later, it was found that good results were given if the auxiliary aerofoil were made of duralumin sheet, bent to suit the shape of the nose of the main aerofoil. Fig. 13 shows a leading edge slot of this type fully open. The main aerofoil section is the Handley-Page A.1, which is a slightly modified R.A.F. 15, shown in fig. 9, having increased camber to permit deeper spars being employed. It will be noticed that there is a rear slot provided between the back of the rear spar and the leading edge of the aileron. When the aileron is depressed the slot remains

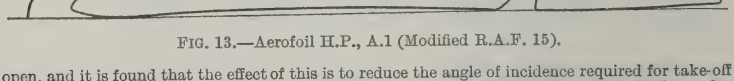

FIG. 13.—Aerofoil H.P., A.1 (Modified R.A.F. 15).

open, and it is found that the effect of this is to reduce the angle of incidence required for take-off or landing from an excessive figure above 20°, to one in the region of 18°. With the front slot open and the aileron at 0°, the results of wind-channel tests (for which k_D and α have been corrected for channel restraint) are shown compared with those for a standard R.A.F. 15 section in figs. 11 and 12. It will be seen that an increase in lift coefficient of nearly 100 per cent. is obtained, but at the expense of an increased angle of incidence. The model used for these observations was 36-in. span by 6-in. chord (6·4 ins. with slot open), and the experiments were performed in a channel 4 ft. × 4 ft. at a wind speed of 44 ft./sec.* It is clear, therefore, that by the use of a leading edge slot extending the whole main plane span, a greatly increased speed range is possible.

As a result of subsequent research, the principle of the slot may be applied to give full lateral control at and beyond the stalling speed of the aeroplane. In this case the leading edge slot is fitted near the main plane tips only, but slightly inboard, over a distance roughly corresponding with the length of the ailerons, but the leading edge of the latter is still so shaped as to produce a slot between itself and the back of the rear spar. Further, for control purposes, the slot need only be fitted to the top plane of a biplane combination. The type of control is known as the slot and aileron control, since the auxiliary aerofoil and the aileron must be operated together. For the successful operation of the gear, the hinge position of the auxiliary aerofoil is very important, as also is the path along which it travels. These points are satisfied experimentally as there is a very wide range of direction of the resultant force on it as the angle of incidence is varied, and it is therefore essential that the interconnection of the auxiliary aerofoil and aileron by means of rods and links is so arranged that there is a closing torque operating on the auxiliary aerofoil. The ailerons are rigged in the usual way, *i.e.* when one is depressed the other is elevated. The corresponding movements of the auxiliary aerofoil are as follows :—

(*a*) With ailerons normal, both front and rear slots are open ;
(*b*) with one aileron depressed, front slot is fully opened and rear slot open ;
(*c*) with one aileron elevated, front slot is closed and rear slot open.

The value of the slot and aileron control lies in the rolling and yawing movements set up. For further information a number of references are given below.†

The latest development is due to the work of the staffs of the Royal Aircraft Establishment and N.P.L. in collaboration with the Handley Page Company, and consists of an arrangement whereby the opening and closing of the auxiliary aerofoil is carried out automatically without the use of link mechanism operated by the pilot.

SLOT AND INTERCEPTOR CONTROL.

Although the automatic slot (which opens or closes according to the angle of incidence) gives lateral stability when the aeroplane is stalled, the ailerons are not powerful in operation.

To improve control, a large yawing moment of correct sign is required—a state of affairs which demands that the slot on one side of the machine is closed or inoperative in its action when the aileron is moved up on that side.

It has been pointed out‡ that to avoid the complicated interconnection of aileron and slot, the desired effect may be obtained by an 'interceptor' connected to the aileron.

Under stalled conditions the interceptor considerably increases the power of the ailerons. It consists of a narrow hinged plate, independent of and behind the slot, and arranged to coincide normally with the main plane section. Through its hinge, the interceptor is connected to the aileron, so that when the latter is moved up the interceptor plate also moves up and comes into a vertical position. In this way the air flow is disturbed and burbling commences as though the slot were closed, thus causing that particular part of the main plane to stall, but giving the desired effect on control.

Factors affecting the Aerodynamic Qualities of an Aerofoil.

Quite apart from its geometrical properties, the results of tests on an aerofoil lose much of their value unless certain data are specified. The model chord, aspect ratio, and wind speed should be quoted, as these quantities have been shown to have a considerable effect on the characteristics. Experiments at the N.P.L. have in the past been undertaken to ascertain the extent of the variations involved when an aerofoil of given section is tested as a monoplane.

(*a*) Changes of Aspect Ratio.

These tests were carried out with models of the same chord, but different spans. Both k_L and $\frac{L}{D}$ were found to be affected. The maximum valve of k_L increases with the aspect ratio, as does the gradient of the curve for which k_L is plotted against α. This effect is still in evidence for aspect ratios well in excess of 10 or 12, but it is most serious for low values up to about 5, becoming less important as the aspect ratio is increased above this amount.

The $\frac{L}{D}$ variation is very large for valves of α above 2° or 3°; below this region the effect is, however, small. For a particular model, by changing the aspect ratio from 4 to 6 it was possible to obtain a 20 per cent. increase in the value of $\frac{L}{D}$. Hence large aspect ratios appear to be desirable from an aerodynamic point of view, but as a rule structural considerations limit the aspect ratio to a figure between 5 and 6.

(*b*) Changes of Wind Speed.

The effect of speed changes may be very serious to both k_L and k_D. Generally both the coefficients increase with speed, though not necessarily over the whole range of the test.

The $\frac{L}{D}$ variation is much greater than that of k_L. Here, the effect tends to reach a limit as the speed is increased, say, from 20 ft. per sec. to 60 ft. per sec. This variation is due to scale effect, and in Part D it is shown that for a series of models of the same aerofoil, but having different chords, the same coefficients are obtained, if for each model the speed is so arranged that the product of speed and chord (*i.e.*, V.*l.*) is the same in every case.

BIPLANE AND TRIPLANE EFFECT.

The aerodynamic characteristics of a given aerofoil when tested as a monoplane are no longer realized when tested as a biplane arrangement. In the case of a triplane a further loss of efficiency is experienced. Approximate results are given in Table III., which show the falling off of both $k_{L\,max.}$ and $\frac{L}{D}_{max.}$ due to the mutual interference of the planes. The justification of the general use of the biplane arrangement in practice lies in its structural advantages.

Table III.—Biplane and Triplane Effect on R.A.F. 15 (R. and M. 432).

Each plane 3 ins. × 18 ins. No stagger. Gap/Chord = 0·75. Wind speed, 40 ft./sec.

	Monoplane.	Biplane.	Triplane.
$k_{L\,max.}$	0·54	0·48	0·44
$\frac{L}{D}_{max.}$	16·5	13·0	11·5

Experiment shows that in a biplane, rounded tips, dihedral angle (if less than 10°), and sweep-back (if less than 20°), have practically no effect on k_L and k_D. On the other hand, however, the gap/chord ratio and stagger are important.

(*a*) Changes of Gap/Chord Ratio.

In experiments on a biplane the gap/chord ratio was varied between 0·67 and 2·33, and in all cases there was no stagger. A summary of the results is shown in Table IV.

Table IV.—Changes of Gap/Chord Ratio for R.A.F. 6c Biplane (R. and M. 196).

Each plane, 3 ins. × 18 ins. Zero stagger. Wind speed, 40 ft./sec.

	Gap/Chord Ratio.					
	0·67	1·00	1·33	1·67	2·00	2·33
k_L max.	0·531	0·562	0·570	0·600	0·598	0·601
k_D min.	0·0131	0·0133	0·0132	0·0132	0·0128	0·0124
$\frac{L}{D}$ max.	14·1	15·3	16·0	16·1	16·7	17·2

It will be seen that the maximum lift coefficient definitely increases with the gap, while the minimum drag coefficient tends to fall.

When the angle of incidence is greater than 1°, for a given lift coefficient, $\frac{L}{D}$ falls as the gap/chord ratio is decreased.

On the whole, there seems little to gain by using a gap/chord ratio in excess of, say, 1·33. Here again, however, structural considerations alone prevent the use of long interplane struts; generally, in practice, a gap/chord ratio in the region of unity is adopted.

The necessity of using a relatively small gap with its attendant loss of efficiency may be partly overcome by the use of a lower plane of smaller chord than the upper.

(*b*) Variations of Stagger.

Using the same aerofoils as in the previous set of experiments, observations of lift and drag were taken for three angles of stagger. The results are shown in Table V.

Table V.—Changes of Stagger for R.A.F. 6c Biplane (R. and M. 196).

Each plane, 3 ins. × 18 ins. Gap/chord, 0·9. Wind speed, 40 ft./sec.

	Angle of Stagger.		
	+ 30°	0°.	− 29°.
k_L max.	0·585	0·555	0·525
k_D min.	0·0133	0·0133	0·0137
$\frac{L}{D}$ max.	14·8	14·6	14·9

For angles of incidence up to about 5° there is practically no aerodynamic difference between the three arrangements. At larger values of k_L the negatively staggered biplane appears to be inferior. The positive stagger increases the lift coefficient, while negative stagger with this aerofoil reduces it.

The Distribution of Forces between the Planes of a Biplane Combination.

Using a R.A.F. 15 combination, the lift, drag, and centre of pressure coefficients have been obtained for angles of stagger of + 30°, 0°, and − 30°.

Regarding the efficiency of a plane in a biplane combination as the ratio of its lift to that of the combination, fig. 14 is obtained by plotting the efficiency of the top plane for various angles of incidence for each stagger considered, and joining the corresponding points with a smooth curve. Assuming this procedure allowable (in the absence of other intermediate values), the following observations may be made :—

(*a*) For zero stagger, the upper plane is always the more efficient.

(*b*) Except for large angles of incidence of a combination employing a large negative stagger, the efficiency of the *forward* plane is the greater.

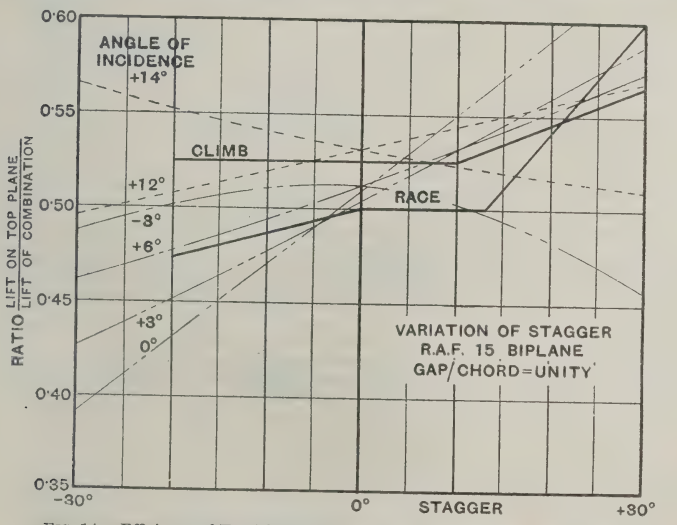

FIG. 14.—Efficiency of Top Plane in Biplane Combination. (R. and M. 589.)

The mean curves in fig. 14 for average conditions of race and climb correspond to those given in the Air Ministry's ' Handbook of Strength Calculations.' *

Reference to the original work in R. and M. 589 shows that the centre of pressure coefficient of each plane changes in the usual way, varying from about $0{\cdot}26\,c$ at $\alpha = 14°$ to $0{\cdot}40\,c$ at $\alpha = 1°$. For a given angle of incidence the C.P. coefficient for both planes is approximately the same.

Distribution of Pressure over the Chord of an Aerofoil.

In order to determine the manner in which the pressure varies over the chord of an aerofoil on both upper and lower surfaces, a special model is prepared, and measurements made of the fluid pressure at various places. The model is preferably made of metal, and the surface drilled deep enough at the desired places, so that all the holes are connected to a common tube, which is finally connected to a Chattock gauge. The holes are filled with plasticene, and one opened at a time, so that the local pressure may be taken. It has been shown that the size of the hole is unimportant; generally it is $\frac{1}{64}$ in. diameter. In this way the distribution of pressure over any chord may be obtained. Except for a region near the tips, the pressure distribution across the chord for the whole

* Air Publication 970, obtainable from H.M.S.O. Price 3*s.* 0*d.* net.

length of plane (of constant chord) is indicated in fig. 15 for two angles of incidence. This refers to experiments on R.A.F. 15 biplane of 6-in. chord, the results of which are given in R. and M. 355. Generally there is a suction on the upper surface and a smaller pressure on the lower surface. Both the positive and negative pressures reach their greatest values near the leading edge where the change in pressure is very rapid. At the point on the nose normal to the air stream, the pressure

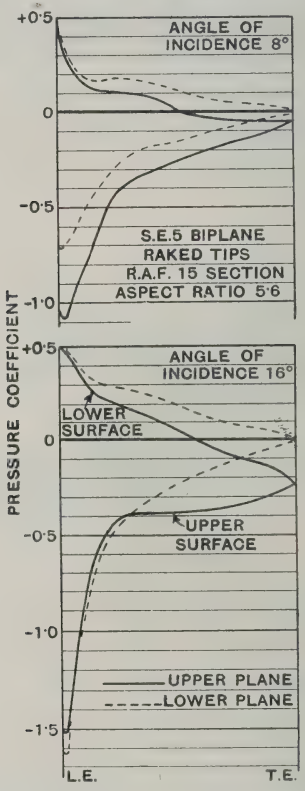

FIG. 15.—Distribution of Load over Chords of Biplane. (R. and M. 355.)

is known to be $\frac{1}{2}\rho V^2$ lbs. per sq. ft. In fig. 15 the coefficient of ρV^2 is plotted for each point, and it is clearly shown that near the nose of the upper surface of the aerofoil the pressure rapidly falls to a local value of approximately $-1{\cdot}5\rho V^2$.

Distribution of Pressure over the Span of an Aerofoil.

The investigation described in the previous paragraph was extended in order to find out how the intensity of load per foot-run of span varied over the whole of the top and bottom planes. For angles of incidence of 8° and 16° the results are exhibited in fig. 16, in which, for convenience, the ordinates are coefficients which represent the normal force per foot-run of span per foot-chord divided by ρV^2.

As would be expected, the normal force on the bottom plane is generally less than that for the top plane, while, with the exception of a temporary rise near the tips, there is a general falling off in loading as the tip is approached.

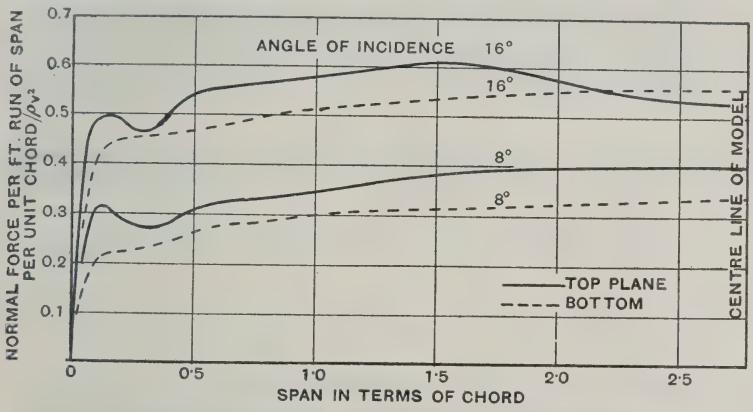

FIG. 16.—Variation of Normal Force along Span. (R. and M. 355.)

By comparison with a similar investigation on a R.A.F. 6 biplane with rounded tips, it appeared that the raked tips of the S.E. 5 biplane now under consideration gave approximately the same type of diminution of normal force towards the main plane tips.

Distribution of Pressure over Airship Envelope.

In the case of a model consisting of a solid of revolution, pressure plotting is carried out in the usual way by arranging holes along one generator, all being connected to a single tube. The

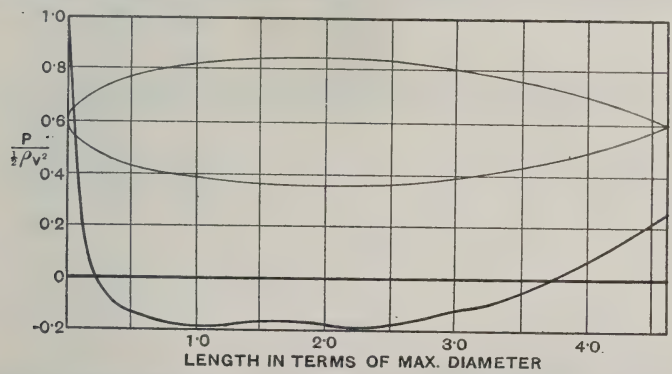

FIG. 17.—Pressure distribution on Model Airship Envelope. Axis along Wind. (R. and M. 600.)

difference in pressure between the point on the model and the suction hole in the channel wall are measured and corrected for the drop in static pressure which occurs along the direction of the axis of a model of this kind, whose length may be several feet.

For a model 39·7 ins. long and maximum diameter 8·59 ins. (fineness ratio, 4·62), at a wind speed of 40 ft./sec., the type of pressure distribution for the axis along the wind is shown in fig. 17.

As would be expected, the coefficient of ρV^2 at the nose is 0·5, which, however, rapidly falls to zero, and changes sign at a short distance behind the nose. The coefficient remains at a negative value until a point near the tail is reached. It will be seen that the maximum pressure coefficient at the tail is only 25 per cent. of that at the nose.

The diagram illustrates very clearly the necessity of strengthening the nose of airships.

When the direction of the wind is inclined to the axis of the model the pressure distribution undergoes important changes. At any cross-section the pressure is no longer uniform round the circumference but varies considerably.

A graphical representation of the kind of distribution is given in 'Applied Aerodynamics' (L. Bairstow), p. 211.

C.—THE AIRSCREW.

A typical wooden airscrew is shown in fig. 18. The shape of the blade changes continually along its length, but at all cross sections the resemblance to an aerofoil is maintained, except that near the boss it becomes more or less streamline.

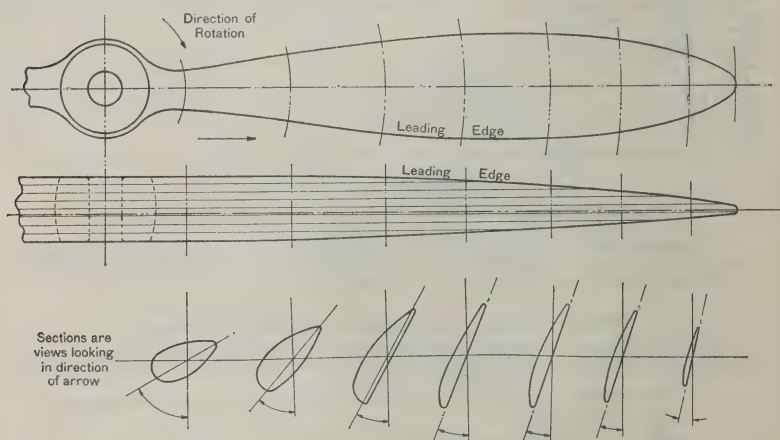

FIG. 18.—Typical Wooden Airscrew showing Laminations.

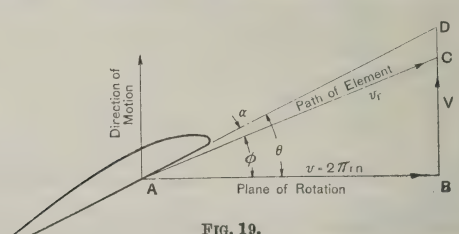

FIG. 19.

Consider an element of the blade as in fig. 19, and let

V = velocity of translation of element, *i.e.* forward velocity of aircraft;

n = rotational airscrew speed;

r = radial distance of element from axis of rotation;

α = angle of attack (or incidence) of blade element to helical path;

ϕ = angle between direction of relative wind at blade element, *i.e.*, the plane of rotation;

θ = blade angle of element, *i.e.*, the angle between chord of element and plane of rotation.

so that $\theta = \alpha + \phi$.

The triangle ABC is development of helical path of element, in which AB represents linear velocity ωr or $2\pi rn$ in the plane of rotation ; BC represents V ; and AC, the path of the element, represents the relative wind velocity v_r.

Thus $$\tan \phi = \frac{V}{2\pi rn}, \quad \text{or,} \quad 2\pi rn \tan \phi = V.$$

Now an airscrew is designed for a definite value of V corresponding to race or climb conditions, hence in a given airscrew $2\pi rn \tan \phi$ is constant at all points along the blade, and hence $\tan \phi$ varies inversely as r, and each element describes a helix of the same pitch.

Slip.

The analogy of a nut working on a bolt breaks down in the case of an airscrew for two reasons, viz. :

(*a*) For a given rotational engine speed the aeroplane, and therefore the airscrew, may have different translational speeds ; and

(*b*) As the air passes the plane of the airscrew it receives an additional backward velocity and the airscrew is said to slip and the stream of air behind the airscrew is called the slip stream.

Pitch.

Considering the airscrew as a whole the term ' pitch ' requires careful definition. Two pitches are in use.

(i) *The Geometrical Pitch.*—Suppose in a certain airscrew each blade element had no angle of attack as in fig. 20. In unit time each element moves forward V feet, but travels along its path

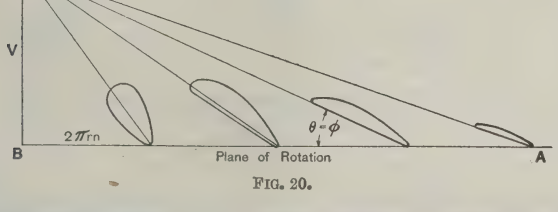

Fig. 20.

in the plane of rotation a distance $2\pi rn$. In these circumstances the advance BC of the airscrew per revolution is called the ' Geometrical Pitch ' P_g and the airscrew is said to have a constant pitch.

Usually, however, airscrews are made with varying angles of attack α along the blade (fig. 19), thus the geometrical pitch of each element varies, and the airscrew cannot be said to have a geometrical pitch.

In such a case the geometrical pitch of an element situated at two-thirds radius from the axis is called the ' Geometrical Mean Pitch ' for the airscrew, *i.e.*,

$$BD = P_g = 2\pi . \tfrac{2}{3}D \tan \theta = 2 \cdot 1 \ D \tan \theta,$$

where D = airscrew diameter.

(ii) *The Experimental Mean Pitch.*—Apart from other factors the thrust of an airscrew depends upon its rotational and translational speeds, n and V.

For any airscrew, at certain corresponding values of n and V the slip-stream entirely disappears, the air in the vicinity of the airscrew remaining practically undisturbed so that the thrust falls to zero. The value of $\frac{V}{n}$, or the advance per revolution when the airscrew thrust is zero, is called the ' Experimental Mean Pitch ' P.

Under working conditions when the airscrew is developing thrust at speeds V_1 and n_1 the slip is given by

$$\frac{V_1}{n} + \text{slip} = P.$$

Airscrew Characteristics.

The thrust T and torque Q of an airscrew are shown in Part D to depend upon ρ, V, n, and some linear dimension, generally taken to be the diameter D.

Provided that $\frac{V}{nD}$ (the advance per revolution as a fraction of the diameter) is constant, T is practically proportional to the mass density ρ, the square of the rotational speed n, and the fourth power of the airscrew diameter D.

∴ We may put

$$\text{Thrust coefficient } k_T = \frac{T}{\rho n^2 D^4} \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

similarly,

$$\text{Torque coefficient } k_Q = \frac{Q}{\rho n^2 D^5} \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

where k_T and k_Q are both non-dimensional, varying only with the value of $\frac{V}{nD}$ provided that the tip speed does not approach the velocity of sound.

Hence, in the same way that k_L and k_D depend upon the angle of incidence α for an aerofoil, so k_T and k_D depend upon $\frac{V}{nD}$ for an airscrew. The complete performance of an airscrew may therefore be expressed in terms of these quantities by plotting experimental results.

A typical set of characteristic curves is shown in fig. 21.

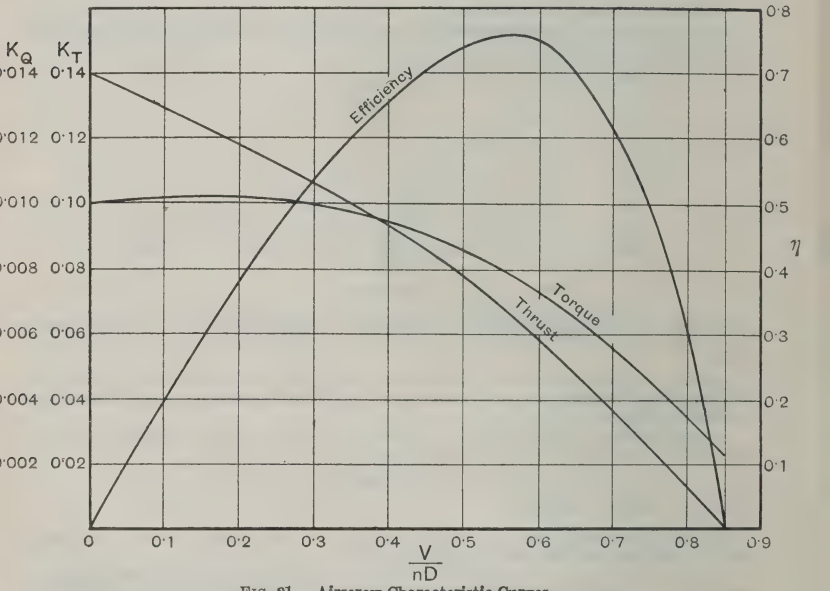

FIG. 21.—Airscrew Characteristic Curves.

The efficiency curve is obtained from the known values of k_T and k_Q from the relation

$$\eta = \frac{1}{2\pi} \cdot \frac{V}{nD} \cdot \frac{k_T}{k_Q} = \frac{1}{2\pi} \cdot \frac{k_T}{k_Q} \cdot J \quad . \quad . \quad . \quad . \quad . \quad (9)$$

where $J = \frac{V}{nD}$.

It is seen that the thrust is maximum when the airscrew has no translational speed V, falling off to zero at a certain value of J. This value corresponds to the experimental mean pitch P as a fraction of D.

The torque remains tolerably constant, first increasing slightly then falling off to a low value when the thrust is zero.

The efficiency is zero when $V = 0$ and also when $T = 0$.

The working range of this airscrew corresponds to values of J between 0·40 and 0·65, the maximum efficiency being reached when J is between these values. Except in special cases the value of J at top speed does not exceed unity.

Airscrew Theories.

A number of theories have been put forward by means of which expressions for thrust, torque, and efficiency may be obtained. Among the most important are :—

(*a*) The Froude momentum theory.
(*b*) The application of Bernouilli's theorem.
(*c*) The simple aerofoil theory.
(*d*) The inflow theory.

The Froude Momentum Theory.

In propounding this theory Froude supposed the actual airscrew replaced by an ideal one consisting of an imaginary disc in whose plane an instantaneous change of pressure occurred under working conditions.

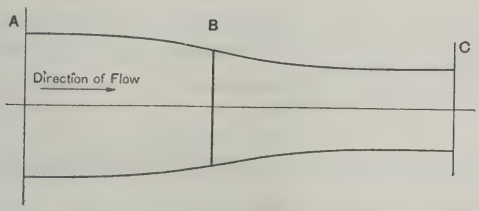

Fig. 22.

Regarding the airscrew as stationary, the ingoing and outgoing streams are indicated in fig. 22. On the upstream face of the disc there is a region of negative pressure which causes motion, and on the downstream face the pressure instantaneously changes to a positive value which increases the pressure of air in the outgoing stream or slip-stream.

Assuming frictionless streamline flow, and considering sections A and C sufficiently removed from the disc B such that the streamlines are parallel, tabulate the quantities concerned :—

Section.	Velocity.	Cross-sectional Area of Stream.	Pressure.
A	V_1	A_1	p_1
B	V_0	$A_0 = \frac{\pi}{4}D^2$	
C	V_2	$A_2 = KA_0$	p_1

The outgoing stream contracts, making the slip stream velocity V_2 greater than V_1.

Thus

$$V_2 = V_1(1 + b), \quad . \quad . \quad . \quad . \quad . \quad . \quad (10)$$

where b is the outflow factor.

Neglecting losses, it may be shown that,

$$V_0 = V_1\left(1 + \frac{b}{2}\right)$$
$$= V_1(1 + a_1) \quad . \quad . \quad . \quad . \quad . \quad . \quad (11)$$

where a_1 is the inflow factor.

Hence, in the ideal airscrew, half the added or slip stream velocity is imparted to the air immediately in front of the airscrew.

THRUST.

Since the thrust is given by the rate of change of momentum of the air stream, it may be deduced that,

$$T = \rho K A_0 (1 + b)\, b V_1^2 \quad . \quad . \quad . \quad . \quad . \quad (12)$$

where T is the thrust.

EFFICIENCY.

The ideal efficiency may be given as,

$$\eta_f = \frac{\text{work got out per sec.}}{\text{work got out per sec.} + \text{added kinetic energy of slip stream}}$$

from which

$$\eta_f = \frac{1}{1 + \frac{b}{2}} = \frac{2}{2 + b} = \frac{1}{1 + a_1}$$

which is known as the ideal or Froude efficiency. Generally the actual efficiency is between 80 per cent. and 85 per cent. of this ideal value.

THE APPLICATION OF BERNOUILLI'S THEOREM.

A consideration of the instantaneous pressure difference at the plane of the airscrew leads to a result identical with equation 11, so that in the ideal airscrew the theoretical inflow factor a_1 is half the outflow factor b. In the inflow theory it is assumed that under all conditions $a_1 = \lambda b$.

Actually λ is less than $\frac{1}{2}$ being more nearly $\frac{1}{2}$.

The Bernonilli and momentum theories may be combined to give results which agree fairly well with practice, so far as thrust is concerned.

The Simple Aerofoil Theory.

Considering the airscrew as made up of independent aerofoil elements moving along helical paths forms the basis of this theory proposed by Froude and subsequently developed by Lanchester and Drzewiecki.

Axial inflow as indicated in the momentum theory is neglected, the velocity of air relative to the airscrew and immediately in front of its plane being taken as V, the translational speed of the aircraft.

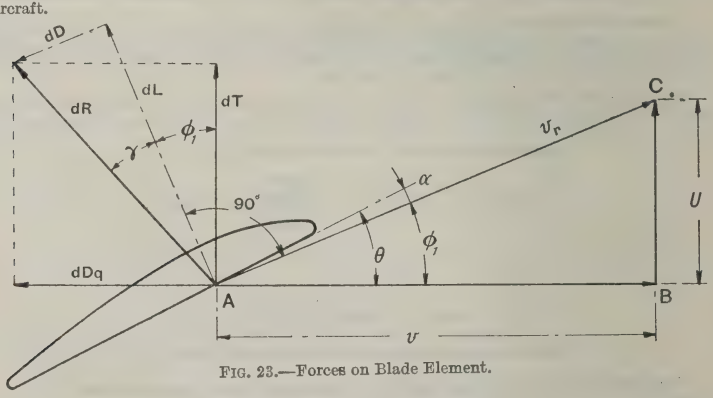

FIG. 23.—Forces on Blade Element.

FORCES ACTING ON BLADE ELEMENT.

Fig. 23 shows the forces acting on an element of blade at radius r from the axis, and substituting V for U and ϕ for ϕ_1, the diagram is applicable to the present case.

We have, treating the element as an aerofoil,

dR = Resultant force on element
dL = Lift " " "
dD = Drag " " "

where,

dL and dD act normal to and along CA respectively.

The direction of dL is in advance of dR by angle γ such that,

$$\gamma = \tan^{-1} \frac{k_D}{k_L}$$

if

dT = thrust on element, *i.e.*, the axial component of dR,
dD_q = transverse component acting at radius r from axis of rotation,
dQ = torque reaction on element,

then

$$dT = dR \cos(\phi + \gamma) \quad . \quad . \quad . \quad . \quad . \quad (13)$$
$$dD_q = dR \sin(\phi + \gamma)$$
$$dQ = r dR \sin(\phi + \gamma) \quad . \quad . \quad . \quad . \quad (14)$$

Efficiency of Whole Airscrew.

The efficiency of the whole airscrew is given by.

$$\eta = \frac{\text{work done by airscrew}}{\text{work done by engine}}$$

which reduces to

$$\eta = \frac{\tan \phi}{\tan(\phi + \gamma)} \quad . \quad . \quad . \quad . \quad . \quad . \quad (15)$$

On this basis, the efficiency of the element is maximum when $\phi = 45° - \frac{\gamma}{2}$.

Since $\frac{\gamma}{2}$ is small, this means that the maximum efficiency occurs when the rotational and translational speeds of the element are approximately equal.

The efficiency of the whole airscrew may be taken to be that of an element situated at a distance from the axis of about two-thirds tip radius. Thus, if an element so situated is working under the above condition, the airscrew would be working approximately at its maximum efficiency.

The Inflow Theory.

The simple theory, which was the first to be applied to design, generally gave efficiencies which were in excess of those obtained in practice. This led to the adoption of the inflow theory which allowed for the fact that the air immediately in front of the airscrew has a velocity greater than that of translation of the airscrew.

The axial inflow factor a_1 may be obtained experimentally for any given model or it may be calculated

There is experimental evidence that in addition to axial inflow, a rotational inflow also exists acting towards the boss. This is, however, small and is generally neglected.

Helix Angle of Blade Element.

Fig. 23 shows the forces acting on an element of blade, as already described, but in arriving at the helix angle ϕ_1, the velocity of the air passing the airscrew disc is now given by

$$U = V(1 + a_1)$$

and

$$\tan \phi_1 = \frac{U}{\omega r} = \frac{V(1 + a_1)}{2\pi r n}.$$

Efficiency of Blade Element.

The efficiency of the element now becomes

$$\eta_a = \frac{1}{1 + a_1} \cdot \frac{\tan \phi_1}{\tan(\phi_1 + \gamma)} \quad . \quad . \quad . \quad . \quad . \quad (16)$$

Thus the actual efficiency is the product of the Froude and Drzewiecki efficiencies except that U and not V is used in calculating ϕ_1.

The Total Thrust and Torque per Blade.

For any element of blade having chord c, treating the element as an aerofoil, the resultant force dR on it is $dR = k_L \rho c\, dr\, v_r^2 \sec \gamma$,

and

$$\text{Total thrust/blade } T_b = \int_0^R pc \sec\gamma \cos(\phi_1 + \gamma)\, dr \quad . \quad . \quad . \quad (17)$$

$$\text{Total torque/blade } Q_b = \int_0^R pc\, r \sec\gamma \sin(\phi_1 + \gamma)\, dr \quad . \quad . \quad (18)$$

where

p = pressure/ft.^{2} or air loading of blade $= k_L \rho v_r^2$.

In an analysis, the integrals in (17) and (18) are evaluated graphically. For this purpose about six sections or elements of blade are considered, approximately corresponding in position with those shown in fig. 18 and the thrust and torque grading for each element, viz.,

$$pc \sec\gamma \cos(\phi_1 + \gamma) \text{ and } pc\, r \sec\gamma \sin(\phi_1 + \gamma),$$

calculated, assuming $\sec\gamma$ to be unity. These are plotted on a base representing the blade radius, so that the area under each curve represents T_b and Q_b respectively.

The efficiency of the whole blade is,

$$\eta_b = \frac{V}{\omega} \cdot \frac{T_b}{Q_b}.$$

The efficiency of a well-designed airscrew is in the region of 80 per cent.

Plan Form of Blades.

The design process generally involves the choice of a particular plan form of blade, the shape of which is expressed in terms of the maximum chord or blade width c, at stated radii (as fractions of the tip radius) from the boss.

A shape of blade known as the Griffith plan form, in which torsional stresses are low, is practically symmetrical, and is shown in fig. 18.

Diameter of Airscrew Required.

It is generally necessary to fix the diameter of an airscrew and determine the necessary blade widths to absorb the available torque by the use of equations (17) and (18).

In order to avoid a trial and error process as far as possible, a preliminary determination of the required diameter may be obtained by formulæ proposed by Watts.* These are given below :—

Two-bladed airscrews

$$P = 1{\cdot}11 \times 10^{-10} D^4 n^2 V \quad . \quad . \quad . \quad . \quad . \quad . \quad (19)$$

Four-bladed airscrews

$$P = 2{\cdot}30 \times 10^{-10} D^4 n^2 V \quad . \quad . \quad . \quad . \quad . \quad . \quad (20)$$

where

P = h.p. absorbed ; n = r.p.m. ;
D = required diameter in ft. ; V = translational speed in m.p.h.

Note that here V is an estimated speed which will, among other things, depend on the efficiency of the airscrew when designed. In view of this there is every justification for looking upon the first airscrew for a particular case as experimental, making any necessary modifications after the initial trials have been completed.

In a particular design the diameter may be restricted to one smaller than that given by equations (19) or (20) above, for reasons of, say, ground clearance.

Horse-Power Absorbed.

The engine power curve, supplied by the engine manufacturers, gives the power to be absorbed at stated engine revolutions. The corresponding airscrew revolutions are known from the gear ratio of the engine, and at this speed the airscrew torque must be such as to absorb the power developed.

Thus, if

b = number of blades ; P = horse-power absorbed.

$$P = \frac{2\pi\, Q_b\, \text{n.b.}}{33{,}000} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (21)$$

where Q_b is the torque absorbed per blade as given in equation (18).

In design, the unknown maximum blade width c is determined from equation (21) and the remaining chords at specified sections are immediately known from the plan form adopted.

* *Screw Propellers for Aircraft.* H. C. Watts.

Rotational Speed.

In order that it may develop maximum power, the engine, and therefore the airscrew, must be run at or near a certain rotational speed. For a given flight or translational speed, the airscrew must have its maximum efficiency when the engine is running at that rotational speed. It follows that every combination of engine and aircraft will require its own particular airscrew.

Neglecting inflow, the maximum efficiency of a blade element at radius r from the boss occurs when $\phi = 45°$ approximately.

From fig. 19, $\tan \phi = \dfrac{V}{2\pi rn} = 1$ when $\phi = 45°$.

This means that for the element, $\dfrac{V}{nd} = \pi$ for best results. In any case the whole blade cannot work under this condition of maximum efficiency, and in practice it is not possible to cause the airscrew to rotate slow enough to give a value of π for the pitch diameter ratio.

On the other hand, in order to obtain a light airscrew for a given diameter, the blade widths must be small and the rotational speed high.

For conditions of maximum efficiency, airscrews operate, as a rule, at a value of J between 0·6 and unity.

The question is one of compromise, but, other things being equal, a slow-running airscrew has a greater efficiency than a high-speed one.

Number of Blades.

Airscrews are made with either two or four blades. Attempts to produce three-bladed airscrews do not appear to have given satisfactory results.

The choice of the number of blades usually rests with the designer. The advantages of two- and four-bladed airscrews are given below :—

Two-bladed airscrew—

Weighs very much less than the corresponding four-bladed airscrew.
Easy to transport.
Easier to manufacture than four-bladed airscrew.
Stronger at boss " " "
Cheaper " " "

Four-bladed airscrew—

Smaller diameter than corresponding two-bladed airscrew, which may be an advantage when clearances are important. Better balancing effect so that engine tends to run better and without vibration. Generally somewhat more efficient than two-bladed airscrew.

Manufacture.

Airscrews are made in either wood or metal, the materials being American walnut, Honduras mahogany, duralumin, or steel. In the case of wood, the moisture content should average 13 per cent.

A very great disadvantage of wooden airscrews is that in tropical countries the blade warps, and consequently its efficiency seriously falls.

Metal airscrews, which do not give this trouble, are, on the other hand, much heavier than corresponding wooden ones. It is hoped that before long the present high weights of metal airscrews will be reduced by modifying the method of manufacture.

Wooden Airscrews.

Laminæ.—An airscrew is produced by gluing together the requisite number of laminations, each 20 mm. thick. The shape of each lamination is determined from the drawing, but for the gluing operation each lamination is cut longer than the finished size.

The timber must be straight-grained and free from knots and, in general, must be cut so that the grain runs lengthwise and parallel to the surfaces to be glued. The surfaces are toothed before gluing (about 25 to the inch).

In a four-bladed airscrew the laminations are half-lapped at the boss, but the joints in adjacent laminations are slightly staggered. It is, however, permissible to have one lamination full thickness right through and employ butt joints for the two remaining blades.

The heavy arms of each lamination are marked, so that on gluing up, a heavy arm is in contact with a light one ; this facilitates final balancing.

Gluing.—All laminations are warmed to 70° F., glued together, and left under pressure for 24 hours.

Bore.—It is convenient to bore the airscrew before shaping.

Shaping.—When the airscrew has been out of the press for 2 days it is roughed out in plan form and on the blade face by band-saw, after which it is left for 4 days. After this period it is taken down to size by using templates at the sections indicated on the drawing and the whole blade cleaned up.

Balancing.—The airscrew is arranged on a horizontal mandrel, and tested for static balance. Material may, if necessary, be removed from the face of the blade only. A 1-oz. weight in a bolt-hole must cause the airscrew to turn.

Fabric Covering.—The blade is covered with fabric for about two-thirds the radius from the tip. In the case of a local failure of the timber, the fabric may hold the material together and prevent possible serious damage to the aircraft.

Metal Sheathing.—It has been found advisable to protect the leading edge and tip from rain, hail, etc., by covering them with thin sheet-brass. This is connected to the blade by countersunk screws for which purpose the brass is drilled and punched with a conical depression to receive the screw.

Metal Airscrews.

Wooden airscrews are being rapidly replaced by metal ones, manufactured from light alloy (generally duralumin) or mild steel.

At present they are more expensive and heavier, especially in the case of mild steel.

There are, however, very definite advantages in the use of metal airscrews, among which are :—

(*a*) Damage to blades by rain and hail is very rare.

(*b*) They withstand large and rapid changes in temperature and variations in atmospheric conditions generally, whereas the blades of wooden airscrews twist in tropical countries, causing a falling off in efficiency.

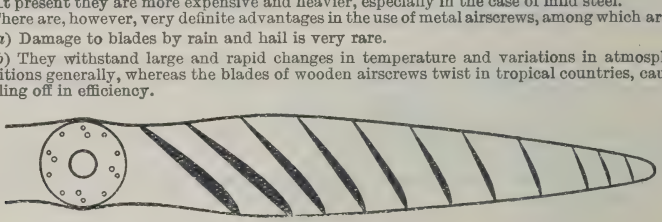

FIG. 24.

(*c*) As the blade tip sections can be made quite thin, as indicated in fig. 24, very high tip speeds may be employed, such as occur in high speed or racing aircraft.

DURALUMIN AIRSCREWS.

These airscrews were introduced by Dr. S. A. Reed in America, and developed and manufactured by the Fairey Aviation Co. in this country. Briefly, the manufacture of the standard D type airscrew is carried out in the following manner :—

1. A flat forged strip of duralumin, with a hub thickness up to 1½ ins., according to the size of airscrew, is sawn to suit the plan form of the blades.
2. By milling or shaping machines the blades are profiled to the desired aerofoil section.
3. The thick portion of the airscrew near the boss is twisted by a hydraulic press.
4. The outer portion of each blade is set by a twisting machine.
5. Blade angles checked.
6. Boss built up from wooden laminations or specially shaped metal blocks, the whole being held together by countersunk bolts.
7. Airscrew balanced on its own hub. A typical finished airscrew is shown in fig. 25.

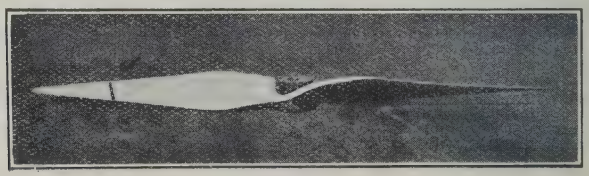

FIG. 25.—A Standard Fairey Metal Airscrew.

Advantages.

Particular advantages of this type of airscrew are :—

(*a*) After preliminary trials the blades may be adjusted to suit the aircraft and engine speeds. The blades may also be altered to suit any subsequent change in these speeds.

(*b*) The single forging avoids joints in the blade just where a joint is least desired. The extra complication of blade attachment fittings are also avoided.

(*c*) In cases of accident these airscrews bend where wooden ones would break. Damaged duralumin airscrews are frequently corrected and put into service again.

(*d*) Bent blades may be straightened up to 5° without thermal treatment.

Blade Stresses.

Cases have been known of airscrews working satisfactorily at a stress of 27,500 lbs./in.², corresponding with a factor of safety of 2.

Fatigue has not been known to occur.

Variable Pitch Airscrews

A variable pitch airscrew improves the performance of an aircraft, since by a small rotation of its blades about their own axis, its efficiency under varying flight conditions may be maintained.

There are three classes of variable pitch airscrews—namely, those in which the pitch is varied by :—

(1) Centrifugal force ;

(2) manual effort of pilot ;

(3) an entirely automatic action.

In (1) the pitch increases with the engine r.p.m., and there is the disadvantage that there is no control over the actual pitch. In take-off, therefore, when the engine speed is greatest and the aircraft speed small, the blades are rotated to give a large pitch when a small one is desired.

In (2) objections arise through the extra work thrown on the pilot, apart from any mechanical difficulties.

In (3) the problem has been solved by the Gloster Helo-Shaw Beacham variable pitch airscrew, which is entirely automatic in action, but under the control of the pilot, so that the engine r.p.m, may be varied to suit prevailing conditions.

The mechanism is so arranged that by means of a wheel or lever the pilot can set the airscrew to run at any desired rotational speed, which will be maintained under all flight conditions. This speed will not vary unless or until the pilot again operates his airscrew speed control.

In fig. 26 the airscrew hub A carries blades B_1B_2, which can rotate in the hub, while the centrifugal force set up by the blades is taken by ball thrust races. The airscrew shaft, C, is attached to the hub through a flanged coupling. A piston, D, is rigidly fixed to the front half of the hub, the former working in a cylinder, E, to which two tie rods, F_1F_2, are fixed. A sleeve, G, is connected to the other ends of these rods, the former being arranged concentrically with the airscrew shaft, so that it can slide fore and aft on bosses projecting from the hub. The sleeve and crank pins, I_1I_2 (which are fixed to the blades), are connected by short rods, H_1H_2. In this way, if cylinder E is displaced, the crank pin and blades are also displaced.

Three concentric oil pipes, 1, 2, and 3, run through the hollow airscrew shaft and rotate with it, for which purpose a rotating oil-tight joint, R, is provided. Pipes 1 and 2 communicate with opposite sides of piston D. The pitch of the blades is controlled, or maintained, by the oil pressure in these two pipes, the pressure variation causing cylinder E to move.

The oil pressure is obtained from a variable stroke pump, J, which, together with a governor are both driven by the engine. Engine lubricating oil is employed.

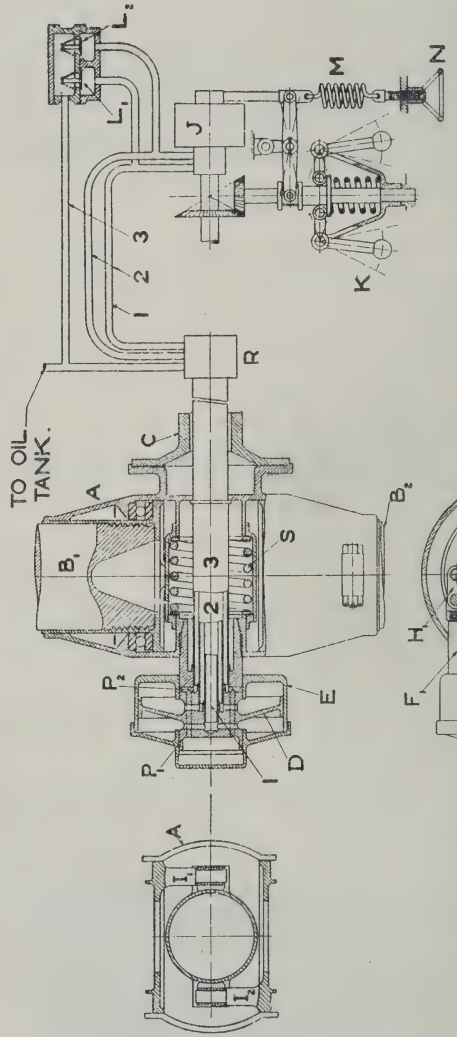

FIG. 26.—Gloster-Hele-Shaw Beacham Variable Pitch Airscrew.

The pump is of the type in which the pressure can be modified or changed to suction by altering the stroke of the pump. The governor is connected by links to the pump stroke rod and the controlling springs of the governor, being so arranged that at normal engine speed the pump has no stroke, and thus there is no oil delivery.

Pipes 1 and 2 are connected to the pump, so that either pipe 1 is on the pressure side and pipe 2 on the suction side, or *vice versa*.

Loss of oil is made up by leading branch pipes from pipes 1 and 2 to non-return valves, L_1L_2.

The speed at which the governor will float is controlled by a spring, M. It is adjusted by a handwheel, N, which also controls the normal speed at which the governor will take up its mid-position.

If the direction of rotation of the airscrew be such that a movement of cylinder E to the left will increase the pitch, then the pump is arranged so that when the governor commences to operate oil is pumped into pipe 1 and sucked from pipe 2.

Suppose the control wheel is set to any desired rotational speed with the airscrew at normal pitch. If, during flight, the forward speed of the machine increases, the r.p.m. will increase and the governor will cause oil to flow into pipe 1 to the front cylinder, thus increasing the pitch. This increases the torque, and the engine r.p.m. decreases, until the r.p.m. is again normal.

The maximum displacement of the cylinder from its normal position is limited in both directions by stops. When either limit is reached the oil pressure is kept normal by the opening of either of the relief ports, P_1 or P_2, in the piston communicating with pipe 3, which allows oil to reach the non-return valves and get back to the pump.

Should the hydraulic system fail a stiff spring, S, in the sleeve returns the airscrew to normal pitch.

D.—DYNAMIC SIMILARITY AND SCALE EFFECT.

Flight tests and experiments on full-scale aircraft are an expensive matter, but in many instances the required information may be obtained from a test on a geometrically similar model in a wind channel.

It does not necessarily follow, however, that because the model and full-scale machine are geometrically similar, there will be similarity of flow of fluids past these bodies, nor similarity of motion of the latter. In other words, there may not be dynamic similarity. The whole of the utility and application of model test results to full-scale depends on the conditions of dynamic similarity being known and satisfied.

Generally the model test cannot be carried out so as to satisfy all the required conditions simultaneously, but as a rule one particular condition has a predominating effect on the motion concerned, and if this is fulfilled the model results may generally be applied to full-scale. Owing to the neglect of the secondary conditions there is frequently a discrepancy between the full-scale results as predicted from model experiment (depending, for instance, on the shape of the body concerned) and those obtained directly from full-scale flight tests. Due to this 'scale effect' a correction has to be applied to the model test figures to bring them into agreement with full-scale results.

Sufficient full-scale tests have been carried out to enable certain scale effects to be determined.

The particular conditions which have to be satisfied when testing models of an aerofoil, a fuselage, flying-boat hull or an airscrew may be obtained by a method developed by Lord Rayleigh, and consists of an examination of the dimensions (in mass, length, and time) of the quantities thought or known to be involved.

A summary of the conditions governing the use of models in experimental work in order to predict the full-scale results is given below.

The Main Planes.

In the case of an aerofoil, the expression for the resultant force acting on it when in a stream of fluid is given by

$$R = \rho l^2 v^2 f\left(\frac{vl}{\nu}\right) \quad . \quad . \quad . \quad . \quad . \quad . \quad (22)$$

where

ρ = mass density of fluid (generally air) (ML^{-3});
l = some linear dimension (L);
ν = kinematic viscosity $(L^2 T^{-1})$.

The dimensions of these quantities are shown in brackets.
Also f is some function of the variable to be determined by experiment.

This result represents the resistance to steady motion arising from skin friction, due to the viscosity of the fluid but neglects the effect of compressibility of air which becomes important only when v approaches the velocity of sound v_s in the medium, viz., air. It may therefore be applied to aeroplanes and airships in steady flight.

In equation (22) the term l^2 in the case of an aerofoil is taken to be its area S, so that

$$R = \rho S v^2 f\left(\frac{vl}{\nu}\right) \quad . \quad . \quad . \quad . \quad . \quad . \quad (23)$$

Since for aerodynamic bodies, R is proportional to v^2, approximately, $f\left(\frac{vl}{\nu}\right)$ is practically constant for a given angle of incidence of the body.

$$\therefore \quad R = k\rho S v^2.$$

Resolving R vertically and horizontally

$$\text{Lift } L = k_L \rho S v^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (24)$$

$$\text{Drag } D = k_D \rho S v^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (25)$$

where k_L, k_D, the lift and drag coefficients, are non-dimensional, since $\frac{vl}{\nu}$ is non-dimensional, and depend upon α.

Owing to the slight inconstancy of $f\left(\frac{vl}{\nu}\right)$ there is only a small correction to be applied to model results in passing to full-scale.

Application of Law to Model and Full-Scale.

Consider model and full-scale geometrically similar machines, for which the effects of viscosity are of paramount importance.

It follows from equation (22) that the resultant force on full-scale machine is given by

$$R_1 = R_m \frac{l_1^2 v_1^2}{l_m^2 v_m^2} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (26)$$

if

$$f\left(\frac{v_1 l_1}{\nu}\right) = f\left(\frac{v_m}{\nu} l_m\right) \text{ where suffix } m \text{ refers to the model.}$$

The condition is clearly satisfied if in this case (*a*) $v_1 l_1 = v_m l_m$, or more generally if (*b*) $\frac{vl}{\nu}$ is the same in each case.

A law of corresponding speeds is represented by condition (*a*) in that for no scale effect the required speed of test for a model is given by $v_m = \frac{v_1 l_1}{l_m}$ when the force on the model would be that on the full-sized machine, which may be undesirable.

If in a certain case $l_1 = 10 l_m$, then $v_m = 10 v_1$. This is a clearly impossible condition, for assuming a full-scale machine to have a speed of 150 m.p.h. the speed of air in the wind channel would have to be 1,500 m.p.h.!

In actual wind-channel work the model size and wind speed are arranged to work at a value of $v_m l_m$ as near as possible to $v_1 l_1$ for the full-scale machine.

Condition (*b*) suggests the variable density wind channel (see p. 1989) in which ν_m is decreased by increasing the air pressure.

The Flying Boat.

The resistance to motion of that part of the hull of a ship or flying boat in contact with water is made up of two parts viz. (*a*) skin friction (due to the viscosity of water), and (*b*) wave formation (due to the gravitational effect).

The general equation now takes the form

$$R = \rho v^2 l^2 f\left(\frac{vl}{\nu}, \frac{v^2}{lg}\right) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (27)$$

Assuming these two effects to be independent

then

$$R = \rho\, v^2 l^2 f_1\left(\frac{vl}{\nu}\right) + \rho\, v^2 l^2 f_2\left(\frac{v^2}{lg}\right) \quad . \quad . \quad (28)$$

Wave-making Resistance.

At high speeds the resistance due to skin friction is relatively unimportant so that the wave-making resistance alone may be considered.

In order to give the function f_2 the same value, Froude's law of comparison demands that the corresponding speed of the model should be

$$v_m = v_1 \sqrt{\frac{l_m}{l_1}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (29)$$

both for model and full-scale hull.

This means that for wave-making resistance

$$R_1 = R_m \frac{l_1^3}{l_m^3} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (30)$$

Hence the resistances at corresponding speeds are as the displacements. This forms the basis of tests on flying-boat hulls.

Total Resistance.

As it is, however, impossible to satisfy the conditions for both skin and wave-making resistance simultaneously, the model must be made full scale.

Thrust and Torque of Airscrews.

Expressions for the thrust and torque of an airscrew as given below show that its performance depends upon the value of J $\left(i.e. \frac{V}{nD}\right)$ at which it is working.

Consider first the case of airscrews whose tips speeds are less than 800 ft./sec. Then the effect of compressibility of the air may be neglected, although it is then becoming important.

Static Airscrew.

Consider a static airscrew, *i.e.*, one which rotates in a fixed plane and has no forward motion

If the thrust T depends only upon airscrew diameter D, rotational speed n, mass density ρ, then

$$T = k_T \rho n^2 D^4 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (31)$$

where k_T is a constant called the thrust coefficient.

Similarly the torque,

$$Q = k_Q \rho n^2 D^5 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (32)$$

where k_Q is a constant called the torque coefficient.

Moving Airscrew.

Let the airscrew be moving with translational velocity V. If the thrust now depends only upon V, D, n, and ρ,

$$T = \rho n^2 D^4 f_1\left(\frac{V}{nD}\right)$$

or

$$T = \rho n^2 D^4 f_1(J) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (33)$$

where J is non-dimensional.

Similarly

$$Q = \rho\, n^2\, D^5 f_2(J) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (34)$$

Equations (33) and (34) show both T and Q to be dependent on J. In a given airscrew, D is fixed so that T and Q depend upon $\frac{V}{n}$. If then $\frac{V}{n}$ be kept constant $f_1(J)$ and $f_2(J)$ are also constant, so that we have

$$f_1(J) = k_T = \frac{\text{Thrust}}{\rho\, n^2\, D^4} \quad . \quad . \quad . \quad . \quad . \quad . \quad (35)$$

$$f_2(J) = k_Q = \frac{\text{Torque}}{\rho\, n^2\, D^5} \quad . \quad . \quad . \quad . \quad . \quad . \quad (36)$$

High-Speed Airscrews.

From experiments on high-speed *static* airscrews, it appears that when the tip speed of such approaches the velocity of sound (in air) the airflow undergoes changes, until, if the tip speed be increased, the outflow ceases, and the slip-stream disappears when the velocity of sound is reached; the airscrew then appears to operate as a centrifugal fan. With high-speed airscrews this is serious for the phenomenon is associated with a falling off of the thrust.

It seems reasonable to suppose that at such high speeds the compressibility of the air plays an important part.

Considering compressibility effects only, if v_s is the velocity of sound in air, the resistance to motion takes the form

$$R = \rho l^2 v^2 f\left(\frac{v}{v_s}\right) \quad . \quad . \quad . \quad . \quad . \quad . \quad (37)$$

and the effect of compressibility depends upon the velocity v as a fraction of the velocity of sound v_s in the undisturbed fluid. The relative importance of this may be obtained by applying Bernouilli's equation to a compressible fluid and assuming adiabatic transformation.

Let δp = increase in pressure at a stagnation point in the body.
v = velocity of undisturbed stream.
ρ = mass density where speed is v.

Then, if $\gamma = \frac{7}{5}$,

$$\delta p = \tfrac{1}{2}\rho v^2\left[1 + \tfrac{1}{4}\left(\frac{v}{v_s}\right)^2 + \tfrac{1}{40}\left(\frac{v}{v_s}\right)^4 + \ldots\right] = \lambda\rho v^2. \quad . \quad . \quad . \quad (38)$$

Since the series in equation (38) rapidly converges, the effect of compressibility may be neglected so long as $\frac{1}{4}\left(\frac{v}{v_s}\right)^2$ is small compared with unity.

The following table gives the approximate values of λ for the whole range of values of V from zero to v_s.

V *ft./sec.*	0	200	400	600	800	1,000	1,100 (v_s)
λ	1·000	1·008	1·033	1·077	1·149	1·224	1·275

When V = 220 ft./sec. (150 m.p.h.), $\lambda = 1{\cdot}01$, so that the neglect of compressibility at this speed would introduce an error of 1 per cent. On the other hand, it is clear that for velocities of 800 ft./sec. and over the effect of compressibility can no longer be disregarded.

Complete Expressions for Thrust and Torque.

In addition to the quantities already defined, let the following notation apply to the material of blade:

Δ = mass density (ML^{-3})
E = coefficient of elasticity, *i.e.* Young's modulus ($ML^{-1}T^{-2}$).

Assuming that T and Q depend upon

$$V, v_s, D, n, \nu, \rho, \Delta \text{ and } E,$$

it may be shown that

$$T = \rho n^2 D^4 f_1\left(\frac{V}{nD}, \frac{\nu}{nD^2}, \frac{v_s}{nD}, \frac{E}{n^2D^2\Delta}, \frac{\Delta}{\rho}\right) \quad . \quad . \quad . \quad (39)$$

and

$$Q = \rho n^2 D^5 f_2\left(\frac{V}{nD}, \frac{\nu}{nD^2}, \frac{v_s}{nD}, \frac{E}{n^2D^2\Delta}, \frac{\Delta}{\rho}\right) \quad . \quad . \quad . \quad (40)$$

For direct comparison of, say, the thrust, the function f_1 must be the same for both model and full scale, hence each of the five variables must be the same in each case. Of these variables it should be noted that:

(i) May be satisfied in that $\frac{V}{nD}$ may be made the same for both model and full scale.

(ii) The viscosity term is satisfied if nD^2 is the same if both airscrews are operating in the same medium. Thus, in order to ignore viscosity effects, a high rotational speed is necessary for the model.

(iii) The compressibility of the medium may be neglected if the tip speeds nD are the same.

(iv) Represents the blade distortion and if the material of the model and full-scale screws are the same, the distortion effects are the same if the tip speeds nD are the same.

(v) Is always satisfied if the material of the blade and density of the medium in which the screws are working are respectively the same.

Clearly these five conditions can only be satisfied simultaneously when the model is full size.

The question then arises as to the relative importance of these terms.

For airscrews of tip speeds not more than 700–800 *ft./sec.*—Experiment shows that the neglect of viscosity, compressibility, and distortion effects do not lead to serious error. With regard to the latter, the adoption of Griffith's symmetrical plan form of blade (fig. 18) greatly reduces the angle of twist. Under these circumstances equations (35) and (36) may be used for thrust and torque, as the variation of k_T and k_Q for a stated $\frac{V}{nD}$ is small, though definite.

For airscrews whose tip speeds are in excess of 800 *ft./sec. and approaching the velocity of sound.*—It has been shown in R. and M. 884 that in the case of model experiments:

(i) T increases up to V = 0·9 v_s, afterwards falling off rapidly.

(ii) Q increases more rapidly to V = 1·0 v_s, afterwards falling off slowly.

(iii) η falls away rapidly after V = 0·75 v_s (850 ft./sec.). In a particular case the efficiency fell from 68 per cent. at V = 850 ft./sec. to 40 per cent. at V = 1,300 ft./sec.

Full-scale experiments show that—

(i) Serious losses in efficiency occur at high tip speeds, resulting from a decreased thrust and increased torque.

(ii) Strength considerations are not likely to limit tip speeds.

(iii) At these speeds the noise emitted is very great and is apparently largely confined to the plane of the airscrew.

E.—PERFORMANCE.

In the estimation of aeroplane performance, two important quantities are involved, viz., horse-power required, and horse-power available. Both of these are usually required for all attitudes of the aeroplane over the flying range for a stated series of altitudes, from ground level to say, 10,000 ft. or 15,000 ft.

On the one hand, the horse-power required is calculated from the known or estimated drag coefficients of the various components and the aerodynamic characteristics of the main planes; on the other hand the horse-power available is a quantity which is not obtained without considerable calculation. Apart from the characteristics of the airscrew itself, its performance also depends on the particular combination of engine and aeroplane.

Account has to be taken of (*a*) the variation of engine power consequent upon the decrease in density, pressure, and temperature, with altitude; (*b*) the changing value of J under which the airscrew operates with varying attitudes of flight; (*c*) the continual change of atmospheric conditions from day to day and place to place.

The Standard Atmosphere.

In order to afford a basis of comparison of full scale tests, an International Standard Atmosphere has been defined * which corresponds with the average conditions in Western Europe.

It is assumed that:

(i) The air is dry and its chemical composition the same at all altitudes, by volume being 78·03 per cent. nitrogen, 20·99 per cent. oxygen, 0·94 per cent. argon, and 0·04 per cent. carbon dioxide.

(ii) The temperature at mean sea-level is 15° C., and the barometric height reduced to °0 C. is 760 mm.

(iii) The weight of air under these conditions is 1·2257 kg./m.^{3} (0·07656 lbs./ft.^{3}). The value of 'g' is taken to be uniform at 980·62 cms./sec.^{2} (32·17 ft./sec.^{2}). The mass density ρ_0 of air at mean sea-level is therefore 0·00237 slug/ft.^{3}

* Air Publication 1173.

(iv) For any altitude Z metres above mean sea-level up to a limit of 11,000 metres, *i.e.* to the bottom of the Stratosphere, the temperature (°C.) varies thus :—

$$\theta_z = 15 - 0{\cdot}0065\mathrm{Z} \quad . \quad . \quad . \quad . \quad . \quad (41)$$

(v) Above 11,000 metres θ is constant and equal to $-56{\cdot}5°$ C.

(vi) It follows that for any altitude Z less than 11,000 metres, where the barometric pressure is p_z and specific weight a_z and specific mass ρ_z, these quantities are connected by the equations :—

$$\frac{p_z}{p_o} = \left(\frac{T_z}{T_o}\right)^{5{\cdot}256} = \left(\frac{288 - 0{\cdot}0065\mathrm{Z}}{288}\right)^{5{\cdot}256} \quad . \quad . \quad . \quad . \quad (42)$$

and

$$\frac{\rho}{\rho_o} = \frac{a_z}{a_o} = \left(\frac{T_z}{T_o}\right)^{4{\cdot}256} = \left(\frac{288 - 0{\cdot}0065\mathrm{Z}}{288}\right)^{4{\cdot}256} \quad . \quad . \quad . \quad (43)$$

(vii) For altitudes above 11,000 metres the relations are :—

$$\log_{10}\frac{p_1}{p_z} = \log_{10}\frac{\rho_1}{\rho_z} = \log_{10}\frac{a_1}{a_z} = \frac{\mathrm{Z} - 11{,}000}{14{,}600} \quad . \quad . \quad . \quad (44)$$

where suffix 1 refers to conditions at Z = 11,000 metres.

Table VI. shows the approximate values of relative density and pressure and temperature for various heights as given by equations (42) and (43). For convenience, altitudes in feet have been tabulated.

TABLE VI.

International Standard Atmosphere.

The Variation of Engine Power with Altitude.

The engine power is now thought to depend on atmospheric pressure only, and as a result of a large number of full-scale experiments the variation appears to be roughly proportional to the pressure. It has actually been found by H. L. Stevens (R. and M. 960), that the variation in power is approximately proportional to $\left(\frac{p}{p_o}\right)^{1{\cdot}05}$.

For a given r.p.m., therefore, the b.h.p. in a standard atmosphere at mean sea-level (generally referred to as ground-level) must be multiplied by a horse-power factor $f(h)$ in order to obtain the corresponding b.h.p. at altitude h.

In symbolic form

$$(\text{b.h.p.})_h = \text{Std. b.h.p.} \times f(h) \quad . \quad . \quad . \quad . \quad . \quad (45)$$

the r.p.m. being the same in each case;

where

$$(h) = \left(\frac{p}{p_o}\right)^{1{\cdot}05} \quad . \quad . \quad . \quad . \quad (46)$$

which is given in Table VI., col. 4.

Generalised Airscrew Curves.

From an examination of a large number of airscrew tests, Bairstow and Coales have shown in R. and M. 474, that the results relating to thrust and torque coefficients may be expressed with fair approximation by a single curve for each when referred to the advance per revolution as a fraction of the experimental mean pitch, *i.e.* $\frac{V}{nP}$.

For this purpose two coefficients T_c and Q_c are introduced such that by multiplying k_T and k_Q respectively, by them, the products are each unity when $\frac{V}{nP} = 0{\cdot}5$.

Let $$\frac{V}{nP} = J_1$$

then, for all airscrews plotted on a base of J_1 we have,

(i) A curve representing thrust in which $T_c k_T$ is $1{\cdot}0$ when $J_1 = 0{\cdot}5$;

(ii) A curve representing torque in which $Q_c k_Q$ is $1{\cdot}0$ when $J_1 = 0{\cdot}5$;

where, for a given airscrew, T_c and Q_c are constant coefficients.

Now the airscrew efficiency may be expressed

$$\eta = \frac{1}{2\pi} \cdot \frac{T_c k_T}{Q_c k_Q} \cdot \frac{Q_c}{T_c} \cdot \frac{P}{D} \cdot J_1 \quad . \quad . \quad . \quad . \quad . \quad (47)$$

Using the fact that η is $\eta_{\text{max.}}$ when $J_1 = 0{\cdot}725$, a third curve showing the relation between $\eta/\eta_{\text{max.}}$ and J_1 may be obtained. These curves, known as 'Generalised Airscrew Curves,' are shown in fig. 27.

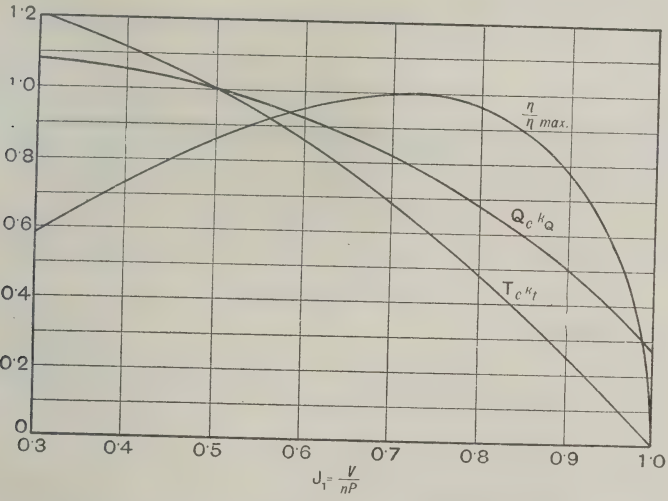

FIG. 27.—Generalised Airscrew Curves.

The curves of $T_c k_T$ and $Q_c k_Q$ were initially thought to be independent of $\frac{P}{D}$. Later work showed small variations in the value of the former with $\frac{P}{D}$. The curve in fig. 27 represents mean values. In the case of $Q_c k_Q$ larger variations were found with $\frac{P}{D}$. The curve shown in fig. 27

corresponds very approximately with $\frac{P}{D} = 1 \cdot 2$. For greater accuracy a family of curves should be drawn for $Q_c k_Q$.*

When $J_1 = 1 \cdot 0$ the corresponding values of $Q_c k_Q$ and $\frac{P}{D}$ are given in Table VII.

TABLE VII.

$\frac{P}{D}$	0·8	1·0	1·2	1·4	1·6
$Q_c k_Q$	0·48	0·38	0·30	0·25	0·21

Estimation of H.P. Available.

An approximate estimate of this quantity may be calculated if slip-stream effects of the airscrew are ignored. The problem then reduces to finding the airscrew efficiency for various engine speeds and therefore various flight speeds.

The generalised airscrew curves are used and the following data are required :—

(i) Engine power curve.

(ii) Estimated top speed $V_{max.}$ as given by some rapid method.

(iii) Airscrew diameter.

It is further necessary to assume that :—

(*a*) The engine runs at maximum permissible revolutions at maximum flight speed, and

(*b*) At this speed $J_1 = 0 \cdot 8$ say.

Rapid Estimation of Top Speed.

The probable maximum speed $V_{max.}$ at ground-level may be quickly obtained by using equations given in R. and M. 776. They are :—

For single-engine aircraft,

$$\left(\frac{V}{\sqrt{w}} - 25\right)^2 = 16 \cdot 6 \left(\frac{N}{\sqrt{w}} - 11 \cdot 8\right) \quad . \quad . \quad (48)$$

For multi-engine aircraft,

$$\left(\frac{V}{\sqrt{w}} - 23\right)^2 = 15 \cdot 7 \left(\frac{N}{\sqrt{w}} - 11 \cdot 6\right) \quad . \quad . \quad (49)$$

For boat seaplanes,

$$\left(\frac{V}{\sqrt{w}} - 20\right)^2 = 14 \cdot 4 \left(\frac{N}{\sqrt{w}} - 11 \cdot 35\right) \quad . \quad . \quad (50)$$

where

V = flight speed in m.p.h. at ground-level.

N = power per 1000 lb., i.e. $\frac{1000 \times \text{H.P.}}{\text{Total weight}}$.

w = main plane loading $\left(\frac{W}{S}\right)$ lbs./ft.^{2}

The value of $V_{max.}$ (in non-supercharged engines) falls as the altitude increases. For an aeroplane having a ceiling of about 20,000 ft., the values of $V'_{max.}$ at altitude h, may, with reserve, be taken to be the fractions of the ground-level value given in Table VIII.

* *Applied Aerodynamics*, Bairstow.

TABLE VIII.

h, ft.	5,000	10,000	15,000	17,500
$V'_{max.}$	97·5%	95%	90%	85%

Table VIII, in conjunction with the appropriate equation, 48, 49, or 50, therefore gives a rough estimate of the top speed at any desired altitude.

GENERAL PROCEDURE.

For flight at a given altitude h, proceed thus :—

(i) Calculate torque coefficient k_Q for a range of airscrew speeds n from the equation,

$$k_Q = \frac{550}{2\pi\rho_0 D^5} \cdot \frac{f(h)}{\sigma} \cdot \frac{\text{Std. b.h.p.}}{n^3} \quad . \quad . \quad . \quad . \quad (51)$$

Tabulate as in Table IX.

TABLE IX.—ESTIMATION OF H.P. AVAILABLE.

1	2	3	4	5	6	7	8	9	10
Engine speed r.p.m.	Airscrew speed r.p.s. n	Std. b.h.p.	k_Q	$Q_c k_Q$	$J_1 = \frac{V}{nP}$	$\frac{\eta}{\eta_{max.}}$	η	V ft./sec.	$H.P._A$
1,200									
1,400									
1,600									
1,800									
etc.									

(ii) Calculate experimental mean pitch P. From assumptions (a) and (b) we have

$$\frac{V_{max}}{n_{max} P} = 0{\cdot}8, \text{ so P is given at once.}$$

(iii) Calculate aircraft speed V for various airscrew speeds n.

Here $$V = \left(\frac{V}{nP}\right) \times n \times P.$$

This gives column 9.

(iv) Calculate Q_c.

For $J_1 = 0{\cdot}8$ corresponding to $n_{max.}$ and $V_{max.}$ read off $Q_c k_Q$ from fig. 27.

Then

$$Q_c = \frac{Q_c k_Q}{k_Q}, \text{ which is constant for all airscrew speeds.}$$

Column 5 may now be completed. Using the values of $Q_c k_Q$ thus found, read off and tabulate the corresponding values of J_1 and $\frac{\eta}{\eta_{max.}}$.

(v) Calculate $\eta_{max.}$.

Plot J_1 and n and read off n_1 when $J_1 = 0{\cdot}725$ which corresponds to $\eta_{max.}$.

Hence when airscrew is working at its maximum efficiency, aircraft speeed V_1 is given by,

$$V_1 = 0{\cdot}725\ n_1\ P.$$

The Froude efficiency η_F is then obtained by successive approximation in the following manner:

Assume $\eta_1 = 0{\cdot}8$ and calculate thrust T_1 from H.P.$_1$ and V_1.

From Froude's momentum theory

$$T_1 = \rho k A_0 (1 + b)\, b V_1^2,$$

where KA_0 = area of slip stream and $K = 0{\cdot}6$

$$A_0 = \frac{\pi}{4} D^2.$$

This gives b, and

$$\eta_F = \frac{2}{2 + b}.$$

If η_F is not equal to η_1, take η_F as a second approximation and repeat.

Finally, the actual efficiency $\eta_a = 0{\cdot}8\eta_F$ whichis the required $\eta_{\max}$.

The efficiencies at other aircraft speeds are then obtained from the tabulated ratios of $\frac{\eta}{\eta_{\max}}$.

(vi) Calculate the horse-power available, H.P.$_A$.

For each aircraft speed,

$$\text{H.P.}_A = \eta.\ \text{Std. b.h.p.} \quad . \quad . \quad . \quad . \quad (52)$$

Finally plot H.P.$_A$ against V as in fig. 27.

Horse-Power Required.

The amount of labour involved in the calculation of the horse-power required depends, as in the case of the horse-power available, upon the data available and the degree of accuracy required. The value of the result depends upon a fairly accurate knowledge of the resistance of the several parts or components as deduced from model tests. Fortunately, for most components the resistance is proportional to the square of the velocity over a very large range, but in the case of elongated aerodynamic bodies such as a fuselage or flying-boat hull, where skin friction effects are important, the index of V is less than two. Unless due care is taken serious errors in the estimated resistance may arise. It is found, however, that if the resistance of such bodies is known for a speed approximately mid-way over the flying range of speeds, the error at the extreme speeds in applying the V_1^2 law is small.

Resistances of Components.

The following list gives the resistances of various details or components at 100 m.p.h. at ground level which may be used in the absence of other data. In all cases the resistance may be assumed to vary as the square of the speed.

Fuselage (good streamline) when $\alpha = 0°$	2·6 lbs./sq. ft., projected area.
,, (two cockpits and nose radiator) when $\alpha = 0°$	8·0 ,, ,, ,, ,,
Tail plane and elevators	0·75 lbs./sq.ft. of plan area.
Fins and rudders	0·60 lbs./sq. ft. of side area.
Wheel, 800 × 150 mm.	13·5 lbs. with shield to tyre.
Struts, fineness ratios 2·5 to 5·0	2·3 lbs./sq. ft. projected area.
Add 0·4 lbs. for each end.	

Streamline wires.

4 B.A.	0·051	lbs./ft. run.	For end fittings add 2 ft. to the length of each wire.
2 B.A.	0·056	,, ,,	
$\frac{1}{4}$ in. B.S.F.	0·075	,, ,,	
$\frac{5}{16}$,, ,,	0·094	,, ,,	
$\frac{3}{8}$,, ,,	0·112	,, ,,	
$\frac{7}{16}$,, ,,	0·131	,, ,,	
$\frac{1}{2}$,, ,,	0·150	,, ,,	

Miscellaneous details. 5 lbs./sq. ft. projected area.

Simple Method of Calculation.

In an approximate method of calculating the horse-power required ($H.P._R$) the following assumptions are usually made :—

(i) The tail load may be ignored.
(ii) The variation in resistance of components due to changes of α may be neglected.
(iii) The line of thrust passes through the C.G.
(iv) The obliquity of the line of thrust may be neglected.
(v) The airscrew slip-stream diameter is 0·8 D.
(vi) The resistance of parts in the slip-stream is increased by 25 per cent. for any speed of flight (i.e., the slip-stream velocity is always $\sqrt{1{\cdot}25}$ V).

In view of condition (iii) the method outlined below cannot be applied to flying boats without modification.

The total resistance is composed of two parts (a) that due to main planes ; (b) that due to remainder.

For the former,
in steady flight,

$$L = W \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (53)$$

$$D = \frac{W}{L/D} = \frac{W}{\delta} \quad . \quad . \quad . \quad . \quad . \quad . \quad (54)$$

Let V_1 = flight speed in m.p.h.

then

$$V_{m.p.h.} = 1{\cdot}465\ V_{ft./sec.} \text{ and } (V_{m.p.h.})^2 = 2{\cdot}15\ (V_{ft./sec.})^2$$

and

$$V_1^2 = \frac{W}{2{\cdot}15\ k_L \rho S} \quad . \quad . \quad . \quad . \quad (55)$$

For the latter,

if R_1 = resistance of parts outside slip-stream at 100 m.p.h.
R_2 = " " inside " " " "
R = total resistance at 100 m.p.h.

then

$$R = R_1 + 1{\cdot}25\ R_2 \quad . \quad . \quad . \quad . \quad . \quad . \quad (56)$$

For a single-engined tractor, R_2 includes the fuselage, centre section struts and wires, part of tail unit, and undercarriage.
Hence, using equations (54) and (56).

At any speed V_1, the total drag of the aeroplane is given by

$$D_W + D_B = \frac{W}{\delta} + R\left(\frac{V_1}{100}\right)^2 \quad . \quad . \quad . \quad (57)$$

But for steady flight, using equation (3),

$$T = \frac{W}{\delta} + \frac{R}{10^4}\left(\frac{W}{2{\cdot}15\ k_L \rho S}\right) = \frac{W}{\delta} + D^1 \quad . \quad . \quad . \quad . \quad (58)$$

Finally,

$$H.P._R = \frac{V_1 T}{375} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (59)$$

Draw up Table X. for equal increments of k_L up to $k_{L\,max.}$ and plot the results as in fig. 27.

Table X.—Estimation of H.P. Required.

k_L	$\delta = \frac{L}{D}$	$\frac{W}{\delta}$	D^1	T	V_1	$H.P._R$

Deductions from Performance Curves.

Range of Flight Speeds.

In fig. 28, the curves of H.P.$_A$ and H.P.$_R$ both relate to the same height, viz., ground-level. The extreme flight speeds are given at the points of intersection of these curves. At A the stalling speed is obtained whilst at B the maximum flight speed is revealed.

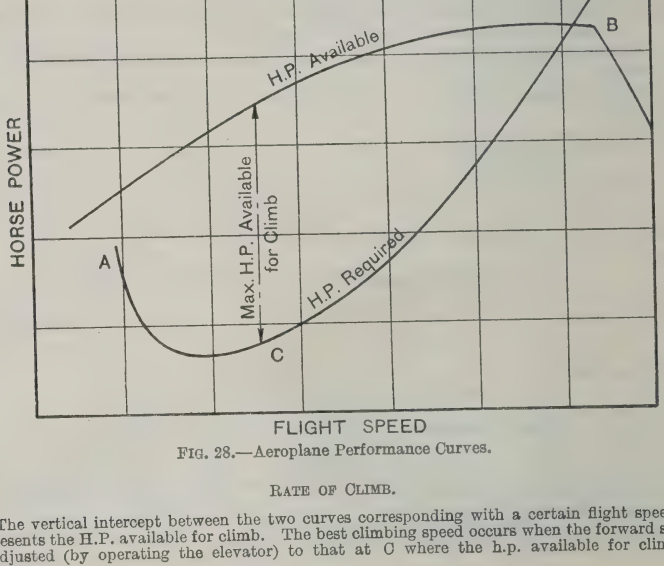

Fig. 28.—Aeroplane Performance Curves.

Rate of Climb.

The vertical intercept between the two curves corresponding with a certain flight speed V, represents the H.P. available for climb. The best climbing speed occurs when the forward speed is adjusted (by operating the elevator) to that at C where the h.p. available for climb is maximum.

It will be seen that the rate of climb r (or vertical velocity of ascent) will vary with the forward speed, in fact

$$r = \frac{(\text{H.P.}_A - \text{H.P.}_R)\,33{,}000}{W} \text{ ft./min.} \quad . \quad . \quad . \quad . \quad (60)$$

At the extreme speeds r is zero.

Flight at Altitude.

In order to obtain the horse-power required H.P.$_R$ for altitudes other than ground-level it is not necessary to go over a similar set of calculations.

If H.P.$_R$ and V refer to ground conditions, then at altitude h where the relative density is σ the corresponding powers H.P^1.$_R$ and speeds V^1 are given by

$$\text{H.P}^1.{}_R = \frac{\text{H.P.}_R}{\sqrt{\sigma}} \quad . \quad . \quad . \quad . \quad . \quad (61)$$

$$V^1 = \frac{V}{\sqrt{\sigma}} \quad . \quad . \quad . \quad . \quad . \quad . \quad (62)$$

Thus all the powers and speeds in Table X. are divided by the appropriate $\sqrt{\sigma}$ to obtain the corresponding figures at any desired altitude.

Water Performance of Flying Boats

In a proposed design, although according to calculation the machine would be able to fly in the air with a reserve of power, it would not necessarily follow that there would be sufficient power to enable the boat to leave the water in getting off. The water resistance is very large, so that floats and hulls have to be designed to reduce this as much as possible. For fuller information on this subject reference should be made to available published data.*

F.—DESIGN.

All Service aircraft have to be manufactured in metal. It is not permissible to use wood for a structural member. Constructors use either steel, duralumin, or both.

Steel.

Steel may be used in either of two forms, viz., as seamless tubing, or rolled sheet.†

Seamless Tubing.

Apart from manufacturing difficulties,‡ the use of round tubing in aircraft construction is limited to those members subjected to end loads only, for the material in a round tube is not disposed at a sufficiently large distance from the neutral plane as to allow it to be used efficiently for the transference of bending moments.

Since fuselage members are generally subjected to end-loads only, 50-ton round or square section tubing is frequently used in fuselage construction.

Rolled Sheet.

Rolled sheet steel is obtainable in various widths and lengths in thicknesses approaching 0·01 in. The material will withstand a compressive stress between 75 and 100 tons per sq. in.

Much of existing knowledge and technique of the production of rolled steel spars is due to the early investigations of Low, Robertson, Wylie, and others.

Duralumin.

The remarkable mechanical properties of duralumin depend on its heat treatment. When normalized at 485° C. it develops an ultimate stress of 25 tons per sq. in. after four days.

Being about one third the density of steel, duralumin may be used in more reasonable thicknesses than that necessary for members in rolled steel sheet.

Actual Examples.

The source of the diagrams used to illustrate the following notes is in each case indicated. Thanks are due to the Bristol Aeroplane Co. and the Gloster Aircraft Co. for diagrams and technical data. Special thanks are due to the Technical Editor of '*Flight*' for permission to reproduce a number of illustrations from that journal representing various types of construction.

Sir W. G. Armstrong-Whitworth (Aircraft), Ltd.

Fuselage Structure.—Round steel tubes are used throughout. At all panel points the longerons are fitted with short sleeves slipped over them and bolted in position.

The vertical struts are fitted with a cupped socket to take the ball-head of a bolt through the longeron. A typical joint for the rear portion of the fuselage is shown in fig. 28 (1). The port and starboard sides are erected on jigs and the structure completed by connecting the horizontal transverse struts.

A joint on the bottom longeron at the point of attachment of the front spar and lift wire is shown in fig. 29 (2), while (3) shows the corresponding joint for the rear spar. In this particular design the longeron is connected to a fork-end at this joint so that the front and rear portions of the fuselage are detachable.

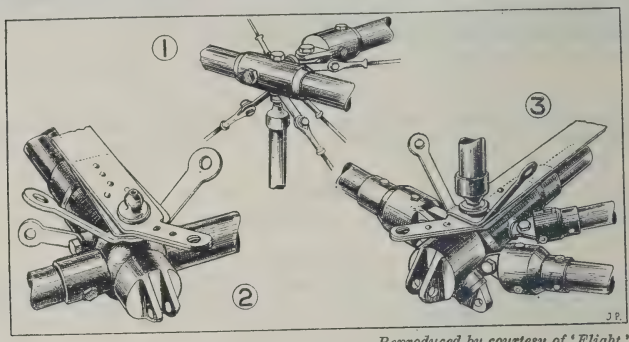
MAIN PLANE STRUCTURE.—Strip steel is used throughout for both spars and ribs.

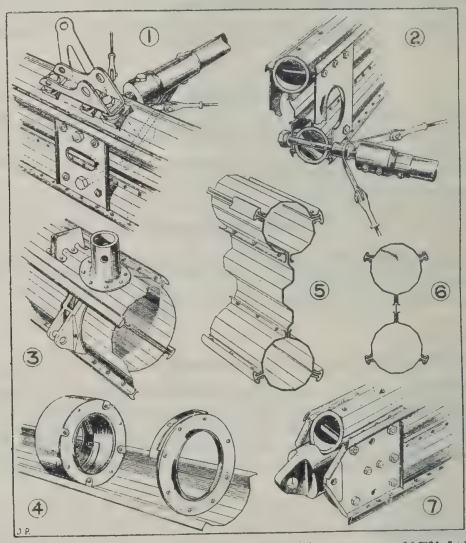
MAIN SPARS.—Two types of spar have been standardised. They are shown in fig. 30 (5) and (6). The section of the flanges or booms is polygonal and is built up in three equal sections with



Reproduced by courtesy of 'Flight.'

FIG. 29.—Armstrong-Whitworth Fuselage Construction.

flanged edges. Adjacent edges are held together by specially formed U strips, riveted at intervals. In the deep spar the web is corrugated as shown by flat surfaces joined by small curves. In the small spar the web consists of a narrow flat strip. Typical interplane and drag strut fittings for



Reproduced by courtesy of 'Flight.'

FIG. 30.—Armstrong-Whitworth Steel Strip Wing Spar Construction.

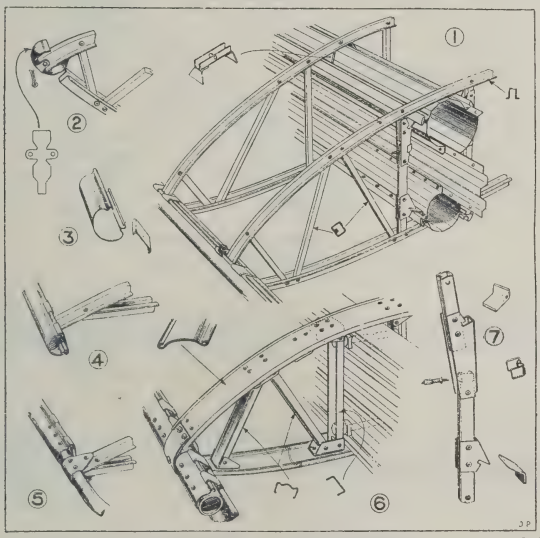
the deep type of spar are shown in (1) and (2). The spar is stiffened locally by short lengths of round tube inserted in the booms.

DRAG STRUTS.—The drag struts, which are of round seamless tube, are not attached at the neutral plane of the spar but to one of the booms. External flanged stiffeners are provided on each side of the spar.

End fittings for a shallow spar are shown in (7).

AILERON SPARS.—For members such as aileron spars which are required to transmit torque, a section approximating to a circle is necessary. Spar sections as in (5) and (6) are unsuitable. The type adopted is shown in (3) and consists of a polygonal form built up of four strips secured as in the case of the spar booms. Internal built-up stiffeners are provided where necessary, similar to those shown in (4). A rib clip, hinge, and strut socket are shown in (3).

RIBS.—Main plane ribs are built up in channel section for the flanges and square section for the bracing members, as indicated in fig. 31 (1). The ribs are not connected directly to the spars by riveting, but are held in position by the use of the toggle arrangement shown in (7).



Reproduced by courtesy of 'Flight.'

FIG. 31.—Armstrong-Whitworth Steel Wing Construction.

The leading edge is shown in (3). The ribs are connected to the leading edge by the upper rib boom only. For this purpose the end of this boom is fitted with a bent plate, shown in (2), which slides inside the leading edge strip. A friction grip between these two is obtained by sliding small plates up against each side of the rib. These are shown in postion in (1).

The fixing of the trailing edge to the rib is indicated in (5).

For strength ribs a further set of sections are used as illustrated in (6). The same section which is used for the flange of these ribs is employed for the fuselage fairing, to which the fabric is attached.

HEAT TREATMENT.—The operations of rolling or drawing are carried out on the flat strip while soft, and the necessary heat treatment given when the various units are made. The operation is done by using the finished unit as an electrical resistance. The scale which is subsequently formed on the material is removed by wire brushes.

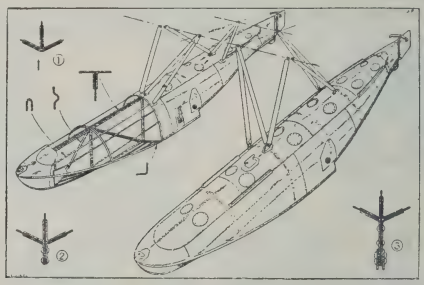
PREVENTION OF CORROSION.—The formation of rust is prevented by dipping in a specially constructed tank containing enamel, and stoving the complete units. Service conditions show that the process is entirely satisfactory.

The Blackburn Aeroplane and Motor Co.

BLACKBURN SPRAT.

The Blackburn 'Sprat,' fitted with a 270-h.p. Rolls-Royce 'Falcon' engine, is a training machine convertible into a seaplane or landplane.

FLOATS.—These are of duralumin and are fitted as shown in fig. 32. It will be seen that water rudders are fitted for good manœuvrability on the water. Each float has twelve inspection



Reproduced by courtesy of 'Flight.'

FIG. 32.—Floats (Blackburn 'Sprat').

holes, and the section of some of the members of the main framework is given. Inset (1) shows the joint of the keelson to keel near the bows; (2) Shows the same joint at some distance aft the step; and (3) the joint immediately aft the step, at which place the keel is fitted with a steel shoe as shown.

Boulton and Paul, Ltd.

A number of sections suitable for various structural elements have been standardised, both steel strip and duralumin being used.

THE B. AND P. PARTRIDGE.

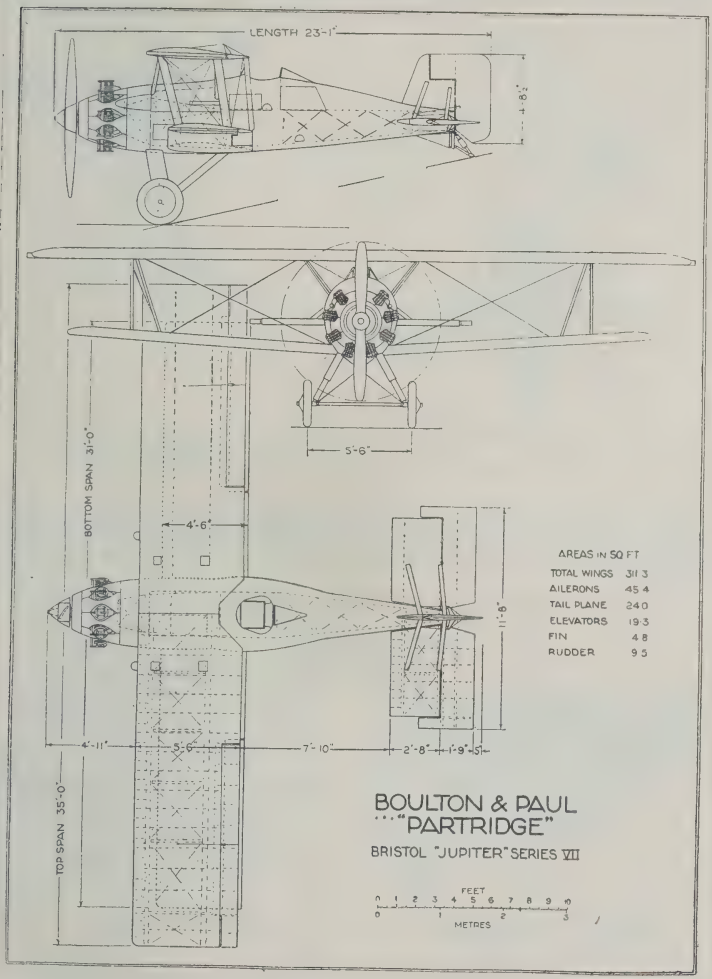
The latest product of this firm is named the 'Partridge,' which is a high-performance tractor biplane single-seater fighter. It is, of course, entirely in metal. The general arrangement of the machine is shown in fig. 33.

FUSELAGE STRUCTURE.—The front portion of the fuselage consists of seamless high-tensile steel tube. Fuselage struts are of four kinds, viz., solid drawn steel or duralumin tubes, or closed joint tubes made from steel or duralumin strip. In the manufacture of closed-joint tubes the longitudinal edges of the metal are brought together and rolled over inside the tube itself. This is seen in fig. 34 (3) at the lower broken end of the longeron.

The main plane spar joint is shown in (4), and it will be seen that the longeron is fitted with a light alloy sleeve. Two high-tensile steel discs are employed to receive and transmit the spar and lift-wire loads. The rear portion of the fuselage is carried out in locked joint tube longerons and duralumin struts. A typical joint is shown in (3).

MAIN PLANE STRUCTURE.—This is unusual in that there is no top centre section. The top spars are joined together on the centre line by fish plates.

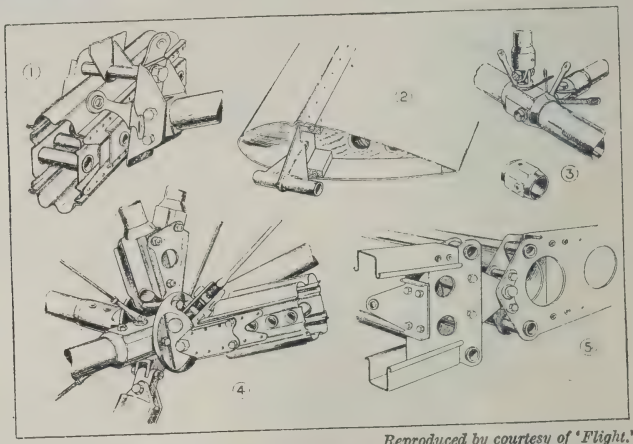
MAIN SPARS.—These are made from high-tensile strip steel and are of standard stock sections. Both flanges and webs are corrugated with frequent tubular stiffeners. Plate stiffeners are supplied at the various joints. A typical main plane joint is shown in fig. 33 (1).



Reproduced by courtesy of 'Flight.'

FIG. 33.

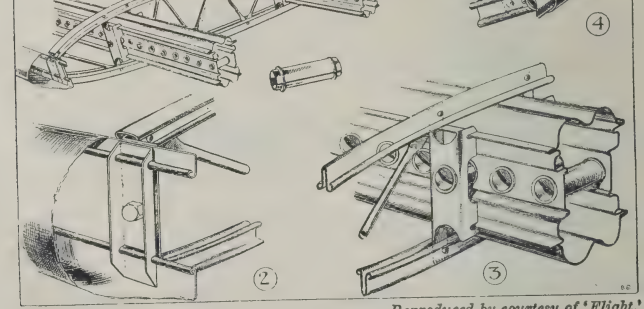
INTERPLANE STRUTS.—These employ standardised duralumin sections. The load is transmitted by a channel-shaped section connected to the spar by a **T** fitting shown in fig. 34 (1) and (2). The nose of the strut is in the form of a thin **U** section riveted to the main channel so that it takes part of the end load. The tail of the strut is faired off in wood.



Reproduced by courtesy of 'Flight.'

FIG. 34.—The Boulton & Paul 'Partridge' Wing and Fuselage Construction.

RIBS.—These are all made in duralumin, the sections used being shown in fig. 35. The ribs are attached to the spars in the following manner. Channel pressings are riveted to the top and bottom rib booms and the former are slotted to receive the riveted edges of the spar. The rib is then located by a long tubular rivet which passes through one of the tubular stiffeners of the spar. See fig. 35 (3).



Reproduced by courtesy of 'Flight.'

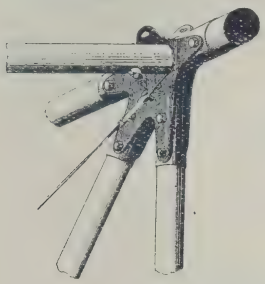
FIG. 35.—The Boulton & Paul 'Partridge' Wing Construction.

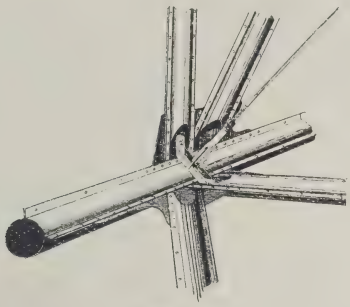
LEADING AND TRAILING EDGES.—The method of connection of ribs is indicated in fig. 35 (2) and (4). It will be seen that the leading edge is a **U** section with turned-in edges.

Bristol Aeroplane Co., Ltd.

FUSELAGE STRUCTURE.—For the front portion of the fuselage, which has to carry large loads, solid drawn high-tensile steel tubes are used, a typical joint being shown in fig. 36.

In the case of the rear portion, high-tensile strip steel is used.





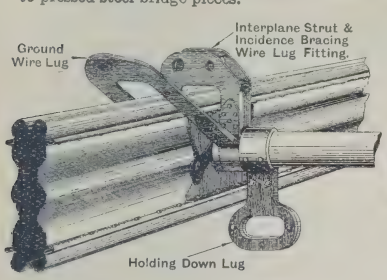
Reproduced by courtesy of Bristol Aeroplane Co.

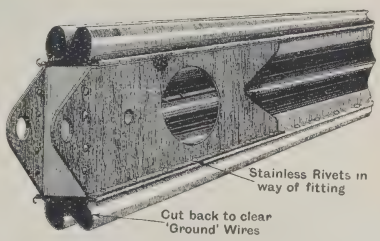
FIG. 36. FIG. 37.

LONGERONS.—These are built up from two sections, one of which subtends an angle of 90 degrees. In this way there are two riveted flanges.

PANEL STRUTS AND CROSS MEMBERS.—These are made from two similar sections riveted together.

TYPICAL REAR FUSELAGE JOINT.—In fig. 37 the manner of connecting the panel struts to the longerons by means of plates riveted in position is shown. Bulkhead bracing wires are connected to pressed steel bridge pieces.





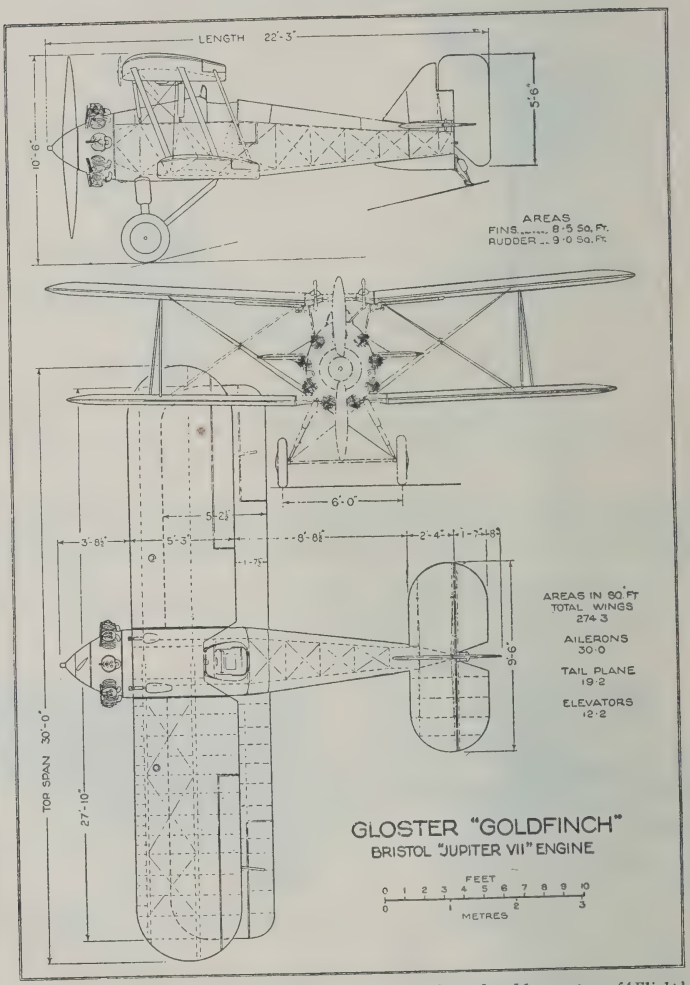
Reproduced by courtesy of Bristol Aeroplane Co.

FIG. 38. FIG. 39.

MAIN PLANE STRUCTURE.—Strip steel is used throughout.

MAIN SPARS.—The spars are made by riveting together two flange and two web sections, the upper and lower riveted edges being connected by internal plates running the whole length of the spar.

MAIN PLANE JOINTS.—Typical joints are shown in figs. 38 and 39.



Reproduced by courtesy of 'Flight.'

FIG. 40.

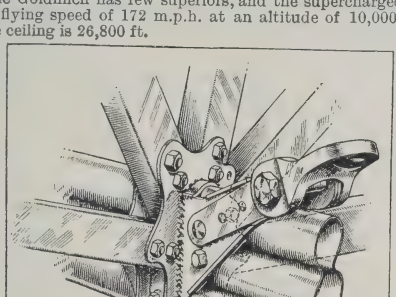
The Gloster Aircraft Co., Ltd.

The Company is well known as designers and constructors of high-speed aircraft.

GLOSTER GOLDFINCH.

This machine is an all-metal single-seater fighter, fitted with a Bristol Jupiter Mark VII supercharged engine (fig. 40). The Goldfinch is of the same family as the Gamecock, but embodies all the latest improvements on its predecessor and has many additional points worthy of note.

In performance the Goldfinch has few superiors, and the supercharged Jupiter enables it to develop a maximum flying speed of 172 m.p.h. at an altitude of 10,000 ft. and 157 m.p.h. at 20,000 ft. Its service ceiling is 26,800 ft.

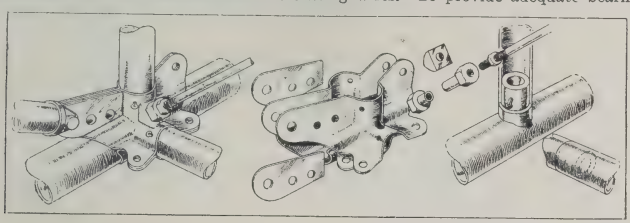


Reproduced by courtesy of 'Flight.'

FIG. 41.—The Gloster 'Goldfinch' Spar and Fuselage Joint.

The Goldfinch is constructed principally of steel with duralumin used for portions of the substructure and aluminium for the majority of the front fairing and cowling.

FUSELAGE STRUCTURE.—The front frame of the fuselage is a rigid structure built up of square tubes rigidly jointed by means of flat mild-steel plates bolted through the struts and longerons. Fig. 41 shows the joint at the spar attachment. In the rear frame the struts and longerons are round tubes braced together by means of tie rods. The joints are made in the form of pressed steel plates wrapping round the longeron and shaped to house the strut ends as shown in fig. 42. Provision also made for the attachment of bracing wires. To provide adequate bearing area



Reproduced by courtesy of 'Flight.'

FIG. 42.—The Gloster 'Goldfinch' Rear Fuselage Construction.

for the struts, hollow duralumin bushes are fitted into the ends of the dural struts which in turn go inside the longeron fitting—a small split pin retaining the strut in position during erection.

Bracing wires have special Gloster design high-tensile steel fork-ends and pins which allow of an appreciable weight reduction when used in conjunction with high-tensile steel wiring lug attachments. Robustness of design is always considered to be of primary importance to a doubtful gain in weight which would result from the using of ultra-light gauge members which would not stand up to handling conditions.

MAIN PLANE STRUCTURE.—The main planes are of high-tensile steel construction with the Gloster type of lattice girder in the thick upper wing, and in the lower wing a rolled high-tensile steel strip spar having continuous webs shown in fig. 41. To provide adequate aileron control, long, narrow chord ailerons have been fitted, supported on light false spars, the latter helping to stiffen up the main wing structure and cutting out excessive deflections of the spars under

maximum loading. Petrol tanks are fitted into each of the upper wings, following usual Gloster practice, and admit of quick detachment and a simplified petrol system.

THE UNDERCARRIAGE.—This is of the normal Gloster type. The pilot's seat is adjustable in use, being raised or lowered by the movement of a lever. The weight of the pilot is taken by rubber shock absorbers, thus facilitating the raising of the seat.

EQUIPMENT.—The Goldfinch is provided with a very full equipment, including wireless, parachute, two machine guns, ammunition, oxygen apparatus, and electrical equipment, as well as the usual navigation and engine instruments. Owing to its relatively low landing speed (under 60 m.p.h.) and wide wheel track, the Goldfinch might well be used as a night fighter. In that case, an exhaust ring is fitted. The installation of the two generators (wireless and lighting and heating) is unusual in that they are built into the top centre-section, thus giving a minimum of drag.

FLYING QUALITIES.—Pilots who have flown the machine report that the Goldfinch is very manœuvrable and easy to control, and that the cockpit is well arranged, roomy, warm, and comfortable, while the view is good for fighting, bombing, and ground machine gunning. It is stated to have no vices, and to be very easy to land.

COMPONENT WEIGHTS.—The following details of item weights are interesting in showing how the total loaded weight of 3,200 lbs. (1,450 kg.) is made up :—

Component.	*Weight.* Lbs.	Kg.	*Component.*	*Weight.* Lbs.	Kg.	*Component.*	*Weight.* Lbs.	Kg.
Airscrew . .	69	31·4	Instruments .	19	8·64	Wireless equipment . .	25	11·35

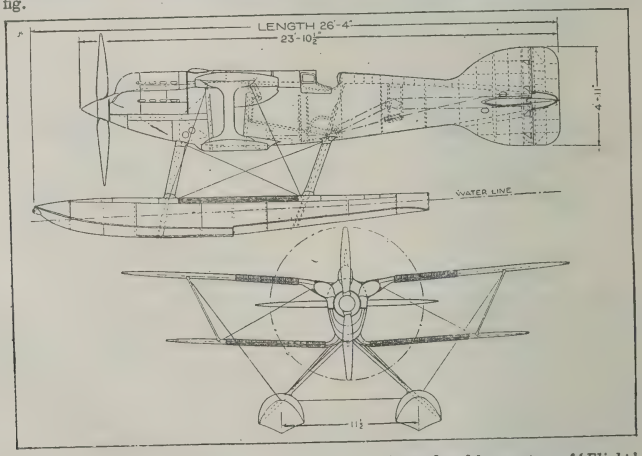
Total loaded weight 3,200 Lbs. 1,450 Kg.

GLOSTER IVB.

This is a racing seaplane fitted with an 875-h.p. Napier Lion racing engine. This machine (fig. 43) distinguished itself at Venice, 1927, on the occasion of the Schneider Trophy Race. A machine of this type requires a fuselage of the minimum cross section, while the main planes and engine cylinder blocks must be very carefully faired into it. Both these features are in evidence in the fig.



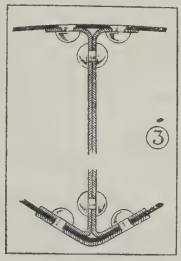
Reproduced by courtesy of 'Flight.'

FIG. 43.—Gloster IV P. Racing Seaplane (Napier Lion Racing Engine).

FLOATS.—The Gloster Company have gone very carefully into the design and construction of all-metal floats, both for use on their Schneider type racing seaplanes and on service type seaplanes.

From an aerodynamic viewpoint the research carried out has enabled a float to be designed which has a wind drag of 1·4 lbs./sq. ft. at 100 ft./sec. whilst still retaining good hydrodynamic qualities.

The form of construction now standardised consists of a main longitudinal duralumin girder lightened wherever possible, attached to which are transverse frame members of lightened sheet duralumin which support the decking of the float and the longitudinal planing bottom stiffeners,



Reproduced by courtesy of 'Flight.
FIG. 44—Gloster Float Joint.

which latter in turn take the skin. Bending is assumed to be taken by the skin and shear by the longitudinal girder. Attachment of the float to the undercarriage legs is made by means of watertight linings fitted to main transverse bulkheads at approximately one-third and two-thirds of the bulkhead measured from the nose.

For a float having a displacement of 5,700 lbs. the approximate weight would be of the order of 238 lbs.

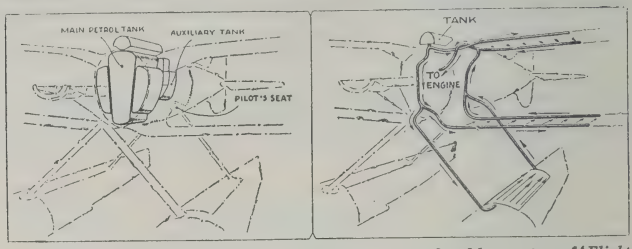
To provide the limit in cleanness the Gloster Company have developed a special form of joint whereby it is possible to have all the rivet heads flush with the skin, as indicated in fig. 44.

Reproduced by courtesy of 'Flight.'
FIG. 45.—The Gloster IVB. Wing Surface Radiators.

COOLING SYSTEM.—Surface radiators are employed, being installed on both top and bottom planes and on each float, and are shown in fig. 42. The radiators are made in thin corrugated copper sheet. Those mounted on the planes extend over the whole chord, brass waterways being placed at the leading and trailing edges. The outer end of the lower plane radiator and duralumin interplane strut are shown in fig. 44 (1) and the water-pipe entering the fuselage at the trailing edge of the lower plane is shown in fig. 45 (2).

Half of the complete radiator system is given in fig. 46.

PETROL TANKS.—These are housed in the fuselage and are shown in fig. 46.



Reproduced by courtesy of 'Flight.'

FIG. 46.—Petrol Tanks and Cooling System (Gloster IVB.).

Short Bros.

This firm for a number of years have been engaged in the design and production of duralumin marine craft.

THE 'CALCUTTA' FLYING BOAT.

This boat, ordered by Imperial Airways, has accommodation for 15 passengers. Drawings are given in fig. 48. It is the first commerical flying boat to be built in this country. The entire structure is in duralumin.

HULL.—The hull is of the type patented by this firm. It has no longitudinal members, being formed by frames connected together by duralumin plates. The latter are stiffened by V stringers so that the metal skin can transmit the necessary forces without crinkling.

MAIN PLANE STRUCTURE.—This is of normal biplane type with tip floats.

MAIN SPARS.—The spar construction is shown in fig. 47. In (1) the top rear centre section spar joint is shown together with steel fittings for struts and lift wires.

The spars are stiffened at such joints by additional plates shown in (2).

The bottom centre section spars are slightly different and are indicated in (4).

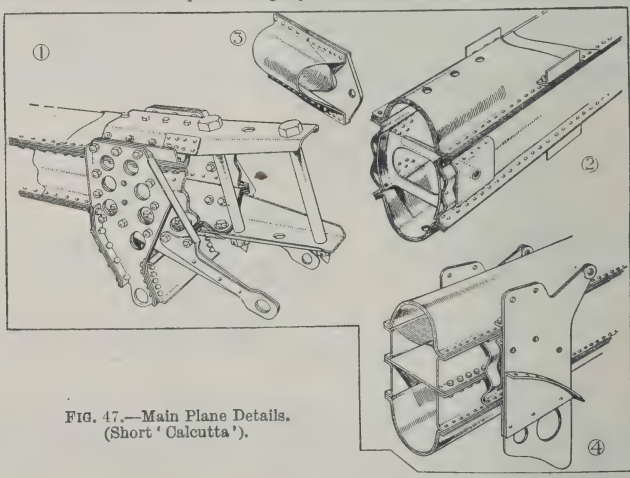


FIG. 47.—Main Plane Details. (Short 'Calcutta').

Reproduced by courtesy of 'Flight.'

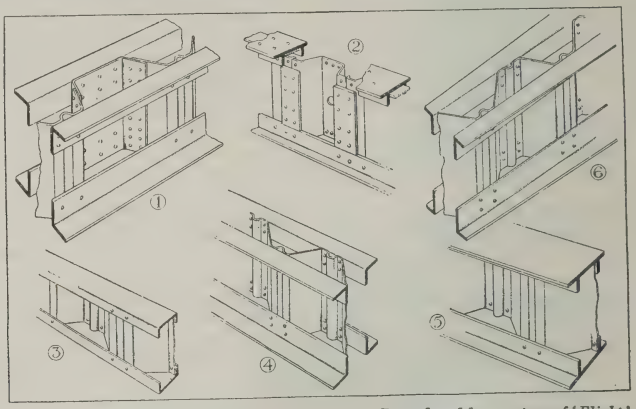
DRAG STRUTS.—These are built up from duralumin sheet and a stiff plate riveted at the ends for the spar connection. See fig. 47 (3).

Reproduced by courtesy of 'Flight.'

FIG. 48.

Vickers, Ltd.

This firm, proprietors of the patents covering the manufacture of duralumin, have produced a number of sections which have been standardised for aircraft construction. The use of the metal in the form of sheets or strips is augmented by the introduction of extruded sections similar to those in steel used by structural engineers, including angles, ties, channels and a section having a comparatively wide flange and twin webs.



Reproduced by courtesy of 'Flight.'

FIG. 49.—Duralumin Spar Construction (Vickers).

MAIN PLANE STRUCTURE.—In the various types of spar shown in fig. 49 the flanges in each case consist of a rolled section or sections connected by a web of sheet metal so pressed that it is connected alternately to the back of the front flange to the front of the rear flange by rivets, and because of this has been called a 'wandering web.' Vertical flutings at the points of connec-

FIG. 50.—Duralumin Construction of Main Planes (Vickers).

tion give the necessary stabilisation of the web. The web in general is a continuous strip, but a splice, if required, is carried out as in (1).

A particular advantage of this type of construction is that the spars may, in general, be tapered in both planes.

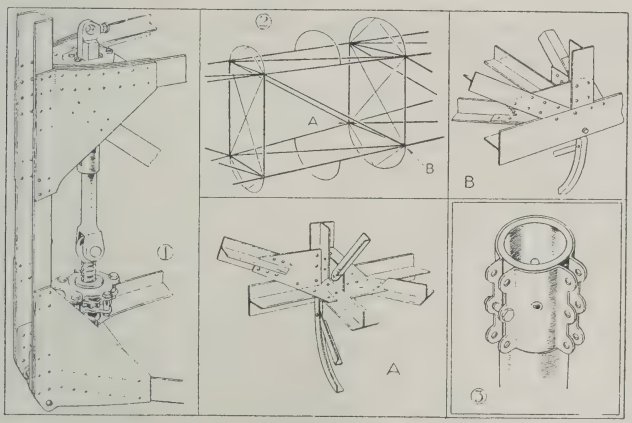
DRAG STRUTS.—These are solid drawn tubes and at the connection to the spar the web is stiffened locally as in fig. 49 (2).

MAIN PLANE RIBS.—Light and nose ribs are made from tubes, and are of the fully-braced type, while end ribs are made with T booms, as shown in figs. 50 (1) and (2).

For replacements, should a rib be damaged, a special rib with a detachable bottom boom has been produced and illustrated in (3). No riveting is required as it is designed to be fixed by bolts.

The rib lay-out is indicated in (4) and also shows the plates used for attaching the bracing diagonals to the booms.

INTERPLANE STRUTS.—Interplane struts of approximately streamline section are made by riveting together at the leading and trailing edges two curved sheets of heavy-gauge duralumin.



Reproduced by courtesy of 'Flight.'

FIG. 51.—Duralumin Fuselage Construction (Vickers).

FUSELAGE CONSTRUCTION.—This is carried out in tee and angle sections. Typical joints of the fuselage shown in skeleton in fig. 51 (2) are indicated at A and B.

The stern post and tail adjusting gear is indicated in (1), while (3) shows a fuselage fitting when tubular longerons are used.

Particulars of Various Aeroplanes.

Geometrical particulars of various types of aeroplanes are given in Table XI., pp. 2037–2039. The performance of these aeroplanes is given in Table XII., pp. 2040–2042.

Throughout this Section free use has been made of Reports of the Aeronautical Research Committee for which thanks are due to the Controller of H.M. Stationery Office from whom permission has been obtained.

ADDENDUM.

AIRSHIP DRAG.

In its general form the drag coefficient k_D is given in eqn. (4) on p. 1991.

In airship work it is convenient to use a coefficient which is related to the gross lift, *i.e.* to the airship volume or capacity.

Thus airship drag coefficient is given by

$$C = \frac{D}{\rho V^2 (\text{vol})^{\frac{2}{3}}}$$

where D is the drag in pounds.

The following table gives comparative predicted values of C for R 33 and R 101, based on model tests.*

Item.	R 33.	R 101.
Bare Hull	0·01150	0·00725
Control Car	—	0·00015
Engine cars	0·00277	0·00081
Fins	0·00251	0·00152
Interference between cars and hull	0·00057	0·00055
Miscellaneous	0·00121	0·00090
Radiators	0·00121	0·00038
	0·01977	0·01156

For R 33 and R 101 the values of (volume) $^{\frac{2}{3}}$ is 16,100 and 31,600 (before modification) respectively.

* *R.Ae.S. Jour.* 1929, p. 690.

SECTION XXXIII

PART II

AERO ENGINES.

(Contributed by Ernest W. Birch, A.M.I.A.E.)

Engines for Aircraft are either air- or liquid-cooled, and the majority operate on the four-stroke cycle. The various types in use are Vertical, Vee, 'Broad Arrow,' 'X,' Horizontal, Radial, and Rotary. Air-cooled engines are largely used, and the following advantages are claimed for this type of engine: (*a*) Less sensitive to sudden heat or cold; is easier to start and requires less warming up in cold weather; the oil does not heat unduly, and remains at working temperatures. (*b*) Top overhauls are easier to make. The grinding of valves involves only the removal of a cylinder, with no alteration to the timing—water-cooled engines, as a rule, require either the removal of the engine, or the dismantling of the camshafts and valve mechanism, and the whole engine requires retiming on assembly. (*c*) Due to the reduction in the number of parts, the radial air-cooled engine can usually be built cheaper than the water-cooled engine. The tendency in water-cooled engines is towards block construction to give a more rigid and lighter structure; this, however, involves the rejection of an entire block for the defect of a single cylinder.

Under certain conditions the liquid-cooled engine has definite advantages over the air-cooled engine, and at the present time both types have wide and varied application.

Air-cooled engines are not confined to fixed-radial and rotary types. In America the 'Liberty 12,' which is normally a water-cooled engine, has been developed as an air-cooled engine, and as such has developed slightly more than its rated output as a water-cooled engine.

In this country a four-cylinder in line air-cooled vertical engine has proved highly successful, and a six-cylinder in line with similar features is in production.

The most successful engines at the present time are really refinements of types available for some years past. Some of these improvements are greater compactness, resulting in lighter weight and increased rigidity; higher crankshaft speeds; improvements in valve operating mechanism, valve cooling and valve materials; improvement in bearing design, and improvement in volumetric efficiency. The success of the inverted 'Vee' type, and the static radial air-cooled engine, of reduction gearing and of the rotary inductor supercharger, has contributed a large share to recent progress in engines.

The Pressure-Ignition engine is now receiving great attention, and several engines have passed the experimental stage.

Rolls-Royce Engine, Type F.

Twelve-cylinder water-cooled type, having two rows of cylinders at 60° fitted with spur drive reduction gear for airscrew.

The engine can be supplied with either 0·632 to 1 or 0·553 to 1 ratio reduction gear, also with either 6 to 1 or 7 to 1 compression ratio pistons. With 6 to 1 compression pistons the engine will develop 490 b.h.p. at normal speed at ground level. If fitted with 7 to 1 compression pistons 480 b.h.p., and this power can be regained at an altitude of 3,000 ft. by opening the throttle to full open.

The engine is designated by four series numbers according to the gear ratio and ratio of compression, the leading particulars of each series being as follows:—

Series No.	F.XI.A.	F.XI.B.	F.XII.A.	F.XII.B.
No. of cylinders	12	12	12	12
Bore and stroke	5″ × 5·5″	5″ × 5·5″	5″ × 5·5″	5″ × 5·5″
Normal b.h.p.	490	480	490	480
Normal speed (crankshaft)	2,250	2,250	2,250	2,250
Maximum speed	2,500	2,500	2,500	2,500
Normal speed of propeller	1,421	1,421	1,244	1,244
Reduction gear ratio	0·632	0·632	0·552	0·552
Compression ratio	6 : 1	7 : 1	6 : 1	7 : 1
Fuel consumption at normal power and speed gallons/hour	30	28¼	30	28¼
Oil consumption pints/hour	5	5	5	5
Weight, including carburetters, magnetos, engine feet, reduction gear, and airscrew hub—lbs.	865	865	865	865

Cylinders in banks of six, mounted on crankcase at 60° with each other, are of cast aluminium provided with steel liners and renewable valve seats. Heads integral with cylinder blocks. Two inlet and two exhaust valves per cylinder, operated by camshaft and rockers mounted on top of cylinder heads, the whole being totally enclosed by means of a removable cylinder head cover.

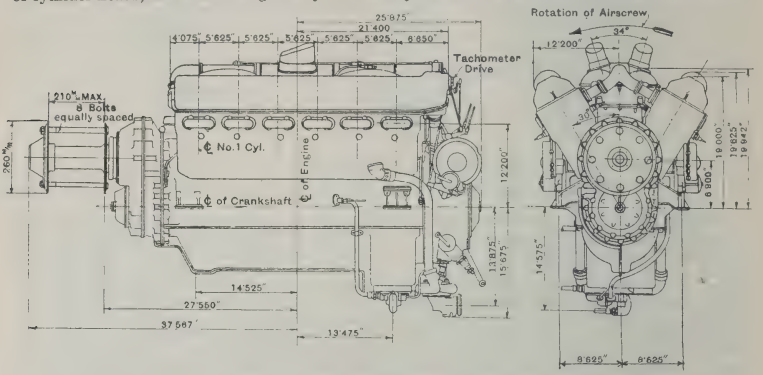


FIG. 1.—Rolls-Royce Engine (Type F).

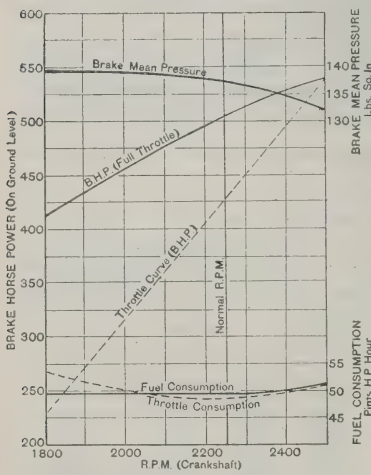
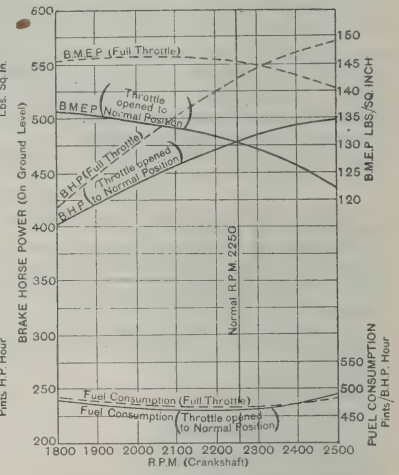
Valve mechanism positively lubricated. Inlet and exhaust valves of each cylinder block operated by one camshaft.

Gears for driving camshaft and all auxiliaries driven from rear end of crankshaft through the medium of a spring drive to eliminate crankshaft torsional vibrations. The camshafts are driven



Compression ratio = 6 : 1.
Atmospheric temperature = 16° C.
Atmospheric pressure = 29·97 ins. mercury.
Curves shown are correct to within 2½%.

FIG. 2.—Brake Horse Power and Consumption Curves of Rolls-Royce F. XI. A. and F. XII. A. Engines.



Compression ratio = 7 : 1.
Atmospheric temperature = 16° C.
Atmospheric pressure = 29·97 ins. mercury.
Curves shown are correct to within 2½%.

FIG. 3.—Brake Horse Power and Consumption Curves (on ground level) of Rolls-Royce F. XI. B. and F. XII. B. Engines.

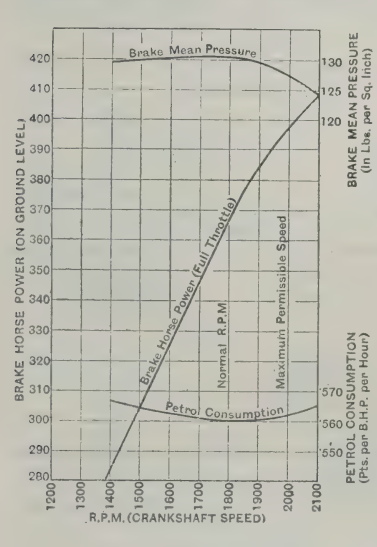
by means of inclined tubular driving shafts with bevel gears at upper and lower ends. Out-of-alignment and expansion effects are allowed for by hardened serrated couplings. Pistons, special aluminium alloy forgings, machined all over. Four piston rings, three arranged as compression rings above gudgeon pin and one scraper ring at base of piston skirt. The compression rings are prevented from rotating by means of stops.

Gudgeon pins 'floating' fit in piston bosses and connecting rod small end.

Connecting rods are 'H' section of the 'forked' type, machined all over to reduce weight variations. A divided white metal lined steel block is bolted to the forked rod. The plain rod works upon the centre portion of the steel block, the latter having white metal bearing surface. Small ends of both rods fitted with floating phosphor-bronze bushes. All bearings positively lubricated under pressure.

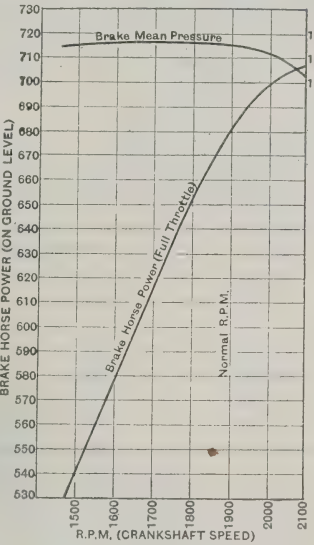
Six-throw crankshaft carried in seven bearings. All journals and crankpins bored for lightness and to convey oil to all bearings and connecting rods.

Crankcase of aluminium alloy, made in two halves of box section suitably stiffened by ribs.



Rolls-Royce 'Eagle,' Series IX.*

Compression ratio = 5·22.
Atmospheric temperature = 16° C.
Atmospheric pressure = 29·97″ Hg.



Rolls-Royce 'Condor,' Series III.

Compression ratio = 5·3.
Atmospheric temperature = 16° C.
Atmospheric pressure = 29·97″ Hg.

FIG. 4.—B.h.p. and Consumption Curves for Rolls-Royce Engines.

Main bearings, consisting of divided mild steel shells, white metal lined, are held in the upper half crankcase by special caps which are secured by bolts on each bearing. Facings are formed on either side of the caps which fit between corresponding facings formed on cheeks within the upper half crankcase. Transverse bolts pass through the crankcase and cups. This arrangement secures the rigidity of one in which the caps are integral with the lower half, while retaining the advantages of caps bolted only to the upper half.

A single spur gear reduction is fitted at the front end of crankshaft. The pinion is driven from the crankshaft through a short shaft, having teeth at the inner edge to engage an internally toothed flange bolted to the crankshaft, and at the outer end teeth engaging with teeth cut inside a part of the gear pinion. This shaft prevents loads from the gear pinion coming on to the crankshaft. A centrifugal water circulating pump is fitted below the auxiliary gear case. Lubrication is on the 'dry sump' systems.

* For details of Rolls-Royce 'Eagle' Series IX. engine, see *Engineer's Year Book*, 1928, pp. 2055–7.

The 'F' series of engines can be fitted with a supercharger of two different types, *i.e.* the moderate type, which permits a certain amount of supercharging at take-off and maintains the normal horse-power to 3,000 ft. or with a full supercharger, which is capable of maintaining the ground level rated power up to 11,500 ft. The supercharger consists of a high-speed centrifugal fan mounted co-axially with crankshaft at rear of engine and drawing its air through the carburettors. Aluminium alloy impeller with radial blades driven a speed multiplying gear comprising a system of three planets. These are frictionally driven from a pinion on crankshaft by means of slippers held in engagement with the insides of the gear rims by light springs. As the speed of rotation of crankshaft and slippers increases, the radial pressure of springs is augmented by centrifugal force, and consequently the torque which the planets can transmit increases as the square of the speed. As the torque required to drive impeller increases at a like rate, the gear is capable of driving the impeller with a predetermined margin of torque above that causing slip which is constant throughout the working range of speed. The object of this drive is to protect the gearing against damage on sudden acceleration or deceleration of the crankshaft due to inertia of impeller. Gear ratio between crankshaft and impeller is 1 : 5·5 or 1 : 10, giving calculated impeller speeds of 12,375 and 22,500 r.p.m.

Rolls-Royce 'H' Type Engine.

General design similar to 'F' type. Leading particulars as follows :

Number of cylinders	12	Normal speed propeller	954
Bore, in.	6·6	Gear ratio	0·477
Stroke, in.	6·6	Fuel consumption at normal power and speed, galls. per hour	53
Normal b.h.p.	825	Oil consumption, pints per hour	9
Normal speed (crankshaft), r.p.m.	2,000		
Maximum speed (crankshaft), r.p.m.	2,200		

Weight of engine, including carburettors, magnetos, engine feet, reduction gear, airscrew hub, but excluding exhaust boxes, radiator, airscrew, oil, fuel, and water = 1,460 lbs.

Performance.—Test at full throttle at ground level. Compression ratio, 5·25 : 1. Series HX.

R.P.M. Crankshaft.	B.H.P.	B.M.E.P. Lbs. per sq. in.	Fuel Consumption. Pints/b.h.p./hr.
1,730	700	143·0	0·540
1,800	740	146·0	0·535
1,900	784	146·5	0·530
2,000	830	147·5	0·525
2,100	866	146·5	0·530
2,200	900	145·0	0·537

Rolls-Royce Engines. ('Condor' Series IIIA.)

The 'Condor' engine is of the 12-cylinder water-cooled 'Vee' type, fitted with a spur drive reduction gear for the airscrew.

The leading particulars are :—

Number of cylinders, 12 ; bore, 5½ ins. ; stroke, 7½ ins. ; normal b.h.p., 665 ; normal speed (crankshaft), 1,900 r.p.m. ; maximum speed (crankshaft), 2,100 r.p.m. ; normal speed (propeller) with 0·477 reduction gear, 907 r.p.m.

Fuel consumption at normal power and speed, 41 galls. per hour.

Oil consumption, 1·3 galls. per hour.

Weight of engine, 1,182 lbs. (including carburettors, magnetos, engine feet, distributor, and pipes for power starter, etc., but excluding reduction gear, exhaust boxes, radiator, airscrew, oil, fuel, and water).

Weight of engine as above, but including reduction gear, 1,338 lbs.

Napier Engine. (Lion.) Series XI.

The leading particulars are as follows :

Number and arrangement of cylinders, 12, three blocks of four each, one vertical, two at 60° ; bore, 5½ ins. ; stroke, 5½ ins. ; Compression ratio, 6·0 : 1 ; normal b.h.p. and speed, 530 b.h.p. at 2,300 r.p.m. ; direction of rotation of crank, anti-clockwise, viewed from front ; direction of rotation of air screw, clockwise, viewed from front, *i.e.* L.H. tractor or R.H. pusher ; ratio of gear reduction to airscrew, 49–26 ; oil pressure, maximum 70 lbs./sq. in., normal 55–60 lbs./sq. in., minimum 40 lbs./sq. in. ; oil consumption, 6–12 pints per hour ; type of carburettor, special Napier Claudel Hobson Triplex (see page 2068).

Fuel consumption, 280 pints per hour at normal load near ground.

Type of magneto, two B.T.H. A.V. 12E (dual ignition), or A.V. 12F.

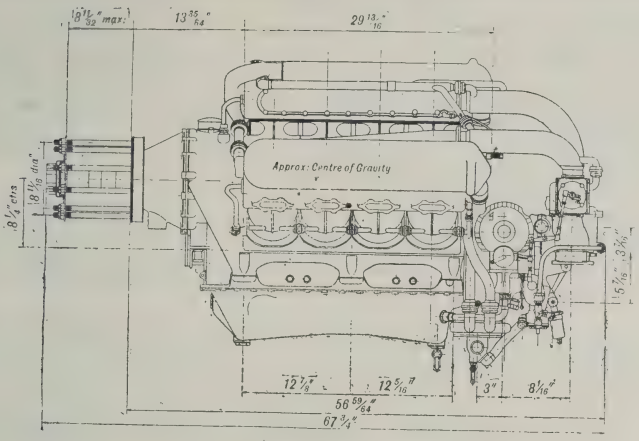


FIG. 5. Napier 'Lion' Engine.

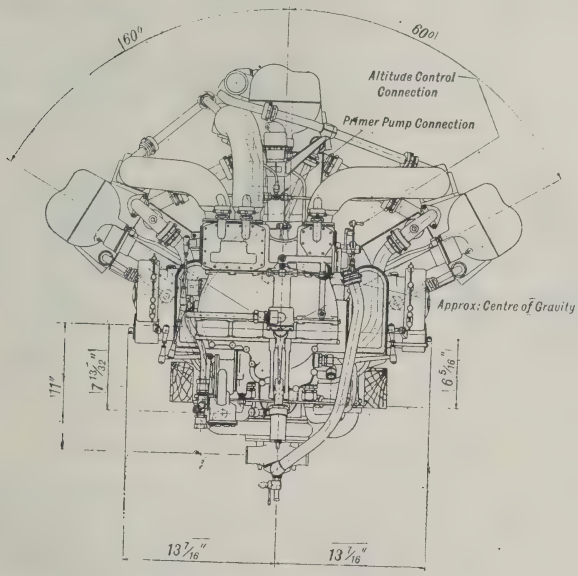

FIG. 6.—Napier 'Lion' Engine (Rear View).

Firing order, 1, 5, 9, 3, 7, 11, 4, 8, 12, 2, 6, 10.

Numbering of cylinders, airscrew { 12, 11, 10, 9 / 5, 6, 7, 8 / 4, 3, 2, 1

Speed of magneto, 1½ engine speed.

Magneto timing, 40° before t.d.c. at full advance on exhaust side, 45° before t.d.c. on inlet side.

Inlet valve opens (deg. on crank), 10° after t.d.c.

Inlet valve closes (deg. on crank), 51° after b.d.c.

Maximum lift of inlet valves, 0·344 ins.

Clearance of inlet valve, 0·020 in.

Exhaust valve opens (deg. on crank), 48° before b.d.c.

Exhaust valve closes (deg. on crank), 10° 44′ after t.d.c.

Maximum lift of exhaust valves, 0·354 in.

Clearance of exhaust valve, 0·020 in.

Weight of engine complete without water, fuel, or oil, 995 lbs. (approx.).

Maximum speed, under any conditions, 2,585 r.p.m.

Cylinders.—Machined from steel forgings with integral combustion heads. Separate sheet-steel jackets to each cylinder barrel. Cylinders are assembled in rows of four with a single aluminium head and camshaft casing combined for each row.

Pistons.—Forged aluminium alloy, trunk type, with flat tops. Hollow gudgeon pin floats in piston and is located sideways by bronze buttons. Two gas rings and two scraper rings fitted.

Connecting Rods.—The rods for central cylinders are master rods with two lugs on each side to accommodate wrist-pins for auxiliary rods. All rods of ' H ' section, split white-metal lined big ends for master rods and bronze-bushed for gudgeon and wrist-pins.

Crankshaft.—Of normal four-throw type, supported on five roller bearings and one plain bearing (fig. 7). The bearings between crank-throws are bored so that they may be threaded over the crankwebs and pins into place, and split packing bushes to make up diameter of shaft to fit inner races are then pressed into place.

Crankcase.—Aluminium alloy casting. Upper half provides three sets of cylinder facings, contains the crankshaft bearing supports, and includes a housing at forward end for airscrew reduction gear. Lower half of crankcase forms an oil sump.

Valve Gear.—Four symmetrically arranged valves per cylinder operated by two separate camshafts, one for inlet and one for exhaust. Two camshafts geared together by equal pinions at rear end of camshaft casing. One shaft is prolonged beyond pinion and carries a bevel pinion which mates with a bevel gear or camshaft drive shaft for that row of cylinders.

Airscrew Drive.—Airscrew shaft driven through spur reduction gear of 0·53 to 1 ratio.

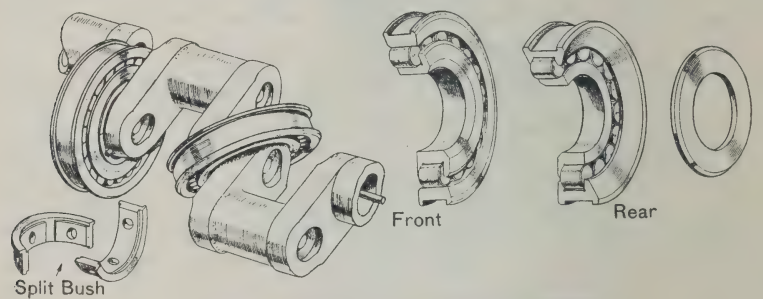

FIG. 7.—Crankshaft Bearings of Napier ' Lion ' Engine.

Auxiliary Drives.—Rear end of crankshaft drives a short extension shaft through a dog coupling. This carries a pair of bevel wheels back to back. The inner bevel drives the two camshaft drive-shafts for outer rows of cylinders. Vertical (central) camshaft drive is taken from a bevel on port shaft. A downward-projecting vertical shaft, driven from this first bevel drives water pump directly, and oil pumps through worm gears. Second bevel on crankshaft extension drives two horizontal shafts for magnetos. All auxiliary gears contained in separate casing bolted to rear end of crankcase.

Carburation.—A triple carburettor, carried on a bracket at rear of engine supplies gas to trough section aluminium induction channels, bolted to one side of each cylinder-head casting.

Lubrication.—Two scavenger pumps and one pressure pump fitted. Oil from pressure pump passes into the hollow crankshaft and is supplied direct to each big-end. A separate pressure lead taken to each camshaft.

Ignition.—Dual ignition provided by two 12-cylinder magnetos. Two sparking plugs per cylinder.

Weight Dry.—995 lbs. (452 kg.).

Performance.—Rated output 530 b.h.p. at 2,350 r.p.m. (1,247 airscrew r.p.m.). Average power actually developed, 540 b.h.p. at 2,350 r.p.m., and 575 b.h.p. at 2,585 r.p.m. Average fuel consumption at full load, 0·50 lbs. per b.h.p. hour, using a fuel mixture of Aviation spirit to B.E.S.A. spec. No. 121, part B, and Benzol. Average oil consumption, 0·0235 lb. per b.h.p. hour during Air Ministry 2-hour endurance test at $\frac{9}{10}$ full power.

Overall Dimensions.—Length to centre of airscrew, 5 ft. 1 in.; width, 3 ft. 6 ins.; height, 3 ft. 3 ins.

Napier 'Lion,' Series VIIa.

This is a direct drive high-compression engine specially developed for high speed. Main characteristics as for standard 'Lion' engine. Bore, 5½ ins.; stroke, 5½ ins. Chief modifications introduced to decrease head resistance, shorter connecting rods, and magnetos fitted at front end of engine. Compression ratio, 10 : 1. Maximum H.P. developed, 900 b.h.p. at 3,300 r.p.m. Weight, 850 lbs., or 0·944 lbs. per H.P.

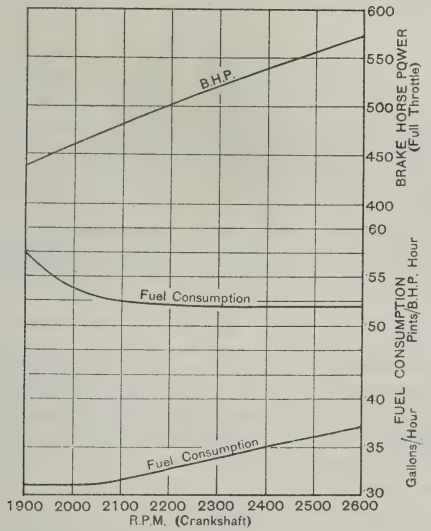
Napier 'Lion,' Series VIIb.

Similar to Series VIIa except that a double reduction gear is fitted. This reduction is obtained through a layshaft, mounted over airscrew shaft and crankshaft, which are co-axial. Reduction ratio, 1·306 to 1. Maximum power developed, 875 b.h.p. at 3,300 r.p.m. Weight, 930 lbs., or 1·063 lbs. per h.p.

Overall Dimensions.—Series VIIa and b. Length, 5 ft. 6½ ins.; width, 3 ft. 2⅜ ins.; height, 2ft. 10½ ins. A special Benzol-petrol fuel with admixture of Ethyl fluid is used. Consumption under racing conditions, 50 galls. per hour (approx.), or 0·46 pint per b.h.p. hour.

Napier 'Lion,' Series V.

Details of this engine are given in the 1929 edition, page 2154.



Consumption ratio = 6 : 1.
Fuel 77% British Standard Aviation Spirit Spec., No. 121—1923, part B, 23% Benzole.

Fig. 8.—Full Throttle Power and Consumption Curves. Napier-Lion Engine, Series XI.

Armstrong-Siddeley Engines.

A series of engines of the static radial type, known as *Leopard*, *Jaguar*, *Lynx*, *Mongoose*, and *Genet*, the general construction of which is similar.

Special functions of the engines are as follows :—

Leopard.—Fourteen cylinders, 700–805 h.p., for civilian use or for carrying troops or torpedoes.

Jaguar Major.—Fourteen cylinders, 500–550 h.p. Interchangeable with the 'Jaguar,' and recommended where extremely high performance is required. 'Jaguar,' 14 cylinders, 460–500 h.p. geared, for civil or service requirements. The supercharged 'Jaguar,' suitable for all types of military aircraft in which the maintenance of power at altitude is essential.

Lynx Major.—Seven cylinders, 260–280 h.p., for civil and service uses. 'Lynx,' 7 cylinders, 215–230 h.p., for use in land or sea-training machines, civil aircraft, photographic and survey duties, and for application to twin or multi-engined aircraft, two-seater reconnaissance training machines. Single seater fighter, deck landing, and twin-engined seaplanes. The geared or supercharged 'Lynx' serves the same purpose as the gear or supercharged 'Jaguar,' but the engine is only half the power.

Mongoose.—Five cylinders, 150–165 h.p., for training aircraft.

Genet Major.—Five cylinders, 100 h.p., for light multi-engined aircraft. 'Genet,' 5 cylinders, 80–88 h.p., for light aircraft.

D = direct drive. G = geared. S = supercharged. SG = supercharged and geared.

All types LH tractors. Fixed ignition. Oil pressure, 60 lbs. per sq. in.

Maximum propeller and engine speed, 10 per cent. above normal.

Compression ratio, 5 : 1, except for Genet, 5·25 : 1.

A.D.C. Engines.

Horizontally opposed, air-cooled engines, specially designed for light aeroplanes. Two types, known as *Scorpion* and *Hornet*. *Scorpion*, two cylinders horizontally opposed. Crankcase in one piece with integrally cast induction manifold. Cylinders machined from the solid with fins formed integrally. Detachable cylinder head of cast iron. Inside of head and top of piston

of hemispherical form, with inlet and exhaust valves of same diameter. Two sparkling plugs to each head for dual ignition. Valves of high tensile steel operated by rockers and tubular tappet rods. Crankshaft and connecting rods machined from alloy steel stampings. Pistons of aluminium alloy with two rings at the top only. Camshaft with one exhaust and one inlet cam to serve both cylinders. Roller-type tappets.

Lubrication on dry sump principle, with pressure feed and scavenger pump. Ignition by B.T.H. magneto fitted with impulse starter. *Hornet* engine, four cylinder, horizontally opposed, and comprises the main elements of two *Scorpion* engines mounted in tandem about a common crankcase.

Leading particulars of engines are as follows :—

	Scorpion.	Hornet.
No. of cylinders	2	4
Bore, ins.	4·015	4·015
Stroke, ins.	3·6	4·8
Swept volume, c.c.s.	1,500	3,990
Normal b.h.p.	34	75
Normal r.p.m.	2,300	1,875
Maximum b.h.p.	40	82
Maximum r.p.m.	2,750	2,175
Fuel consumption, pts./b.h.p./hour	0·52	0·53
Oil " " "	0·04	0·035
Weight complete, lbs.	109	225
Specific weight (on normal power), lbs./h.p.	3·2	3·0

SUPERCHARGERS.

Four possible types available : (*a*) reciprocating ; (*b*) eccentric, or sliding vane ; (*c*) centrifugal ; (*d*) Root's blower. Owing to mechanical limitations, types (*a*) and (*b*) are not much used.

The centrifugal type may be driven by an exhaust turbine and this forms a compact unit, but the exhaust turbine involves difficulties in manufacture, and also it has been found that such a combination does not respond as quickly to the control as a mechanically driven supercharger. Further, if the driving ratio is constant, the proportional increase in the air temperature in passing through the supercharger will be constant, irrespective of the altitude, and at ground level the temperature rise will be excessive, necessitating the installation of coolers with a consequent increase in weight. At ground level, where no supercharging is required, the power necessary is as great as that required at high altitude.

With the Root's type a large volume of air is handled at ground level at small power consumption and temperature rise, as there is only slight compression. The power theoretically required to compress adiabatically 1 lb. of air per sec. from an absolute pressure P and temperature T to an absolute pressure P_1 is given by H.P. $= 0{\cdot}336T\left(\frac{P_1}{P}^{0{\cdot}289} - 1\right)$, and the efficiency of a supercharger is equal to the ratio of the theoretical horse-power, to the power actually absorbed (as determined by dynamometer). Tests made on a Root's type supercharger (*National Advisory Committee for Aeronautics, U.S.A.*), with rotors of 9¾ ins. diam. by 11 ins. long, showed a maximum efficiency of 82 per cent. at 600 r.p.m., compression ratio 1·2, the efficiency decreasing uniformly with the compression ratio to a little over 60 per cent. for a compression ratio of 2·3 for all speeds from 1,000–1,800 r.p.m. Volumetric efficiency decreased with increase in compression ratio. With a compression ratio of 2·25, volumetric efficiency was approximately 90 per cent. from 800 r.p.m. upwards. With a compression ratio of 1·5, the efficiency was 95 per cent. at less than 800 r.p.m. The maximum efficiency obtained was 97 per cent.

The volumetric efficiency decreases with the speed, in which respect the Root's type differt from the piston type. The loss in volumetric efficiency is due not so much to the wire drawing as the inlet, as to leakage past the rotors. An important point is the maintenance of a small clearance between rotor and casing.

Tests to destruction of the rotors showed that an aluminium alloy rotor failed at 9,600 r.p.m., and a magnesium alloy rotor at 13,500 r.p.m. The designed speed of the rotor was 2,550–3,200 r.p.m. Complete assembly weighed 151 lbs., being made up of supercharger 88 lbs., coupling 10 lbs., supercharger tank 24 lbs., ducts 29 lbs.

Gudgeon pins	360

HIGH-TEMPERATURE LIQUID COOLING.

For this purpose ethylene glycol $CH_2(OH)\cdot CH_2\cdot OH$ is used. Its boiling point is 388° F.; it has a relatively high specific heat, is non-injurious to metals and has excellent wetting properties. It is a clear, colourless, and odourless liquid, with a slightly sweet taste. It is also used as an anti-freeze for automobiles.

In the ordinary water-cooled engine the normal working temperature is about 180° F., and the most suitable operating temperature with ethylene glycol is 300° F. Using this liquid, the size of radiator required is approximately one-quarter that used for water, this being due to the greater temperature difference between the radiator and the cooling air. A modern military plane (American) has a capacity of 14·5 galls. of water. Using ethylene glycol, 8–5 galls. is sufficient, or a reduction of 41 per cent., and the plane weighs 3·5 per cent. less than with a water-cooled system. The normal radiator of such a plane offers approximately 15 per cent. of the total parasite resistance. Reducing frontal area of radiator 75 per cent. reduces total parasite resistance

of plane by about 12 per cent. When operating an aircraft engine at a cooling liquid outlet temperature of 300° F., it has been found that the following advantages are gained (*G. W. Frank*):—

(1) The amount of cooling area or size of radiator necessary is greatly reduced.

(2) A reduced amount of liquid is required in the cooling system.

(3) A considerable reduction in weight of the installed power plant, due to the reduction in size of radiator and the lesser amount of cooling liquid required.

(4) The parasite resistance of the plane is reduced, due to the reduction in size of radiator.

(5) It permits the engine combustion chamber walls and cylinder barrels to operate at temperatures comparable to those in an air-cooled engine, with the added advantage of uniform cooling.

Evaporative Cooling.

In this system the cooling fluid itself is not passed to the heat-dissipating surfaces but is circulated around the engine through a small tank, which is arranged so that by mechanical or other means the vapour formed is separated and conducted to an air-cooled condenser instead of the normal type of radiator, the condensate being returned from the condenser to the circulating tank by gravity or other means. This system has the following advantages :—

(*a*) Control of the cooling fluid temperature by the pilot is unnecessary.

(*b*) With correctly designed condensers overheating cannot take place.

(*c*) Time for engine warming greatly reduced.

(*d*) For fighting aircraft the exposed radiating surface, which is liable to be punctured by bullets, contains vapour under atmospheric pressure.

(*e*) The system can be so arranged as to provide for cockpit and passenger cabin heating.

Liquid Cooled Engines.

The advantages claimed for the liquid cooled engine may be briefly summarised as follows :—

(*a*) The necessary heat-dissipating surfaces can be provided in such a manner that they present the minimum head resistance or drag. In some cases the existing surfaces of the aircraft itself can be utilised as cooling surfaces.

(*b*) There are no projections around the nose of the fuselage to upset the air flow.

(*c*) Thermodynamic advantage obtained by the use of a cylinder in which it is possible to maintain an equalised temperature throughout the combustion walls while extracting heat at a very high rate.

(*d*) Due to absence of hot-spots a higher m.e.p. can be obtained. Due to this fact the fuel consumption of liquid cooled engines is at least 10 per cent. lower than for directly cooled engines.

(*e*) It is impossible to damage the water-cooled engine by over-heating during times when it is necessary to run at full throttle.

(*f*) After a long glide sufficient heat can be stored in the cooling system and carburetter jackets so as to ensure certain acceleration when the throttle is opened.

(*g*) All the working parts can be totally enclosed, thus minimising mechanical chatter. The silencing of the exhaust of a normal type engine is a comparatively simple matter.

(*h*) The normal type of twelve-cylinder engine with its rigid cylinder block construction and almost perfect balance can be produced, so that if well mounted, vibration is almost entirely absent.

(*i*) The liquid-cooled engine having every working part totally enclosed requires no attention from a grease gun or oil-can after comparatively short periods of running.

(*j*) Owing to the excellent cooling of valves and cylinders, life between top overhauls should be considerably longer than with other types of engines.

(*k*) Water is not the only cooling medium which can be employed. Ethylene glycol has been used which permits of the boiling point being raised to 388° F. The effect of this is to permit the use of smaller radiators, a saving in area of over 60 per cent. being possible. The freezing point is reduced to — 15° F., which removes the difficulties normally experienced with water in severe weather.

(*l*) By the use of supercharging and special fuels, outputs three and four times as great as are normally taken from the cylinders can be obtained. To withstand these increased outputs, larger bearing areas for a given cylinder capacity are necessary, and these can be obtained without seriously affecting the head resistance or drag.

Oil Engines for Aircraft.

Oil engines for aircraft have developed on two main lines : (*a*) reducing the weight of the usual type of Diesel engine ; (*b*) redesign of existing aero and lorry type petrol engines to run on oil fuel.

The air-cooled Vee engine is attractive for oil, as the cylinder spacing necessary for cooling coincides closely with crankshaft requirements. It may be inverted without difficulty, as problems of carburettor location and manifolding do not arise.

There are two principal objectives in the application of the high speed, heavy oil engine to aircraft : (*a*) reduction of fire risk ; (*b*) saving in cost of fuel in commercial operation. In addition, there is the elimination of electrical ignition which is often a source of failure, and also the magneto requires a complicated system of screening to prevent interference with the radio circuits.

The oil used does not give off an explosive mixture at ordinary temperatures, and can therefore be handled with freedom. There is no possibility of formation of an explosive mixture external to the working cylinders, such as always exists in the inlet manifold of a petrol engine. On the other hand, there is reason to believe that a heavy oil is more likely to ignite by flashing off a hot surface, such as the exhaust pipe.

Owing to the high compression ratio necessary to ensure ignition of the fuel, the oil engine has an inherently higher thermal efficiency than the petrol engine. Due to the necessity of promoting a rapid and complete mixing of the fuel with the air it is essential to provide a large excess of air with further improvement in the thermal efficiency. In a multi-cylinder engine the fuel distribution being mechanical can be tuned up more perfectly, especially under varying conditions of load and speed. This timing is more effective in service than carburettor adjustment. The oil engine has a lower mechanical efficiency, chiefly due to its larger size and increased inertia loading of its heavier reciprocating parts, which must deal with higher maximum pressures and the greater friction, especially of the piston and rings. The mechanical efficiency is about 84 per cent., compared with 90 per cent. for a corresponding petrol engine.

The petrol engine has a small pumping loss, but this is offset by the extra power required to drive the fuel pump in an oil engine.

The brake thermal efficiency of the oil engine is better than that of the petrol engine, especially at the lower load factors.

The distinctive feature of the oil engine is the fuel system, and experience goes to show that this can be made as reliable as the carburettor and manifold. Dust and water can be kept out of the fuel by suitable filter.

Ignition takes place by heat of compression alone, and the compression ratio varies between 13½ to 1 and 16 to 1, according to size of cylinder, and this necessitates a powerful starter for the engine. When once warmed up, the engine will continue to fire regularly in spite of a serious loss of compression or fall in air temperature. At altitude the maximum power falls off with decreasing air density, and it may be necessary to warm the inlet air. The oil engine does not suffer from sparking-plug failure, and lends itself to supercharging at all altitudes. Its bulk and frontal area are somewhat greater than those of the petrol engine.

The following figures (*P. E. Biggar*) give a comparison of a petrol and oil engine, being based on a modern British aero engine, and the performance of a number of experimental oil engines.

Rated output, 500 b.h.p.	Petrol.	Oil.
Engine size, twelve cylinder, ins.	5 × 5½	5½ × 7
Engine displacement, cu. ins.	1,296	1,995
Speed at rated output, r.p.m.	2,250	1,800
Piston speed ,, ,, ft./min.	2,060	2,100
B.M.E.P. ,, ,, lbs./sq. in.	136	110·5
Fuel consumption, lbs. per b.h.p./hr.	0·48	0·37
Corresponding brake thermal efficiency	28·5%	36·4%
375 b.h.p. cruising output.		
Estimated speed, r.p.m.	2,100	1,700
B.M.E.P., lbs./sq. in.	109	87·5
Fuel consumption lbs./b.h.p./hr.	0·455	0·35
Fuel consumption galls./hr.	22·5	14·75
Fuel cost (cruising) petrol at 1*s.* 8*d.* per gall.; fuel oil at 5*d.* per gall.	37*s.* 6*d.*	6*s.* 2*d.* per hr.

The lower B.M.E.P. for the oil engine will be raised as the technique of combustion improves. At present if more than 75 per cent. of the air charge is treated with fuel, the air becomes oversaturated with carbon, which is deposited as soot on cylinder walls and seriously interferes with lubrication and free working of piston rings. For non-supercharged engines the limiting value of the B.M.E.P. appears to be about 160 lbs. per sq. in.

The lower B.M.E.P. requires a larger engine for the same output. Owing to the higher maximum pressures of the oil engine, which normally reach 800 lbs. per sq. in. and 1,200 lbs. per sq. in. occasionally, with corresponding values of 450 and 700 lbs. per sq. in. for the petrol engine, the structure of the oil engine must be more robust and have larger and stiffer bearing surfaces. The petrol engine in the above table is specified to have a dry weight of 865 lbs., or 0·66 lb. per cu. in. An oil engine can be built for 0·73 lbs. per cu. in.

Armstrong Siddeley 'Jaguar' Engine.

Air-cooled **static radial type, having 14 cylinders arranged in two banks of seven, and working on two cranks set at 180° to each other.**

The body of the engine consists of a cast aluminium crank case B, which is attached to the aeroplane by means of a pressed steel bearer flange F, and which is bored to receive the cylinders C, and the valve tappet guides T. A back cover attached to the engine body carries the magnetos and carburettors, and also the rear crankshaft bearing R. The inside of the back cover forms a casing for an induction fan M, which is attached to the crankshaft.

The crankshaft is a one-piece alloy steel forging and is balanced by weights W, which are detachable. A master connecting-rod O is rigidly attached to a master ring N, and is attached to the piston of the top vertical cylinder in the front bank of cylinders and to the bottom vertical cylinder in the rear bank.

There are six auxiliary tubular connecting-rods P, which are free to hinge in the master ring, being attached to it by the hardened steel pins L.

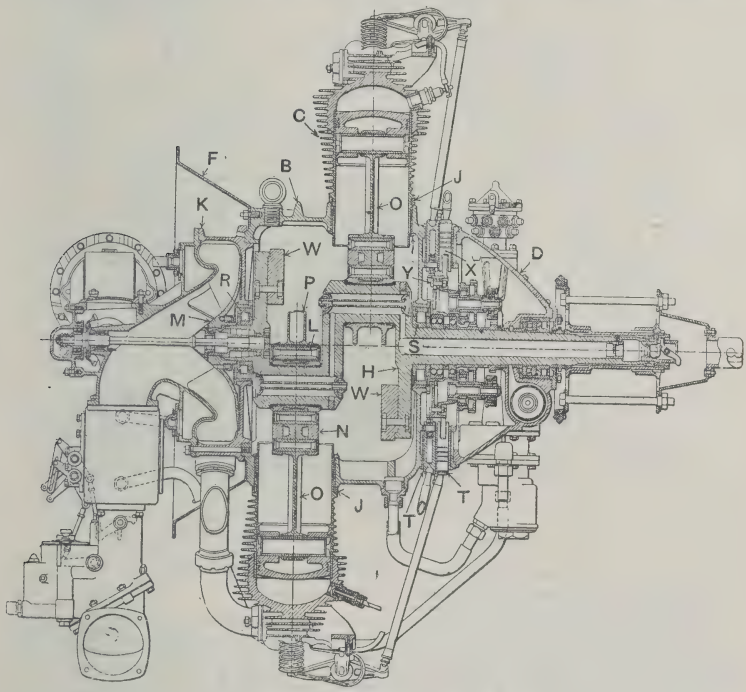

FIG. 9.—Armstrong Siddeley 'Jaguar' Engine.

Hollow floating gudgeon pins are used in the piston, the pistons being of forged 'Y' alloy with two cast-iron gas rings and two scraper rings. A hardened steel ring, Y, embodies three inlet and three exhaust cams, and is operated by planetary reduction gearing which drives it at one-sixth engine speed in an opposite direction to that of the crankshaft.

Lubrication is on the dry-sump system, two gear type pumps being fitted, one to feed and the other to scavenge the oil. Oil is supplied to the feed pump from a supply tank, and is then forced through a filter to the hollow crankshaft at a rate of about 2½ galls. per minute. As released from the engine the oil drains back to the sump, and is returned to the supply tank by the scavenge pump through oil-jackets surrounding the induction-fan casing and heater box. By these means the oil is cooled, and the incoming gas heated.

ARMSTRONG SIDDELEY 'GENET.'

General characteristics are: Five cylinder, air-cooled radial. Steel cylinders, screwed and shrunk on aluminium alloy heads with inclined valves operated by push rods. One piece crankshaft with counterbalance weights. Forged 'Y' alloy pistons. Oil pumps and magnetos mounted on front cover of crankcase, carburettor at back communicating with induction chamber containing a mixing fan. Dry sump lubrication and provision for dual ignition.

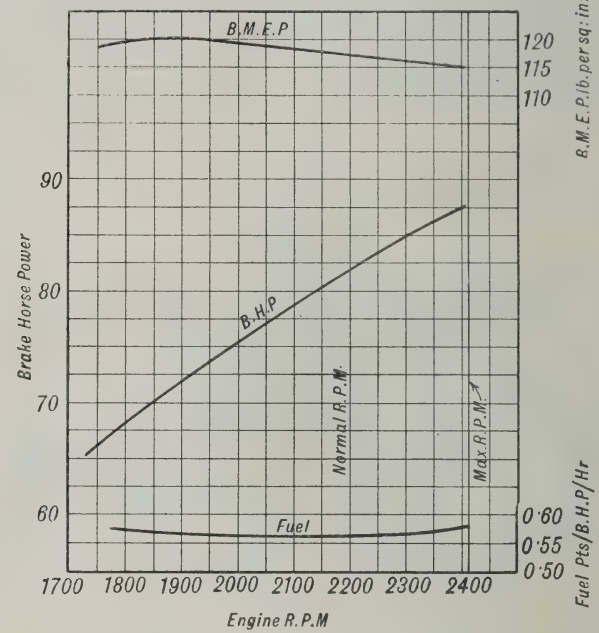

FIG. 10.—Power and Fuel Consumption. 'Genet' Engine.

WRIGHT 'WHIRLWIND' ENGINE. MODEL J–5 SERIES.

This engine (fig. 11) is of the air-cooled, static radial type.

The leading particulars are as follows:—

Number of cylinders, 9; bore, 4½ ins.; stroke, 5½ ins.; displacement, 788 cubic ins.; compression ratio, 5·2 : 1; guaranteed h.p. at sea level, 200 h.p. at 1,800 r.p.m. Average weight (dry), 508 lbs. Length overall (ex. starter), 34 ins. Diameter overall, 45 ins. Distance, mounting flange to end of propeller hub, $27\frac{17}{32}$ ins. Fuel consumption at rated power, 0·60 lb. per h.p. hour. Oil consumption at rated power, 0·025 lb. per h.p. hour.

The cylinder consists of a head H with integral fins cast in aluminium alloy screwed and shrunk on to a forged steel barrel B with integral fins and holding-down flange. Combustion chamber hemispherical with valves inclined at 35° to cylinder axis. Two sparking plugs per cylinder located in bronze bushings, diametrically opposite in the sides of the combustion chamber at an angle of 10° to crankshaft axis. Cylinder head contains two ports, the axes of which are at right angles to each other, one for attachment of inlet pipe, and the other for attachment of exhaust manifold. Cylinder attached to crankcase by eight studs.

Crankcase built up of five aluminium alloy castings. Front section S_1 includes thrust bearing housing, magneto brackets, magneto and cam-driving gears. Intermediate section S_2 contains cam and valve tappet mechanism and housing for front crankshaft bearing. Main section S_3, S_4 provided with pads for attachment of cylinders and contains the flange for mounting the engine, and the housing for rear crankshaft bearing and intake passages P. Rear section S_5

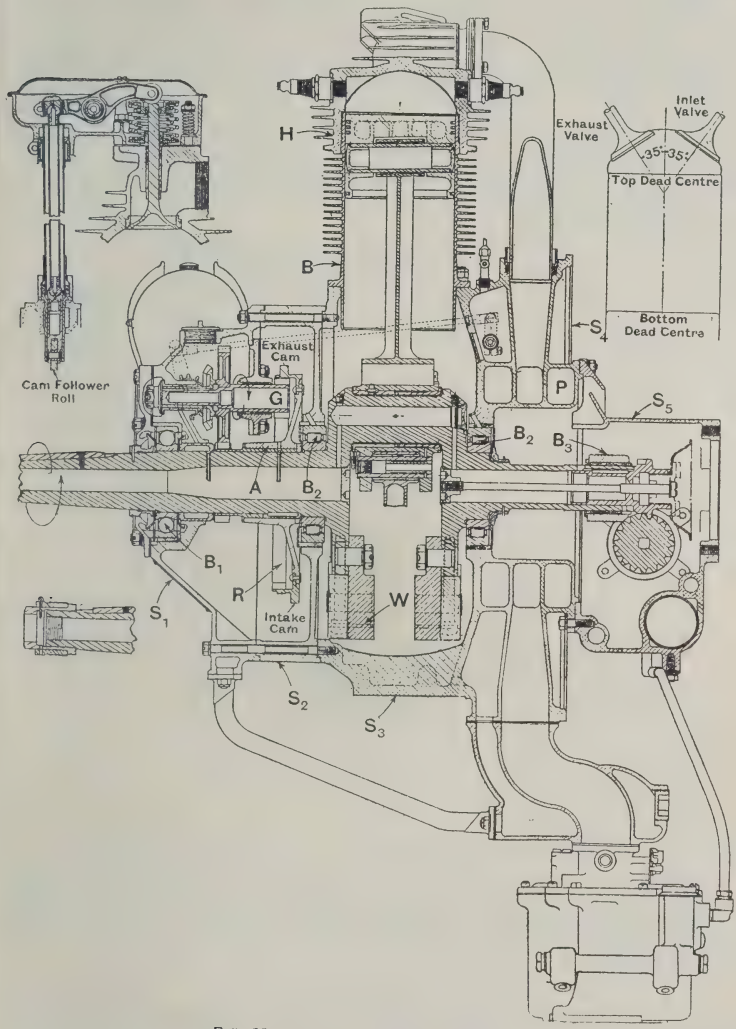

FIG. 11.—Wright 'Whirlwind' Engine.

Model J-5 Series.

contains drives for oil and fuel pumps, gun synchronisers and tachometers. It also provides a mounting for engine starter and housing for main oil strainer.

Crankshaft, single throw, counterbalanced type, chrome-nickel steel forging machined all over and hollow throughout its length. Counterweights W bolted to extensions of crank cheeks. Shaft runs in four bearings, ball thrust bearing B_1, two main ball bearings B_2, and a plain bearing B_3 in rear crankcase section.

Valve-operating mechanism actuated by cam located in intermediate crankcase section, and consists of a hardened steel ring R with eight lobes on the outside, and an internal gear G on the inside, which is riveted to an aluminium hub A riding on the sleeve portion of the cam drive gear, which is keyed to crankshaft. Cam followers of roller type. Push rods of nickel steel tubing with hardened steel balls pressed into either end. Valve gear enclosed by rocker arm housings, which form the support for rocker arm pins. Connecting rods consist of one master and eight link rods machined from chrome nickel steel forgings, master rod provided with steel-backed babbit-lined bearing at big end. Gudgeon and knuckle pin bearings of bronze.

Pistons cast aluminium alloy with three compression rings above gudgeon pin and one oil scraper ring at bottom of skirt.

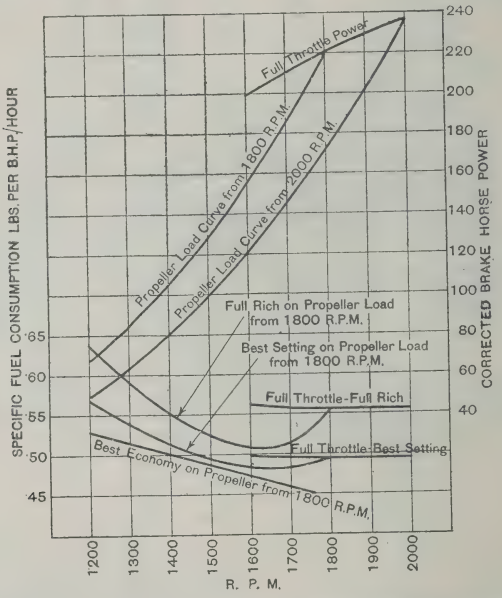

FIG. 12.—Power and Fuel Consumption for 'Whirlwind J-5' Engine.

Tulip-type valves of tungsten steel, exhaust valves being salt-cooled. Valve seats of aluminium bronze of rectangular cross section. Three concentric helical round steel wire springs per valve.

Ignition by two magnetos mounted on front section of crankcase. Carburettor attached to oil jacket, manifold sump attached to bottom of main crankcase section.

Pressure-type system of lubrication, except for cylinder walls and accessories drive gears, which is by spray.

WRIGHT 'CYCLONE' R—1,750 ENGINE.

General Specification.—Nine-cylinder radial. Rated output at sea level, 525 b.h.p. at 1,900 r.p.m. Weight (dry) without starter or hub 760 lbs. Weight per rated h.p., 1·52 lbs. Bore and stroke 6 in. × 6⅞ in., piston displacement 1,753 cu. ins. Outside diameter 54 ins., length over all, without starter 40⅝ in.

Guaranteed fuel consumption at rated h.p. 0·55 lbs. per h.p. hour. Oil consumption 0·035 lbs. per h.p. hour.

ISOTTA FRASCHINI (ITALIAN).

MODEL 'ASSO 1000.'

The engine is illustrated in fig. 13. Leading particulars are: 18 cylinders, water-cooled, three-banks 'W' formation at 40°; bore 150 mm.; stroke 180 mm.; compression ratio 5·3 : 1;

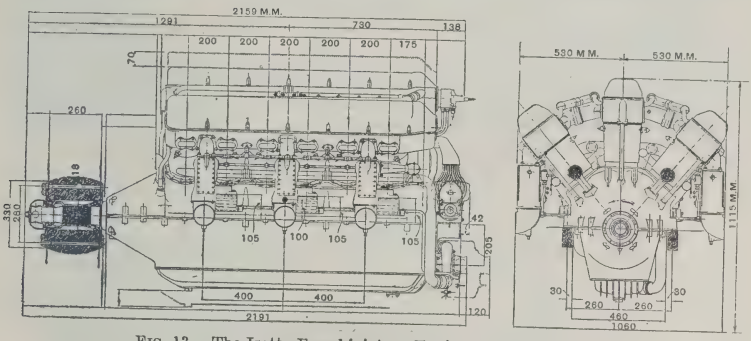

FIG. 13.—The Isotta Fraschini Aero Engine (type 'Asso 1000').

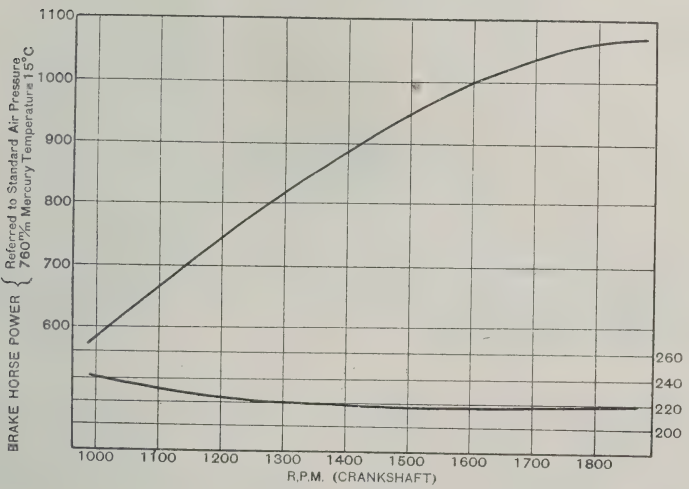

FIG. 14.—Isotta Fraschini Engine (type 'Asso 1000').

normal output 900 h.p. at 1,600 r.p.m.; maximum output 1,000 h.p. at 1,700 r.p.m.; weight (less airscrew) 1,770 lbs., weight per h.p., 1·77 lbs.; fuel consumption 0·485 lbs. per h.p. hour; oil consumption 0·032–0·04 lbs. per h.p. hour.

A.D.C. Aircraft Co.'s 'Nimbus' Engine.

This engine is one of the lightest of its type yet produced. Six-cylinder, vertical, water-cooled, direct drive.

Steel cylinder liners screwed into bottom of water-jacket blocks. Top of liners secured to cylinder head castings, which are in the form of aluminium alloy blocks, by the valve seatings. Water-jackets, aluminium castings, each block enclosing three cylinders. At the top the water-jacket blocks are secured to the cylinder head blocks by bolts. One inlet and two exhaust valves per cylinder, the former being operated from the camshaft by a rocker lever, and the latter direct.

Aluminium alloy pistons, with four rings and floating gudgeon pin.

Crankshaft, direct drive to airscrew, located in seven plain bearings and one roller bearing supporting forward end of shaft.

Camshaft located in a casing which protects the valve gear, and also forms a bridge over the cylinder heads, rigidly locking the blocks together. The shaft is driven by two trains of bevels.

Water circulation by centrifugal pump driven by an extension of the vertical shaft. Oil circulation to crankshaft, camshaft and vertical shaft, by dual oil pump that is combined with water pump.

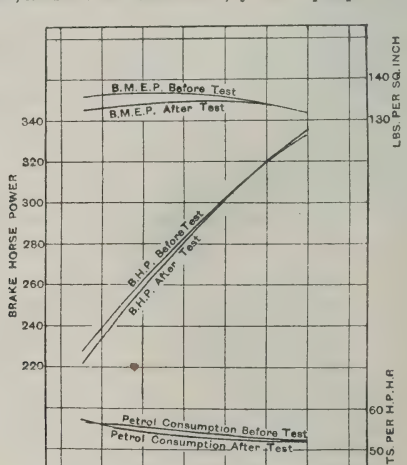

Fig. 15.—Power and Fuel Consumption Curves. 'Nimbus' Engine.

Bore, 152 mm.; stroke, 190 mm.; normal output, 305 b.h.p. at 1,450 r.p.m.; maximum output, 332 b.h.p. at 1,600 r.p.m.; petrol consumption at normal output, 0·52 pint per h.p. hour; oil consumption, 0·017 pint per h.p. hour; compression ratio, 5·4 : 1; b.m.e.p. 132 lbs. per sq. in.; weight dry (complete with airscrew boss, but less radiator and water), 670 lbs. ± 10 lbs. Dry weight per normal h.p. 2·19 lbs.

'Cirrus' Engines (Cirrus Aero Engines, Ltd.).

These engines are 4-cylinder in line, vertical type, cylinders and heads separate, the former being cast-iron and cylinder heads aluminium alloy, with air-cooling fins. Two sparking plugs per cylinder.

One inlet and one exhaust valve in each cylinder head, valves operated by rocking levers actuated by push rods to tappets in crankcase.

Pistons aluminium alloy with three castiron rings, connecting rods duralumin forgings of H section. Hollow gudgeon pin of full floating type. Crankshaft direct drive to airscrew. Located in three intermediate plain bearings and roller bearings at each end.

Airscrew shaft bolted to crankshaft and located in a radial thrust bearing.

Camshaft actuates direct to tappets, supported in three phosphor-bronze and one ball bearing.

Driven by steel gears housed in crankcase and timing gear cover.

Leading particulars are as follows:—

	Hermes.	Cirrus Mark III.	Mark II.
Bore	114 mm.	110 mm.	110 mm.
Stroke	140 mm.	130 mm.	130 mm.
Total swept volume	5,717 c.c.	4,939 c.c.	4,939 c.c.

Compression ratio	5·1 : 1	5·4 : 1	4·9 : 1

'BRISTOL' ENGINES.

A series of engines of the static radial type, comprising the following:—

Jupiter.—Nine cylinders. Mark VI F. Bore, $5\frac{3}{4}$ ins.; stroke, $7\frac{1}{2}$ ins. New cylinder construction. Mark VII F, ditto, supercharged.

Series VI, direct drive. Mark H, M, or L (high, medium, or low compression).

Series VIII, IX, XI, geared engines, high, medium, low compression.

Both direct drive and geared type high compression engines known as 'Standard Service' type, compression ratio, 5·8 : 1. 'General Purpose' type, medium compression, 5·3 : 1. 'Commercial' type, low compression, 5·1 : 1. Supercharged engine compression ratio, 5·3 : 1.

In the new cylinder construction the cylinder is an open-ended barrel, machined from carbon steel forging, fins integral and concentric with bore, screwed at upper end to take cylinder head, which is a 'Y' alloy forging.

Four inclined valves per cylinder, and the combustion head is of the 'pent-house' form, each slope having one inlet and one exhaust valve seating and sparking-plug socket.

Valve seats bronze alloy, valves operated by push rods, and provision for neutralising effect of cylinder expansion incorporated. Each valve has three springs, the inner one being a volute of thin spring steel strip.

Crankcase machined from duralumin drop forging, the centre portion being split on the plane containing the cylinders.

Built up alloy steel crankshaft, airscrew shaft, forward crank cheek and crankpin being formed integral, rear crank cheek formed integral with a short shaft for driving auxiliaries is keyed and clamped to rear end of crankpin. Balance weights fitted to extension of crank cheeks.

Connecting rod assembly consists of master rod with integral big end and eight auxiliary rods secured by articulated joints.

Pistons, slipper type of cast aluminium alloy, gudgeon pins being supported by bosses formed integral with two transverse webs, the skirt being cut away at sides. Two piston and one scraper ring fitted.

Hollow gudgeon pins of full floating type.

Two four-lobed cam rings driven at one-eighth crankshaft speed by means of epicyclic gear. The cams actuate the push rods through roller type tappets. Tappet guides of duralumin.

Rear end of crankshaft drives gear-type oil pumps, and magnetos through bevel gearing at $1\frac{1}{8}$th crankshaft speed.

Lubrication on dry-sump system, the crankcase being drained by scavenger pump.

Carburettor of special design and air intake jacketed by warm oil from scavenger pump.

Supercharger, high-speed centrifugal type, placed at rear of engine between carburettor and induction pipes. The mixture is drawn from the carburettor and passes axially to the impeller,

whence it is discharged at high velocity through a ring of fixed diffuser vanes and then passes into the annular induction chamber, thence to the cylinders.

Rating.—Series VII F (supercharged).

Rated power, ground level, 500 h.p. at 1,775 r.p.m.; at 9,000 ft., 480 h.p. at 1,775 r.p.m. Maximum speed, 1,950 r.p.m.

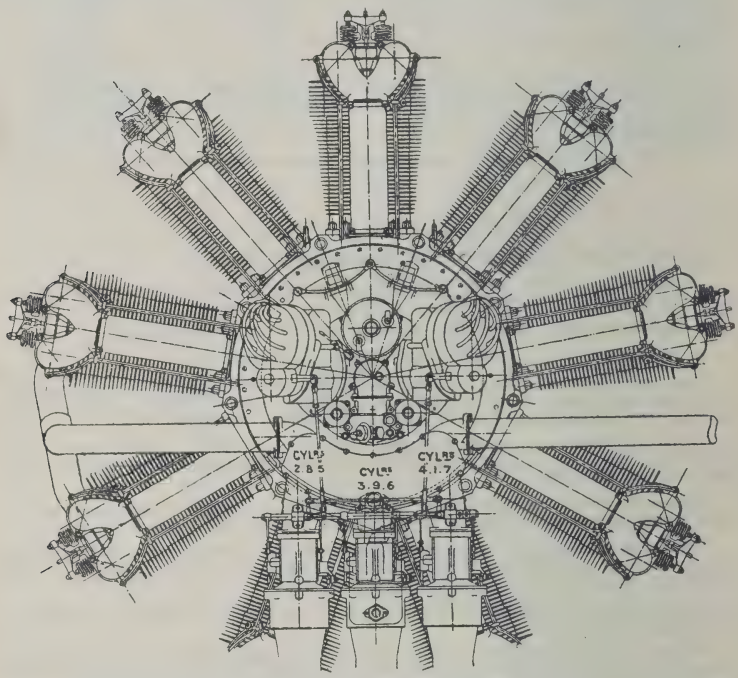

FIG. 16.—The 'Bristol' Jupiter Engine (Rear View).

Series VIII F (standard service engine), geared.

Rated power, ground level, 460 h.p. at 2,900 r.p.m. Output maintained up to 4,000 ft. Airscrew, half engine speed.

Series IX F (general purposes engine), 515 h.p. at 2,000 r.p.m.

Series IX F (commercial engine), 490 h.p. at 2,000 r.p.m.

Neptune.—Series I. engine. Seven-cylinder radial, bore, 5·75 ins.; stroke, 6·5 ins. Normal rated output, 270 b.h.p. at 1,700 r.p.m. Maximum output, 315 b.h.p. at 1,870 r.p.m. Compression ratio, 5 : 1; general construction similar to Jupiter engine. Airscrew driven direct by forward extension of crankshaft.

Titan.—Series II. engine. Five-cylinder radial normal rated output, 205 b.h.p. at 1,700 r.p.m. Maximum output, 220 b.h.p. at 1,870 r.p.m.

Materials used.—	
Connecting rods	Chrome-vanadium steel.
Pistons	Aluminium alloy.
Cylinders	Chrome-molybdenum steel forgings.
Valve seats (exhaust)	High chrome steel.
Valves. Inlet	Tungsten steel.
Valves. Exhaust	Silchrome
Valve springs	Piano wire.
Valve housing	Aluminium alloy casting.
Bearing cups	Duralumin forgings.

Model 3A—1,500 inverted type, is shown in fig. 19.

Beardmore Engines.

Four engines produced known as ' Cyclone,' ' Typhoon,' ' Simoon,' and ' Tornado.'

The ' Cyclone ' and ' Typhoon ' are of the 6-cylinder vertical water-cooled type, the ' Typhoon ' being inverted. The ' Tornado ' is the first practical aero engine to use heavy oil fuel, and is of the compression-ignition type. In general design and construction it resembles the ' Cyclone.' It has, however, eight cylinders of $8\frac{1}{2}$-in. bore, and normal speed of 1,000 r.p.m. Normal b.h.p. 650, maximum b.h.p. 720. The weight, 3,000 pounds, is at present rather high for aeroplane work, but is particularly suitable for airship work when allowance is made for the very low fuel consumption and for the avoidance of fire risk.

* Exhaust valve stems are hollow and fitted with a $\frac{3}{16}$ in. steel tube. Three horizontal holes are drilled near lower end of tube and the valve stem proper is provided with two horizontal holes just below the necked down portion. Oil introduced under pressure at the upper end of the valve stem flows down inside the tube out through the holes at the base and up around the outside of the tube to the two outlet holes in valve stem. When the cam-shaft revolves, the exhaust cam depresses the cam follower and the oil which is trapped in the cam follower guide is forced through the exhaust valves thus cooling them and greatly prolonging their life.

Leading particulars of Beardmore engines are as follows :—

	Engine.

Carburation.

With radial and rotary engines it is usual to fit a simple type of carburettor, there being no float chamber, the petrol flow being hand adjusted to suit engine speed and atmospheric conditions.

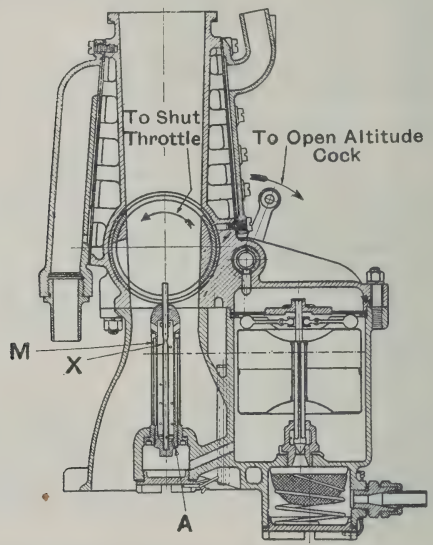

FIG. 20.—Napier Claudel-Hobson Water Jacketed Carburettor.

With stationary engines two or more carburettors are fitted according to the size of the engine. Representative types are the Zenith and Claudel-Hobson, which are fitted with float chambers and designed to give a practically constant mixture under the usual variations of load and speed.

These carburettors require to be carefully adjusted to each engine so as to give the same results, the operation of adjusting being known as 'synchronising.'

Aero engine carburettors must operate under variable circumstances. As the machine rises the density of the atmosphere decreases, and the quantity of fuel required per cu. ft. of free air becomes less. The desired reduction in petrol flow is controlled by hand adjustment, either by throttling the supply to the jet or, in the case of carburettors with float chambers, by reducing the pressure difference between the float chamber and the jet.

The Napier-Claudel Water Jacketed Carburettor, shown in fig. 20, is designed for use with the 'Lion' engine. It operates on the standard Claudel diffuser principle, the holes A and X being the main and pilot jets respectively. Water is delivered into the jackets on the induction pipes through pipes connected to the outlet flanges on the cylinder heads. From the induction jackets the water is led through short pipes to the water jackets of the carburettors, and thence through a return pipe to the water pump.

On tractor type engines the series parallel type main and slow running jets are used, whereas on pusher type engines the series type jets are used.

The jets shown in fig. 20 are the series type; the series parallel type main jets have an additional pilot jet hole drilled through their base central with the pilot jet, the pilot jet being specially calibrated to function correctly with this type of main jet.

The altitude compensation is of the 'Vacuum control' type. The areas of the various passages are specially proportioned for the 'Lion' engine. The functioning of the pressure balance and altitude control systems depends on the maintenance of an air pressure or depression above the petrol in the float chamber.

The arrangement of the induction piping is a most important factor in getting good carburation; sudden changes in the speed of the charge, and sharp bends, cause a considerable loss. Also there must be no dip in the pipes. The usual methods of heating are by water circulation, by exhaust gases, and by hot air taken into the carburettor. The purpose of the choke tube is to obtain the correct velocity of air around the jets in order to get the best mixture at all speeds. The main jet has most influence at high speeds, and the compensator, which corrects the irregularities of the main jet, has the greatest influence at low speeds.

For the Series XI engine a Napier-Claudel-Hobson Triplex Carburettor is fitted. The carburettor works on the standard Claudel diffuser principle.

Water Cooling.

Water cooling of aircraft engines has followed automobile practice in general principles, but there has been great diversity of opinion as to radiator design. The honeycomb type may now be considered as standard, with round tubes and hexagonally bulged ends. This gives a maximum cooling surface with minimum solid frontal area and therefore minimum head resistance.

From a series of tests on different radiators (Aeronautical Research Committee R. & M. No. 934) it was found that:

(*a*) Heat dissipation can be represented as a function of the cooling area ratio $\left(i.e.\ \frac{\text{cooling area}}{\text{frontal area}}\right)$ and drag as a function of cooling area ratio and diameter.

(*b*) A round bulge gave a better performance than the hexagonal, mainly on account of the smaller drag. For tubes of the same length : diameter ratio, large diameters are better than small, mainly on account of the drag.

(*c*) Shutters have comparatively little effect on heat dissipation until they are more than half shut.

(*d*) The shuttered results suggest the use of longer tubes in order to cut down the frontal area.

(*e*) Geometrical considerations suggest the development of hexagonal tube radiators, as they would have greater cooling area for the same tube length and a smaller capacity.

Opinions of designers vary greatly as to the best position of the radiator. The 'nose' position, in which the radiator is placed immediately behind the propeller, has many adherents, but excellent results are also obtained when the radiator is placed in two halves on the sides of the fuselage or below the fuselage. The radiator may also be placed in the top plane centre section.

Radiator Shutters.

In machines designed for flying at high altitudes, it is necessary to provide a variable cooling device to obviate the danger of the radiator freezing when high speeds are obtained as in diving. The device most generally used is a Venetian-blind type of shutter, which can be closed to prevent the air having access to the radiator. It is controlled by the pilot, who is also provided with a radiator thermometer, to indicate the circulating water temperature.

Average Weight of Power Plants.

	Lbs./h.p.		Lbs./h.p.
*Water-cooled engines	2·50	Air-cooled engine accessories	0·383
*Air-cooled engines	2·33	Water-cooled engine + accessories	3·50
Water-cooled engine accessories	1·00	Twin water-cooled engine + accessories	3·75
Twin water-cooled engines accessories	1·25	Air-cooled engines + accessories	2·50

Engine accessories include: radiator and shutters, cooling water, piping and cocks for fuel, oil, and water, exhaust pipes, pumps, starting gear, propeller. Fuel and oil tanks *not included*, as these vary with duration of flight.

* These figures can be considerably reduced with large power units.

FUELS: SOLID, LIQUID, AND GASEOUS.

(Contributed by Harold Moore, M.Sc.(Tech.), M.I.Pet.Tech., F.C.S., R. B. Hobson, A.M.C.T., and W. Newton Booth.)

Commercial fuels owe their heating value to two main combustible elements, carbon and hydrogen. Carbon is capable of forming two oxides, the monoxide CO formed when the oxygen supply is deficient and itself a gaseous fuel and the Dioxide CO_2; Sulphur, which is also contained in many fuels is itself combustible, but its effect on the total fuel value is relatively very small and it has the disadvantage that its oxide SO_2 has strongly acid properties and is thus liable to set up corrosion in metallic parts of the fuel consuming plant.

Provided that a fuel is completely burned, the carbon to CO_2, the hydrogen to steam, and the sulphur to SO_2, the amount of heat generated per unit weight of the fuel is perfectly definite and independent of the speed or method of combustion and is known as the calorific value, usually expressed in calories per gram or B.Th.U. per 1 lb. of the fuel.

(1 cal. per grm. = 1·8 B.Th.U. per 1 lb.).

If the steam produced from the combustion of the hydrogen is condensed, a further definite amount of heat is given out and there are thus two calorific values for any fuel containing hydrogen: the gross or higher cal. val. (H.C.V.) when the produced water is condensed and cooled and the nett or lower cal. val. (L.C.V.) when the produced water is not condensed.

The difference between the two values is

$$\text{H.C.V.} - \text{L.C.V.} = \text{H} \times 95{\cdot}13 \text{ B.Th.U. per 1 lb.}$$
$$= \text{H} \times 52{\cdot}8 \text{ Cal. per gm.}$$

where H is the percentage of hydrogen in the fuel.

In most commerical fuels there is generally some oxygen, and the carbon and hydrogen are combined in a more or less complicated manner. Such combinations may have resulted in the generation or absorbtion of heat and thus the actual calorific value of a fuel is generally different from the sum of the calorific values of its constituent elements.

Certain empirical formulæ have been evolved applicable to particular classes of fuel which give fairly satisfactory results *for those classes*. It is, however, safest to secure an experimental determination preferably by means of a bomb type of calorimeter of the C.V. of actual fuel to be used.

C.V. of Bituminous Coal is given roughly by the following—

Net calorific value = $[8{,}137\ C + 29{,}100\ (H - \frac{1}{8}O) + 2{,}500\ S - 600\ H_2O] \div 100$, where C, H, and O are the percentages of carbon, hydrogen, and oxygen respectively present, and H_2O the percentage of hygroscopic water present.

When the ultimate analysis is not known and it is desired to obtain a rough estimate of the calorific power from the proximate analysis, this can be obtained by the formula:

Calorific value = 1·8 (82C + aV) B.Th.U.

in which C = per cent. fixed carbon, V = per cent. volatile matter, and a is a constant computed from the following : $a_1 = 100V/(C + V)$.

a_1	5	10	15	20	25	30	35	38	40
a	145	130	117	109	103	98	94	85	80

COMBUSTION.

When a fuel is raised to its ignition temperature in contact with oxygen, combustion commences. It consists essentially of the chemical combination of the combustible elements with the oxygen and is accompanied with the generation of considerable quantities of heat, raising the whole mass to incandescence. The chemical processes may be very complicated, but the final results, if combustion is complete, are represented by the following equations :

(a) If oxygen supply is insufficient

$$2C + O_2 = 2CO.$$

(b) If oxygen supply is adequate

$$2CO + O_2 = 2CO_2$$
$$C + O_2 = CO_2$$
$$2H_2 + O_2 = 2H_2O.$$

The amounts of heat generated and the volumes of the products of combustion are given in Table I., p. 2079.

The following are recent figures for the spontaneous ignition temperatures of fuels :—

SPONTANEOUS IGNITION TEMPERATURES (IN OXYGEN).

(*McDavid*, '*J.C.S.*,' *Nov.* 1917, p. 1003.)

When a fuel contains oxygen this is, of course, available, and a correspondingly decreased quantity of external oxygen is required. The amount of external oxygen necessary for the combustion of 1 lb. of a fuel whose ultimate composition is known would thus be

$$\text{Oxygen required} = 8H + \frac{32}{12}C - O \quad \text{or} \quad 2{\cdot}66\left\{C + 3\left(H - \frac{O}{8}\right)\right\}$$

where HC and O are respectively the proportions of hydrogen, carbon and oxygen present. A dry atmosphere air contains 21 per cent. by volume of oxygen (23·3 per cent. by weight), the weight of air required is :

$$11{\cdot}6\left\{C + 3\left(H - \frac{O}{8}\right)\right\}.$$

In accurate calculations it is necessary to make allowance for the moisture contained in the fuel and in the air used for combustion. The latter depends on its temperature and humidity. (See Table on p. 2079.)

* Per cub. ft. CO. Other figures per 1 lb. carbon.
† Assume preliminary oxidation in Air.

The formula assumes that all the carbon is burned to CO_2, no CO being formed, and that combustible constituents other than those named are negligible.

Rich coals require more air than those low in calorific value, and, in fact, for coals such as those used in steam raising, over a wide range of qualities, the 'theoretical' air required may be taken with fair accuracy as proportional to the calorific value, and calculated by the formula

$$\text{Lbs. air per lb. coal} = \frac{\text{higher calorific value} \times 7{\cdot}2}{10{,}000},$$

the calorific value being in B.Th.U. per lb.

Perfect regulation is never attained in practice, and in order to secure that at least sufficient air is present in every part of the combustion chamber it is necessary to provide an average excess. This mixes with and dilutes the products of combustion, lowering their average temperature and carrying away heat when it finally leaves, and it is thus advisable to reduce its amount to the lowest which will avoid waste of fuel and smoke. This necessary excess will vary from 100 per cent. in the case of small direct hand-fired furnaces, 50 per cent. in the case of good mechanically stoked boiler installations, 25 per cent. in anthracite or coke burning furnaces, 30 per cent. in good powdered fuel firing, to practically nothing in the case of carefully regulated gaseous fuel fired furnaces.

If too little air is used, unburned fuel will escape with the chimney gases and cause serious reduction in efficiency.

Quantity of Flue Gases.

In order to specify suitable fans for induced and forced draught, it is necessary to know the weight of flue gases and the weight of air actually used per lb. of fuel burned. From this the volume to be dealt with by the fans at the appropriate temperatures can be ascertained.

The air used influences the percentage of CO_2 in the flue gases. For typical coals, the relation between air used and CO_2 may be expressed by the following approximate formula :—

$$\text{Lbs. air per lb. coal} = \frac{132 \times \text{calorific value of coal}}{CO_2 \text{ percentage} \times 10{,}000}.$$

The weight of flue gases per lb. coal may be taken as (lbs. air + 1).

Excess Air.

The percentage of excess air is approximately

$$\left(\frac{18{\cdot}9}{CO_2 \text{ per cent}} - 1\right) \times 100.$$

Actually the 'constant,' 18·9, should vary for coals in which the proportion of hydrogen to carbon is different. The formula gives therefore merely an approximate figure for a typical coal, also it does not apply if there is any CO in the flue gases.

Combustion of Hydrocarbon Fuels.

In the case of fuels containing hydrocarbon compounds many very complicated physical and chemical changes may take place before complete combustion is effected. Upon heating such hydrocarbons, *e.g.* those in bituminous coal, many commence to melt, or to distil or decompose at temperatures well below their ignition point. In such cases there is a primary evolution of combustible vapours and gases, and these when subjected to the radiant heat in a furnace undergo further decomposition. In an ordinary furnace it is generally not possible to give such a regulated air supply and to mix it sufficiently intimately with the fuel as to give rapid and complete combustion. The combustion is thus a relatively slow and heterogeneous process taking place in long flames, in which fuel vapours and gases and air are flowing in more or less parallel streams which only mix gradually. It is thus necessary to provide combustion chambers sufficiently large to contain the whole of the flames produced.

In addition to these physical effects it must be remembered that the combustion of a hydrocarbon is a stage by stage process somewhat similar in nature to the low temperature oxidation by chemical means, *e.g.* ethane would be oxidised successively to ethyl alcohol, acetaldehyde and acetic acid, which latter would then suffer thermal decomposition to hydrogen and carbonic oxide before being finally oxidised to steam and carbon dioxide. Heat is given out at each step, resulting in a rise in temperature, and a stage is soon reached when the

hydrocarbon molecules suffer thermal decomposition to simpler bodies and free carbon. If there is shortage of oxygen in intimate contact or if the flame is cooled below the ignition point, combustion is stopped and smoke produced. It will be noted also that the final products of the incomplete combustion contain considerable proportions of free hydrogen and carbonic oxide. It will be seen therefore how important it is to secure rapid and intimate mixture of the flame gases with sufficient oxygen if we are to secure complete and smokeless combustion and avoid the loss of fuel gases.

Internal Combustion Engines' Exhaust Gases.

The exhaust gases from internal combustion engines are subject to the same considerations as flue gases. They, however, cannot be regulated so as to produce a definite CO_2 percentage, as to obtain this result it would be necessary to throttle down the incoming air, thus loading the engine by increasing the difference in pressure between exhaust and inlet, in which case a

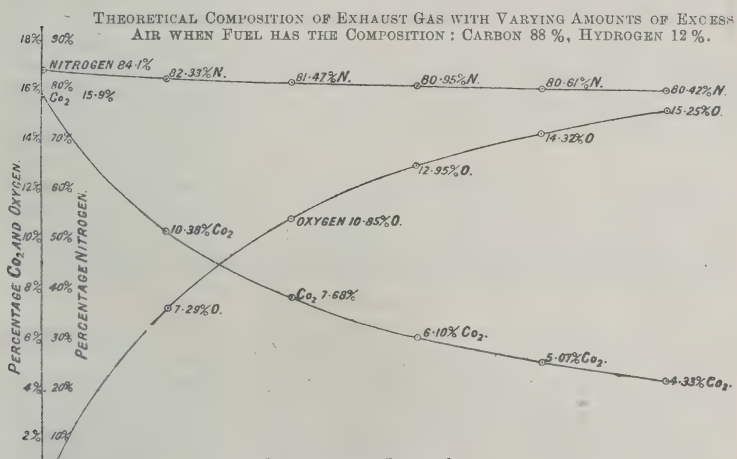

Fig. 1.

loss of efficiency would occur. The graphs in fig. 1 show the composition of the exhaust gases of an engine burning heavy petroleum (about 88 per cent. C and 12 per cent. H) with various quantities of excess air. Diesel oil engines running at full load generally take about 100 per cent. excess air; semi-Diesel engines a somewhat greater percentage excess air.

Heat Losses in Flue Gases.

The heat generated by the combustion of the fuel is communicated to the products of combustion which are thus raised to incandescence. The temperature of the flames thus depends upon the quantity and specific heat of these products and is thus affected greatly by the quantity of excess air admitted to secure complete combustion. As this temperature determines the 'temperature head' available for transmission of the heat, it will be seen what an important effect correct regulation of the air for combustion has upon the capacity of any given furnace plant, as well as upon its thermal efficiency.

When the combustion gases leave the furnace (at some temperature higher than that of the entering air, they carry away a certain proportion of the heat of the fuel and this is wasted. Its amount may be calculated if we know the leaving temperature of the waste gases and the composition of both fuel and gases.

The result with a typical bituminous coal is shown below :—

Ash and Moisture Content.

The question of ash content is a serious one, as its removal from boilers involves labour and expense. The clinker to be removed from a steam plant is greater in quantity than the weight of ash content obtained by calculation from the results obtained in the laboratory.

As the ashes contain from 1 per cent. to 25 per cent. of combustible matter depending upon the class of coal and the efficiency of the stoking arrangements. In addition they leave the furnace hot. For the purposes of assessing losses the C.V. of the combustible matter may be taken as that of carbon (14,500 B.Th.U. per lb.) and the S.H. of the ashes as approximate 0·2.

High moisture content not only shows that water is being bought for coal. It must be remembered that this moisture has to be driven off in the form of steam, and in this way takes up heat from the combustion zone, and is liable to cause smoking, with consequent reduction of efficiency.

Combustion Computation.

The total heat per pound of water vapour as found in air and in flue gases may be computed, within one B.Th.U., by the formula $H = 1{,}057 + 0{\cdot}46t$, where t is the Fahrenheit temperature. This formula frees the computer from all need for tables so far as computing moisture loss is concerned, while at the same time ensures a degree of accuracy sufficient for all practical purposes.

Analysis of Flue Gases.

It is now standard practice to check the regulation of combustion by analysis of the flue gases. The simplest estimation is that of CO_2, but as the 'theoretical' percentage in ideal conditions varies with the hydrogen content of the fuel a knowledge of the O_2 content is really a better guide to the quantity of excess air admitted. For the purpose of checking waste of fuel a knowledge of the amount (if any) of combustible gases is very valuable, especially as there is a likelihood of these being produced when the excess air is being cut down to a minimum.

Most methods for the estimation of carbon dioxide are based on the absorption of this gas by potassium hydroxide (caustic potash) solution, the process consisting in measuring a volume of flue gas at a definite temperature, and then absorbing the CO_2 by means of a 35 per cent. solution of caustic potash, after which the volume of gas is again measured, the reduction in volume indicating the volume of CO_2 originally present. Many simple forms of chemical apparatus are available for this purpose.

It is frequently desirable in gas analysis to estimate carbon monoxide and oxygen as well as carbon dioxide. Similar apparatus with other absorbent solutions for the respective gases may be used. In the common form of Orsat apparatus, pipettes containing absorption solutions of caustic potash (for CO_2), acid cuprous chloride (for carbon monoxide), and alkaline pyrogallol (for oxygen) are used. The apparatus also contains a measuring burette and levelling bottle, and is generally built up in a wooden case to make the complete set easily portable.

The estimation of combustible gases may also be made by differential combustion of the hydrogen at comparatively low temperatures, and of the CO and hydrocarbon gases at a higher temperature in a tube filled with copper oxide, or by exploding the residual gas with oxygen and estimating the resultant contraction in volume and the CO_2 produced. Special forms of apparatus are available for this work.

Precautions in taking Test Samples of Flue Gas.

It is the practice of many engineers when obtaining accumulative test samples of flue gases to collect these samples over water. Owing to the solubility of the component gases, especially carbon dioxide, in water and the variations of these solubilities with the temperature and pressure, this liquid should not be used to collect the sample if accurate results are desired. If water be used, it will absorb carbon dioxide, for example, until it becomes saturated with this gas with respect to that gas mixture. This results in a loss of some of the carbon dioxide that was in the gas. Then if a gas cleaner in carbon dioxide is collected over the same water, the water will give up carbon dioxide and increase the carbon dioxide content of the gas. If, instead of water, a saturated solution of sodium chloride is used, these errors will be greatly reduced, as the gas is much less soluble in this solution.

The common practice of collecting flue gas from the outlet of a boiler by the use of common iron pipe for the sampling tube is objectionable if the temperature of the gas being sampled is sufficiently high to raise the temperature of the sampling tube to 750° F. When the temperature of the iron reaches 750° F. it starts to react with the carbon dioxide in the gas, forming iron oxide and reducing the carbon dioxide to carbon monoxide. Thus a sample of gas drawn through an iron pipe when at or above this temperature would have its composition completely changed, appearing to contain high carbon monoxide and low carbon dioxide. For sampling at these high temperatures the tube should be made of silica or clay, or be fitted with a water jacket so that it may be cooled. (*Power.*)

Automatic CO_2 Recorders.

In all large installations it is customary to instal apparatus to analyse and record continuously the composition of the flue gases. The majority of these record only the percentage of CO_2, but instruments are available for recording also the percentage of oxygen or combustible gases. They are arranged either to—

(1) record the reduction in volume after absorption of the constituent from a regular series of measured samples; or

(2) to measure some physical property of the gas from which the desired result can be inferred.

Typical instruments in Class 1 are:

(*a*) The 'Auto' CO_2 recorder.—This records CO_2 percentage only.

The 'Auto' CO_2 Recorder.

In fig. 2 is shown, in diagrammatic form, the construction of the instrument known as the 'Auto' CO_2 Recorder, which has been designed and constructed by the *Auto Recorder Company*, and is now in successful operation in connection with a large number of boiler installations in this country and on the Continent. The action of the apparatus is as follows:

A small stream of water is allowed to run into the tank A through the small funnel B, which only allows sufficient water to pass to work the instrument at a suitable speed. The water runs from the tank A through the valve C into the chamber D. When the chamber D is filled up to the pipe E, the water overflows down the pipe F and under the float G, which it raises, thereby moving the valve C upwards and shutting off the water supply from the tank A into the chamber D. This motion of the valve C opens a communication from the chamber D through the pipe H, the water rising over the float G until it flows down the pipe I, and the chamber D is empty; the pipe J then acts as a syphon and drains the water from under the float G, which is then allowed to fall again, and the chamber D to be once more filled. By this means the chamber D is alternately filled and emptied, and, as the float is connected by a system of levers to the distributing slide valve K, the water flowing through is the prime mover of the instrument.

The operation of gas analysis is very simple. The pipe L is connected to the supply of gas to be analysed and, as the end of the pipe dips slightly into the water seal in M, no gas can be drawn back. When the water in the chamber D is running out, there is a slight vacuum in this chamber which draws the gas through the pipes L and E, and, as the first measuring vessel N is in communication with the chamber D through the passages O and P and the slide valve K (this valve having moved over to the right by the rising of the float G), it is entirely filled with flue gas. Much more gas is drawn in than is analysed, in order that the sample

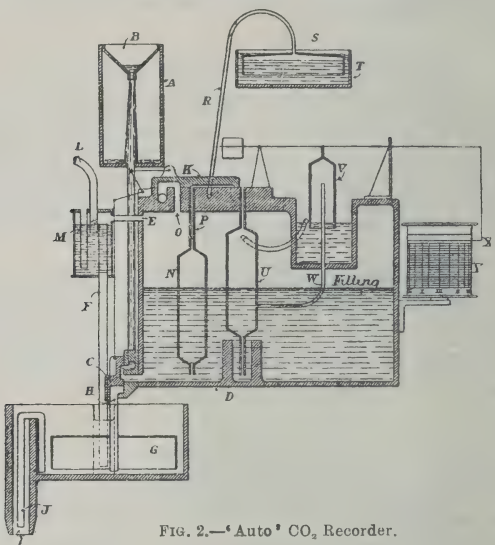

FIG. 2.—'Auto' CO_2 Recorder.

may be as fresh as possible. When the water reverses and begins again to run into D (the valve K having moved over to the *left*, by the sinking of the float G), the gas enclosed in the vessel N is sent through the pipes P and R, and under the dome S, which stands immersed in a solution of caustic potash contained in the vessel T. This dome is of large area, and the gas is in a thin layer between the wet dome and the top of the solution, so that the absorption of the CO_2 is rapid. After the water has risen and expelled all the gas from the vessel N into the absorber, and has again begun to run out, the valve K having moved over to the *right*, the water, as it descends in the second measuring vessel U, draws in from the absorber S the gas which has not been absorbed. As the measurer U is of the same capacity as the measurer N, it follows that, if there is not sufficient gas received from the absorber S to fill it, it will, after emptying the absorber, draw the remainder from under the bell V through the pipe W, and cause the bell to descend; the greater the amount of CO_2 absorbed the lower the bell V will be pulled down. As the bell is suspended from a balanced lever, which has a pen X attached to it, the pen marks the chart Y, which is placed round a clockwork drum, the lines made by the pen being of varying lengths, according to the amount of CO_2 which was in the quantity of gas in the first measurer N.

It has been found that one of the greatest troubles with recorders of this kind is to keep the pipes from the flue to the instrument clean; in the 'Auto' Recorder this is effected by a special filter.

(*b*) The Duplex, Mono Recorder.—This records in addition to the percentage of CO_2 the presence and amount of combustible gases. (Fig. 3.)

Operation.

The operation of the *Duplex-Mono* is briefly as follows:—

The gas sample is taken from the place where the most characteristic sample can be obtained through the ½-in. sampling tube and then through a special filter which removes all suspended matter and moisture, thus obviating the possibility of the piping to the instrument choking, or water-traps forming. The gas then passes through a lead pipe ¼ in. in diameter to the instrument; this sample is taken, and driven, through the instrument by a mercury pump of special design which is an integral part of the apparatus and is operated by either water or compressed air, the pressure required being not less than 14 lbs.

The gas is drawn from the flue by the suction stroke of the mercury pump into a volumeter, which on the pressure stroke accurately measures the sample, after which it is forced through an absorption tank containing caustic potash, where the CO_2 is absorbed. The residue passes into a measuring bell, floating in glycerine, which, as the gas passes into it, rises and turns a balanced wheel, which, through a pin, actuates the pen wheel. This, in turn, operates the pen and causes it to draw a line on the chart indicating the percentage of CO_2.

When the mercury pump has completed its pressure stroke its suction stroke commences, and the measuring bell is put in communication with the atmosphere, and ejects by its own weight the residual gases, whereby the pen returns to zero.

On the next stroke of the mercury pump the gas sample is diverted by a directing valve operated by the water pressure) after being measured in the volumeter, and passed through a small electric furnace where the combustible gases are burnt to CO_2 and water vapour, in the presence of copper oxide, which supplies any required oxygen and also acts as a catalytic agent; from this furnace the gas passes through the absorption chamber where the water vapour and the total CO_2 (the original CO_2 in the flue gas and the CO_2 formed by the complete combustion in the furnace) is absorbed, and the residue measured in the measuring bell and the total percentage of CO_2 and combustible gases registered on the chart.

This process of *alternate analysis* continues automatically, about thirty analyses being made each hour.

Owing to the special design of the gas filter the pipes cannot choke, and in consequence the maintenance is negligible. The gasometer being cooled by a coil in which the operating water circulates and the rest of the tubes being kept at the same temperature by the mercury which is also in constant contact with the water, the gas before analysis, in the volumeter, and after analysis, in the measuring bell, is always at the same temperature, thus the measurements are extremely accurate.

The instrument is supplied with a two months' chart, self-filling pen, and with a special filling device for replenishing the caustic potash in the absorption tank; as well as a filter for filtering the operating water before admission to the instrument.

Typical Instruments in Class 2.

The 'W.R.' Patent CO_2 Indicator.

(International Gas Detectors, Ltd. (Late W.R. Patents, Ltd.), Great Wilson Street, Leeds.)

(*a*) The W.R. CO_2 or Combustion Indicator is an apparatus which continually, automatically, and accurately indicates the percentage of CO_2 which is passing through the flues at any hour of the day and night. With this Indicator installed on the boiler plant the percentage of CO_2 obtained can be seen at once, and the necessary steps taken to increase this amount and thus save fuel.

Fig. 4 shows a new type recently introduced and placed on the market. It can be used in all cases of combustion where any class of fuel is used, and where CO_2 is a product of this combustion. The arrangement adopted differs materially from other CO_2 indicators.

The method employed in the 'W.R.' Patent CO_2 Recorder depends on the difference of pressure generated on the two sides of a porous pot, one side of which is exposed to flue gas whilst the other contains soda lime granules contained in a paper cylinder which absorbs the incoming CO_2.

An aspirator, S, worked by the natural draught which it increases, is fixed at a point as near the chimney base as possible, and continually aspirates gases from the flue it is desired to keep under observation. The path of gases is shown by the arrows. They are first drawn through a filter F, and pass from thence into a chamber containing a porous pot, inside which is a dry reagent, R. The flow of gas is shown by continuous bubbling through water in vessel B. A pipe connects the chamber with a vessel containing water into which dips one end of another pipe, G, the other end of which is taken into the inside of the porous pot. Some of the gases penetrate into the interior of this pot, and are absorbed by the reagent, with the result that a partial vacuum is formed, and the water is forced up the pipe G. The latter is provided with a scale so graduated that the percentage of CO_2 in the flue gases can be read.

The W.R. Indicator is prompt in its action, having a lag of three minutes only. Its deviation from absolute accuracy has been found to be only 0·1 per cent. It is well constructed; has no mechanically moving parts; is fireproof and foolproof, and can be worked by any boy of average intelligence. With each Indicator the manufacturers furnish a blue print showing the method of fitting to each particular boiler, also special detailed instructions for installing the apparatus, which operation can be completed in from four to six hours by any works' engineer

or fitter. In cases where a recording graph is desired, one of a specially approved form can be supplied by W.R. Patents, Ltd. The cartridges last 24 hours of continuous working.

'Galvanised Iron Pipe' should never be used for connecting a CO_2 machine, that draws a continuous sample, to the sampling point at the boiler. The sulphur dioxide in the flue gas attacks the zinc coating on the pipe, forming zinc sulphate. This soon plugs the pipe and prevents the flue gas sample from being drawn through it.

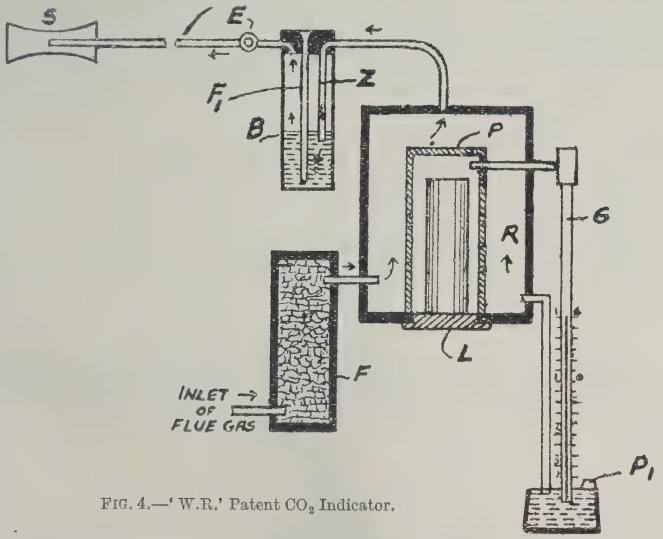

FIG. 4.—'W.R.' Patent CO_2 Indicator.

(*b*) **The Shakespear Electrical CO_2 Recorder** made by the Cambridge Instrument Co., Ltd.

The principle employed in this instrument is one which was devised by Dr. G. A. Shakespear of the University of Birmingham, for the testing of the purity of gases, and has been applied to many other purposes in addition to the recording of CO_2 content of flue gases.

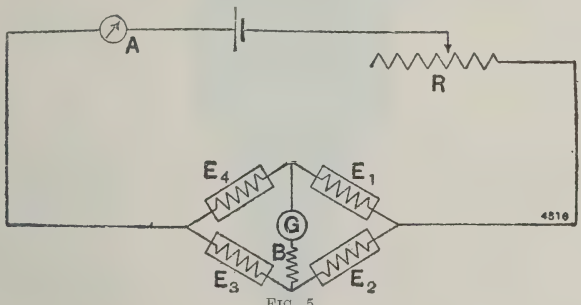

FIG. 5.

In this CO_2 meter, four identical spirals of platinum wire are enclosed in separate cells E_1 E_2, E_3, E_4, in a metal block, as shown diagrammatically in Fig. 5. Each of these spirals forms one arm of a Wheatstone bridge circuit. A definite electric current is allowed to flow through the bridge, thereby causing the spirals to become heated and to lose heat to the walls

of the cells. If two gases having different thermal conductivities are introduced, one into two of the cells (say, E_1 and E_3), and the other gas into the other two cells (E_2 and E_4), the spirals E_1 and E_3 will cool at a different rate to E_2 and E_4, and will therefore be maintained at a different temperature. The consequent difference in the resistance of the spirals will throw the Wheatstone bridge out of balance, causing a deflection of the galvanometer G, the extent of which depends upon the difference in the conductivity of the two gases. The construction is such that changes in the temperature of the gases affect both sides of the bridge equally. If, therefore, the cells E_2 and E_4 contain a pure gas and the cells E_1 and E_3 the same gas mixed with some other constituent, the extent of the deflection will be an indication of the amount of the second gas present, and the galvanometer can be calibrated to show directly the percentage composition of the mixture.

The difference in conductivity between air and carbon-dioxide enables the method to be used to determine the percentage of carbon dioxide in flue gases. These gases consist chiefly of nitrogen and carbon dioxide mixed with small amounts of oxygen, water vapour, and carbon monoxide. Since carbon monoxide, oxygen and nitrogen have all nearly the same thermal conductivity, the small variations of these gases do not affect the readings. The effect of the water vapour can be counteracted by keeping the gases in all the cells saturated.

By passing the gases through an electric furnace in which combustible gases are oxidised the instrument will indicate the change in composition so caused and can therefore be calibrated to read the percentage of combustible gases.

In practice, two of the cells are filled with air saturated with moisture, and the other two are exposed to the gas under test. The difference in conductivity of the gases in the cells then depends solely on the percentage of carbon dioxide in the gas.

The current in the Wheatstone bridge circuit, as shown by an ammeter (marked A in Fig. 5), is adjusted to a constant amount by a rheostat R, while the resistance B in the galvanometer circuit enables the electrical zero of the CO_2 meter to be adjusted.

CO_2 Metering Unit.

The metal block in which are mounted the four cells containing the platinum spirals is combined with a water-bubbler and aspirator to form a complete all-metal metering unit. This unit, which is illustrated in figs. 6 and 7, is so designed as to give accurate readings in

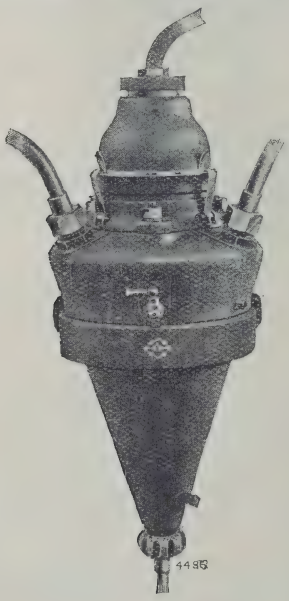

Fig. 6.—7 × 7 × 16 ins.

widely varying boilerhouse conditions, and is exceptionally robust and dependable. In fig. 7 the complete metering unit is shown diagrammatically in section. As mentioned two of the cells in the meter block A contain air. These air cells are sealed, but communicate with a central compensating chamber which contains a wick moistened with clean water, so that the air in the cells is saturated. The wick carries sufficient water to ensure complete saturation for a long period.

The ends of the platinum spirals are connected to terminals T in the head of the meter, which is provided with an easily detachable cover C. All meters of the same type are electrically interchangeable. Four-way cable is taken from these terminals through the screwed gland D in the cover to the indicator or to the recorder, which consists of a special indicating or recording galvanometer. The current is either supplied by an accumulator or the outfits are arranged to run off the local main electric supply.

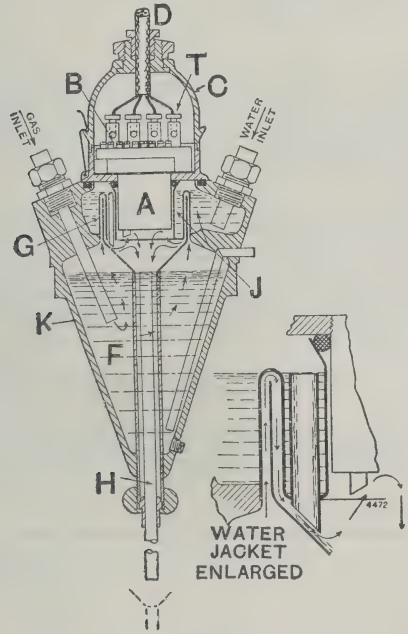

FIG. 7.

The CO_2 meter A is bolted to the top of the gunmetal casting K comprising the bubbler and aspirator, the joint being made gas-tight by a rubber gasket. In Fig. 7 the arrows show the direction of flow of the flue gases. After bubbling through the water in the bubbler vessel F, the gases flow through an annular surface cooler G, and past the CO_2 meter A to the central pipe H which forms the aspirator. The gases diffuse into the remaining two cells of the meter through a shrouded hole drilled in the end of the meter block. The meter block is provided with a water-jacket J, through which the water supply passes to the bubbler; the annular cooler G is immersed in this water-jacket, so that the meter block and the flue gases are brought to the same temperature, thus eliminating temperature gradients. Any excess water vapour present in the gases after their passage through the bubbler is condensed out in the surface cooler and drained back into the bubbler. The gases are thereby brought to saturation at the temperature of the meter block. The bubbler is so designed that there is a continual slow circulation of water through the bubbler vessel F, which ensures that any SO_2 in the flue gases is washed out without any appreciable quantity of CO_2 being removed. A device B provided in the head of the meter enables the electrical zero to be adjusted.

SOLID FUELS.

The most important naturally occurring solid fuels are :—

Coal ; Lignite ; Peat ; Wood.

These may be burned in the raw state, or may be subjected to destructive distillation. In the latter case solid, liquid, and gaseous products are evolved. The more important solid fuels which may be prepared by this treatment are coke (of two kinds, metallurgical and gas-works coke), lignite coke (of little value), peat charcoal, and wood charcoal.

Powdered coal is sometimes made into briquettes by the addition of a small percentage of coal-tar pitch or other binding material, and pressing in moulds.

COAL.

Coal consists of the mineralised remains of ancient vegetation and varies considerably in composition according to the particular portions of the paleolithic plants preserved, the age of the deposit, its depth, and the properties of the surrounding strata. The younger formations are more nearly allied to cellulose, as the lignites and brown coals, and contain a relatively large proportion of both known as coke. The matter distilled off is known as the volatile bituminous matter, and may amount to as little as 1 per cent. or as much as 40 per cent. of the coal according to its nature. (See Table *below*.)

It will be realised that bituminous coal is a very complicated mixture of heavy hydrocarbons, and much work has been done in attempts to determine its constitution. Prof. Phillips Bedson of Armstrong College, Newcastle, uses the selective action of various solvents of which the most useful appear to be chloroform and pyridene, which dissolve out certain constituents.

Workers at Owens College, Manchester, have attempted to separate mineralogical constituents, and recognise four main kinds, viz. Fusain, Vitrain, Clarain, and Durain, but it is doubtful if these constituents are definite compounds, and their composition as well as their proportions vary from one seam to another.

The preparation of microscope sections of coal and the examination thereof by transmitted light has been found to give valuable information as to the nature of the coal and its suitability for particular processes.

The composition of coal from various fields varies considerably according to the conditions to which the coal has been subjected during its formation. Its variation in composition can be seen from the following table of coal analyses :—

Ultimate Composition of Coal (*Brame*).*

Type of Coal.	Carbon.	Hydrogen.	Oxygen and Nitrogen.	Fixed Carbon.	Volatile Matter.
Lignites and brown coals . . .	69·5	5·5	25·0	52·0	48·0
Splint coal (Fife)	82·0	5·0	12·8	61·0	39·0
Gas coal (Durham)	85·0	5·5	8·2	66·0	34·0
Coking coal	87·3	5·05	6·9	73·5	26·5
Smokeless steam (Welsh) . . .	91·3	4·05	3·9	85·5	14·5
Anthracite (Scotch)	91·1	3·5	4·65	88·5	11·5
Anthracite (Welsh)	91·0	3·9	4·28	93·0	7·0

Coal possesses a sp. gr. of from 1·2 to 1·5 (water = 1) mainly depending on its composition. It also varies considerably in hardness and texture. The combustible portion of coal usually consists of from 73 to 93 per cent. carbon, 3 to 6 per cent. hydrogen, 2 to 20 per cent. oxygen, 1 to 2·5 per cent. nitrogen, and 0·5 to 5 per cent. sulphur. When completely burned coals yield from 1 to 15 per cent. ash. The moisture content varies within very wide limits. The heat value of coal is generally from 12,000 to 16,000 B.Th.U. gross. A comparison of the properties of coal with those of other solid fuels may be seen in the following table :—

* 'Fuels: Solid, Liquid, and Gaseous,' p. 32.

CALORIFIC PROPERTIES OF VARIOUS FUELS.

Substance.	Calorific Power.		Observed by
	Calories.	B.Th.U.	
Scotch peat briquettes (16 per cent. H_2O)	4,754	8,558	F. Mollwo Perkin.

Asphaltum (extracted from petroleum)	9,550	17,190	"

Analysis of Coal.

The chemical tests usually made upon coal are to ascertain the calorific value, coke value, ash content, moisture content, and ultimate composition. The volatile matter per cent. is obtained by deducting the coke value of the dry coal from 100. The 'fixed carbon' is obtained by deducting the ash content from the coke value.

12. Anthracite, Kilsyth.

It is manifest that in selecting coal for a fuel considerable care is necessary to ensure that coal of the right class is chosen.

Ash of Fuel.

In addition to the mineral matter naturally occurring in the vegetable detritus from which the coal was formed, there is usually more or less inclusion of further mineral matter in the seam itself, and this may be changed considerably in chemical composition by the infiltration of water containing mineral matter in solution. Such mineral matter is incombustible, and is left behind as an ash or clinker. Not only its amount but its composition and melting point are important matters, as a readily fusible ash may melt into a treacly mass, interfering with the air supply and so impeding combustion, and also rendering ash removal a troublesome operation.

Analysis of Coal.

Before attempting the analysis of a coal it is necessary to secure a truly representative sample, and this is by no means an easy matter. In the case of coal delivered by railway wagon it will suffice to take, say, 14 lbs. from each wagon, the sample being chosen to be as representative as possible. In the case of steamer or barge delivery, similar carefully taken samples should be collected at approximately equal intervals as unloading proceeds. The samples should be collected together, subjected to any screening test desired, and then broken roughly on a clean floor till there is no piece bigger than a walnut; the coal should then be well mixed, quartered, and the selected quarter further broken, mixed, and requartered until a suitable size of sample remains. Messrs. Sturtevant make a useful sampling machine which crushes, mixes, and divides out a sample mechanically.

Great care should be taken to avoid loss or gain of moisture by the coal during this sampling process, as this, of course, vitiates the accuracy of the analysis.

A committee of the British Engineering Standards Association has carefully considered the conditions necessary to be observed in order to ensure that samples taken should be within certain prescribed limits of error from the true mean, and finds that the size of the individual portions taken as samples and the number of such samples necessary to be taken in order to ensure the desired accuracy is dependent upon the sizes of individual pieces of coal and upon the ash content of the coal much more than upon the total quantity of coal in the consignment to be sampled. Their findings are contained in B.E.S.A. Report No. 403 of 1930, entitled, ' Report on the Sampling of Small Fuel up to 3 ins.,' embodying some general principles of sampling. Based on such investigation they have also issued Report No. 404, ' British Standard Specification for the Sampling and Analysis of Coal for Export.'

In the preparation of coal for the market the run of mine coal is first screened to separate the large (over 1 in. or so) from the smalls, and the former is then passed over a picking belt where visible impurities—stone, shale, pyrites, &c.—are picked out by hand. The large coal may be further screened for certain markets into nuts, cobbles, and large screened coals. The small coal may either be sold without further preparation or further screened into various sizes of smalls and duff, and where reduction in the ash content of smalls is considered desirable these may be subjected to washing or dry cleaning processes by which the particles of high specific gravity are separated from the lighter coal. When purchasing coals, therefore, the sizes of screen to be used and the washing or other purifying processes used in its preparation should be known.

The Commercial Selection of Coals.

(Contributed by Chas. F. Wade, A.M.I.Mech.E., A.M.I.E.E.)

The commercial value of a coal for any specific purpose and for direct combustion purposes will be dependent upon the following factors:—

(i) The lower or net calorific value.
(ii) The amount of volatile matter and nature of coke.
(iii) The amount and nature of the ash content.
(iv) Its physical suitability for the particular conditions under which it is to be burned.
(v) The price per ton delivered on site.
(vi) Local cost of labour for handling, firing, and removal of ashes.

The net calorific value (i) calls for both a test for calorific value and also either an ultimate analysis or calculation in order to arrive at the hydrogen content of the fuel. The latter calculation or estimate is made from the percentage of volatile matter in the coal as disclosed by proximate analysis.

The net commercial calorific value will vary with the conditions obtaining in individual installations, and will depend upon the final temperature of the gases leaving the boilers or furnaces, together with the total hydrogen in the fuel as fired.

The total hydrogen will be the sum of the hydrogen combined in the fuel and that forming one-ninth of the moisture. Lower commercial calorific value for any specific plant will be

$$HCV = \left\{ 9H \left([212 - t] + 970{\cdot}4 + 0{\cdot}47\ [T - 212] \right) \right\},$$

where,

HCV = higher or calorimeter value of fuel in B.Th.U. per lb. as fired;
H = hydrogen fraction of the fuel as fired;
t = temperature of the fuel in °F., as fired;
T = final temperature of waste gases.

In the absence of direct ultimate analysis of the coal, the percentage of hydrogen in the fuel may be closely estimated by the following formula (Diederichs'):—

$$H = V \left(\frac{7{\cdot}35}{V + 10} \right) - 0{\cdot}013,$$

where,

H = percentage of hydrogen in the combustible; V = percentage of volatile matter in the combustible.

Combustible = coal, less sum of moisture and ash.

(ii) The amount of volatile matter and nature of the coke are found simultaneously in the proximate analysis. This test will give the correct classification of the coal as to its qualifying characteristics for special uses. The ratio of volatile matter to fixed carbon is of the greatest importance in deciding the suitability or otherwise of a coal for use on any particular plant; all other things being equal, the fuel with the lowest volatile content which can be efficiently consumed in the specific furnace conditions will be the most economical in use. This can only be definitely determined by the careful working test of a sample delivery of the fuel, and careful note made of the percentage of CO_2 in the waste gases, together with the final temperature of the gases and the percentage of combustible on the ash heap. The following general classification of coals will be of assistance in selecting suitable fuels for given purposes from the commercial viewpoint of economy in use.

Class of Coal.	Per Cent. Volatile Matter in Combustible.	Economical Application.
Short flame non-caking, semi-bituminous, or Welsh steam coals	12–20	Steam raising with strong draught.
Short flame caking coals	20–25	As above and coke manufacture.
Medium flame, moderately caking coals	25–32	Steam raising, domestic grates.
Long flame caking coals	32–40	Gas manufacture.
Long flame non-caking North Country coals	over 40	Furnaces, gas producers.

Burning a coal in a furnace which has insufficient draught for complete combustion will result in excessive waste of unburned carbon as coke in the ashes. Burning a coal of an unnecessarily high volatile content will produce an unnecessarily high loss in the waste gases, due to the hydrogen content, smoke will be difficult to avoid.

The amount of ash and moisture will not affect the classification given above.

(iii) The amount of the ash in the coal will not only reduce its commercial value by the reduction in actual calorific value, but also by its physical effect will reduce the value at a greater rate than that of the percentage of ash. For ordinary conditions of firing and draught, without steam jets, the rate of fall in practical value with the ash content will gradually increase until at 40 per cent. ash the fuel will be unburnable and valueless. This is for average ash.

The nature of the ash is chiefly affected by the percentage of iron in its composition, the fluxing effect of ferric oxide in the ferruginous ash coals causing the formation of liquid slag at comparatively low temperatures, which closes up the fire-bar spaces, assists in the fusion of firebars, and entraps appreciable quantities of unburned combustible. Ferruginous ash is distinguished by its red colour, the percentage of iron being roughly indicated by the depth of the coloration of the ash in the crucible after proximate analysis for ash.

(iv) The physical suitability of the coal for particular conditions depends upon the construction of the firegrates, type of mechanical stoker, and the amount of draught available. Under practically every condition of use mixed coals as regards size should be avoided. For hand-fired boilers and furnaces screened cobbles or nuts should always be selected. Large steam coal is

to be avoided; if fired as received, in lumps, efficient combustion is impossible, while breaking down results in uneven fires and waste due to the formation of a quantity of slack in the process.

Fine slacks are unsuited for hand-firing on plain grates, but can be burned very efficiently on special forced-draught grates fitted with steam jets and closely spaced firebars. High ash coals may be more efficiently burned on these grates than with plain natural or induced draught.

(v) The price per ton of coal, delivered, together with the cost of labour in handling and incidental work, is the last test of the value of the coal to be applied after all the technical deductions already referred to have been made, and is to be utilised to arrive at the net number of B.Th.U.'s per unit of cost under practical conditions of work.

Wherever possible, the following procedure should be adopted in selecting the most economically suitable coals for contract purposes:—

A sample delivery should be ordered of sufficient size to allow of observation under practical working conditions for a long enough period to ascertain the maximum hourly evaporation under forced and economical conditions of work, probable ash-heap loss, chimney loss, etc. This cannot be carried out without the proper equipment of testing instruments. This working observation will allow of a close estimate of labour and power costs. A low-grade slack of about 10,000 B.Th.U. per lb. will probably call for a power and labour cost quite double that involved in the use of good quality washed nuts of 14,000 B.Th.U. per lb. This shows the uselessness of evaluation on the calorific value alone. Standing losses on the plant, such as conduction and convection, etc., vary directly as the number of boilers, etc., used.

Final evaluation should be made as follows:—

Gross or higher calorific value of the coal, air-dried, then deduct the following:—

Hydrogen loss under practical conditions of waste gas temperature;

Heat loss in waste gases due to excess air as per CO_2 and temperature readings,

Loss due to unburned carbon in ash-heap per lb. of fuel used.

The final figure thus obtained gives the practical working value of the fuel in B.Th.U. per lb.

To the price of the coal must be added the following costs:—

Cost of attendance for firing per ton of coal used;

" power, such as stoker, fan, conveyor, economiser drive, etc., per ton of coal used;

" ash removal per ton of coal used.

From the data thus obtained the ultimate cost of, say, 100,000 B.Th.U. is obtainable for the actual conditions existing with the particular plant upon which the coal is to be used.

The system which has been used with success is to reduce the value of each coal to a figure of merit consisting of its comparative value with pure carbon as a standard, the latter being taken as '100.' The average final temperature of the gases is ascertained in the usual manner. The chimney loss for pure carbon burned perfectly without excess air is then calculated for the conditions of waste gas temperature obtaining on the plant. Taking the calorific value of pure carbon as 14,544 B.Th.U. per lb., the '100' figure of merit for this plant will be 14,544 minus the gas loss per lb. of carbon. This represents theoretical perfection with the plant. The actual results obtained for the coal under examination are expressed as a percentage of the pure carbon theoretical figure, and this is taken as the relative figure of merit for the fuel.

(*C. F. Wade.*)

Economic Effects of Impurities in Coal.

Each per cent. of sulphur reduces the boiler capacity by about 1·5 per cent. In experiments made in America with a chain grate stoker, using Illinois coal mixed with various percentages of ash, the efficiency dropped gradually as the ash increased up to 35 per cent., after which the efficiency dropped to zero rapidly with a fuel containing 40 per cent. of ash.

Loss of Thermal Value of Coal by Storage.

An average of 741 tests, in America, of a particular coal showed, after three years in the open air, a reduction of from 35 to 28·3 per cent. of volatile combustible matter, indicating a thermal value loss of 20 per cent.

Coal in storage should be inspected regularly. If the temperature reaches 150° F. the pile should be carefully watched, and if the temperature rises to 175° or 180° F. the coal should be removed as promptly as possible. The coal should be thoroughly cooled before being replaced in storage.

Temperature of Decomposition of Coal.

The temperatures at which coals begin to decompose are of considerable importance, both for technical purposes and as an aid to the study of the constitution of coal. There is little published information of a precise nature on this point, and it is frequently assumed that coal may be heated to 250° C., for purposes such as drying, without causing any modification in the coal substance. A general investigation of the behaviour of coal on heating is now being carried out at H.M. Fuel Research Station, and a report recently issued by H.M. Stationery Office deals with the results of experiments to determine the temperatures at which products of decomposition of various types of coal are first given off when the coal is heated. It is shown that when bituminous coals are heated, oil fumes may appear at temperatures as low as 215° C. The investigations are continuing and further reports will be issued in due course.

Utilisation of Anthracite Wastes.

A series of tests made in America, consisting of 30, 50, and 70 per cent. run-of-mine coking coal mixed with anthracite culm, showed that the pulverised bituminous coal alone produced better results, except the mixture of 30 per cent. culm with 70 per cent. bituminous, which was equal to that of the bituminous coal alone.

Stowage Space of Coal.

The stowage space occupied by coal is 40 to 42 cubic feet for one ton of Welsh steam coal, 45 cubic feet for one ton of North country coal, and 45 to 50 cubic feet per ton of Scotch coal.

EVAPORATIVE POWER OF FUELS.

The heat required to evaporate one pound of water at boiling point is 967 B.Th.U.

To raise water from 100° F. to boiling point and evaporate into steam at 212° F., 1,078 B.Th.U. per pound of water are required.

By dividing the calorific power (in B.Th.U.) of a fuel by 1,078 we obtain the *theoretical* quantity of water which it will raise from a feed-water temperature of 100° F. and evaporate at 212° F.

In practice a good boiler develops a thermal efficiency of about 70 per cent., and the actual evaporation obtained is therefore about 70 per cent. of the theoretical figure.

Evaporative Power of Coal.

Coal.	Calorific value. B.Th.U.	Evaporative power from 100° F. (37·7° C.) to Saturated Steam at 212° F. (100° C.).	
		Theory.	Practice. (70 % efficiency.)
Welsh anthracite . .	15,000 to 15,500	13·9–14·4 lbs.	9·7–10·1 lbs.
Scotch anthracite . .	14,500 to 15,000	13·45–13·9 ,,	9·4–9·7 ,,
Welsh navigation coal .	14,000 to 15,000	13·00–13·9 ,,	9·1–9·7 ,,
Average British steam coal	12,000 to 13,500	11·1–12·5 ,,	7·8–8·75 ,,

For every 10° superheat, 0·0055 is to be added to the above factors.

Coke and Coking.

(Contributed by A. H. Middleton and C. Bride, M.A.(Oxon.), B.Sc.(Lond.), A.I.C.)

At the present time nearly all metallurgical coke is made in by-product ovens, where the chief product is still coke, but where other valuable products are recovered. These are: (1) ammonia, marketed mainly as sulphate of ammonia for use as a fertiliser; (2) tar, which is distilled or refined at the coke works, or sold to tar distillers working privately or on a co-operative basis; (3) benzole and its homologues, which either alone or mixed with petrol is sold as motor fuel. The greater proportion of the benzole produced is sold as 'National Benzole Mixture'; (4) (*a*) coke-oven gas, which is essentially the same gas as that produced from gasworks' retorts; or (*b*) waste heat, which serves for steam generation. The type of oven used determines whether gas or waste heat is the by-product produced.

The largest waste which occurs in almost all coke works is in the sensible heat of the coke when discharged from the ovens, and from which it is possible to recover heat equivalent to 0·4 lb. of steam per lb. of coke. The extra plant necessary for the recovery of this heat is costly and not likely to be generally employed unless it can be simplified and cheapened. Sometimes, owing to the unfavourable situation of a coking plant, the whole of the surplus gas cannot be disposed of with advantage.

In 1929, 13,421,998 tons of coke were made, yielding per ton of coal carbonised (according to circumstances) from 12 to 16 cwts. of coke; 20 to 26 lbs. (and occasionally up to 36 lbs.) of sulphate of ammonia; 2 to 3½ gals. of 65 per cent. crude benzole; 85 to 110 lbs. of tar; 10,000 to 13,000 cub. ft. of gas, a large proportion of which is available for external use either as gas or as its equivalent in waste heat.

Coking Coals.

In contrast to gasworks practice, great attention is paid to the condition and properties of the coal used. Coking coals are bituminous in type and pass when heated through a plastic stage between 250° and 450° C., and must possess sufficient coking power to leave a hard and compact residue on further heating.

Usually more than 8 per cent. of oxygen on an ash- and moisture-free basis denotes insufficient coking power. Oxidation or heating destroys coking power, and thus storage of coal, by encouraging this action, often tends to depreciate coking value. The extent of depreciation varies greatly with different classes of coking coals, some such as certain Derbyshire coals becoming practically non-coking after only two or three days in the coke-ovens' service bunkers, whereas certain types of Durham coal have been kept in stock for five or six years without appreciable loss of coking power. Other properties which distinguish coals most suitable for coking are:—

(*a*) Low content of ash and sulphur.
(*b*) Volatile matter between 24 and 29 per cent., since high volatile matter causes the formation of a 'spongy' coke unless special carbonising conditions are adopted.
(*c*) Negligible amount of alkalies, as these have an injurious effect on oven linings.
(*d*) Less than 4 per cent. of moisture as extra heat above that required for carbonising must be applied to evaporate moisture from the ovens. Thus carbonisation is retarded and the steam produced throws extra work on the gas cooling plant, as it has to be subsequently condensed.

In most coke works the coal is crushed more or less finely before being charged into the ovens and only in a few cases are run-of-mine coking smalls used directly. The effect of crushing is to disseminate shale impurities through the charge, so that their effect as sources of cracks in the coke is reduced. The average size and strength of the coke made is increased, with a corresponding reduction in the production of small coke and ballast. Crushing, however, decreases the packing density of the charge, and so reduces oven capacity. A density variation of from 45 lbs. to 52 lbs. per cub. ft. of coal is typical of varying the degree of crushing within the limits possible in the average coke works crushing plant.

Charging the coal in a loose condition through charge-holes in the oven tops is the usual method of loading. The once common practice of using stamped charges of finely ground moist coal in the form of a solid cake is now confined to a few isolated cases where an exceptionally feebly coking or highly volatile coal is used. Under ordinary conditions this method has nothing to recommend it.

Cleaning processes are used in many coke works to reduce ash and sulphur before crushing the coal. Wet washing plants are common, but require large drainage bunkers to reduce the water taken up by the coal to workable amount; they also necessitate screening of the coal at some part of the process to secure efficient washing. In recent years dry cleaning plants have come into use. In these, coal is separated from its impurities by passing it over oscillating tables through which a strong current of air is blown. This method eliminates drainage bunkers and desiccates the coal.

Ovens.

'Beehive' ovens, formerly largely used, are now almost superseded by the 'By-Product' type; in the latter type two systems of oven heating are in use:—

(*a*) The waste-heat system, in which upwards of 80 per cent. of the total gas evolved is burnt in the wall flues with air at atmospheric temperature, or at the most only slightly preheated by

passage under the hot ovens to the flues. Burnt gases leave the flues at a temperature of about 1100° C., and are used principally for steam-raising, and as in beehive practice, up to 1 lb. of steam is obtained per lb. of coal carbonised. This type of oven is simple in construction and operation.

(*b*) The regenerator system, in which chambers under the ovens, filled with chequer brickwork, as in Siemen's open-hearth steel furnaces, are employed to transfer heat from the burnt gas leaving the flues to air entering them. In this way the waste gas is cooled to 250° C. before it leaves the regenerator chambers, and the air entering the flues is preheated to 900° C. approximately. Only 35 to 50 per cent. of the total gas is required for heating the ovens, the remainder being surplus and available for other uses. The thermal efficiency of the two systems is about the same.

The majority of by-product ovens in use to-day are of pre-war construction and have an average length of 35 ft., a width of 20 ins. to 21 ins., and a height varying from 6 ft. to 7½ ft. Their capacity varies from 6 to 9 tons of coal. Working temperatures of the flues are from 1100° to 1200° C., being limited by the fusion point of the semi-silica (75–85 per cent. SiO_2) refractories used for oven linings and flues. On dry coal a carbonising time of 26 to 32 hours is attained, which gives a daily throughput of 5½ to 7½ tons per oven. Heating flues are arranged either horizontally or vertically in the oven walls. In waste-heat batteries combustion occurs continuously in each flue, and the main difference between the various constructions is in the spacing of the flues to obtain uniform heating, and in the methods adopted to regulate air and gas to each flue. In regenerative ovens, the periodic reversal of gas and air flow through the regenerator chambers causes a periodic change in the conditions in the combustion flues. In ovens with horizontal flues this consists of a reversal of the path of travel of the burning gases in the flues with a change in the points at which air is admitted, but necessitates no alteration in the points at which gas is admitted. In vertical flue ovens, which predominate in number, only half the flues are used at a time for combustion, the other half being used for carrying away the burnt gas. Flue designs in existing ovens vary in the arrangement used to eliminate uneven heating from this cause. They differ mainly in the way in which flues are grouped and cross connected to form separate reversal units.

Quenching coke by water in front of the ovens is usual, either on an inclined bench running the whole length of the battery or in some form of car movable from oven to oven. Approximately 1 ton of water is used per ton of coke quenched, and the coke is very slowly pushed from the ovens to allow sufficient time for quenching. Success of quenching depends largely on the skill of the workmen.

A typical modern post-war battery consists of 40 to 60 ovens, each 43 to 44 ft. long, 13 to 14 ft. high, and 16 to 18 ins. wide, heated regeneratively so as to have a maximum yield of surplus gas. In order to withstand the higher flue temperatures used (1200°–1400° C.), flues and oven linings are constructed in 95 per cent. silica material which will withstand temperatures up to 1650° C. without distortion. In some types the heating flues are built vertically and arranged on the 'hairpin' system, in which reversal of air and gas takes place between pairs of adjacent flues. Alternate flues are fed with air and gas, so that combustion takes place up one flue and down the next, at the bottom of which burnt gases are withdrawn. Another method of flue arrangement is by cross connection of groups of flues in opposite walls of the ovens through flues in the oven tops, so that reversal of combustion takes place from one side of each oven to the other. Regenerator chambers filled with firebrick chequerwork, built under each oven, are subdivided, so that each set of flues has its own regenerator system. The use of silica refractories increases very considerably the safety factor when working at high temperatures, with the additional advantage of better thermal conductivity through the oven walls. They are also much more resistant to the action of alkalies than other coke-oven refractories.

Recently erected ovens have a capacity of 14 to 17 tons of coal, which with a carbonising time of 16 hours gives a daily throughput of about 20 to 26 tons per oven.

Subsidiary, but necessary improvements incorporated in post-war ovens are :—

(1) High-speed pushing machines by which a 44-ft. oven is discharged in 30 secs., or approximately in one-tenth of the time required to push the shorter pre-war ovens.

(2) Electrically driven coal cars, in which the volume of the coal charged can be accurately gauged.

(3) Self-sealing and plug doors, which are removed and replaced mechanically and which require at most an extremely small amount of luting to render them gas-tight.

(4) Remote coke quenching, by which the coke pushed from an oven at 900° to 1000° C. is discharged into a steel car which carries it rapidly from the front of the battery to a water-tower some distance from the ovens, where a measured volume of water is sprayed on to it. After draining the coke is taken to a coke bench and discharged to steam and cool off before being taken by high-speed rubber belts to the screening plant. This system of quenching makes work in front of the oven tolerable under high-speed conditions and prevents damage to the hot oven walls by contact with steam and water, such as is possible from quenching in front of the ovens. Rather more water is required than with other systems (from 1¾ to 2 tons per ton of coke), but quenching is more uniform and coke moisture more constant.

Narrow ovens are better suited for the treatment of inferior coking coals. In extreme cases of feebly coking or highly volatile coals, 12-in. to 14-in. ovens are used, carbonising in 12 hours and producing a satisfactory coke, but with the average range of coking coals a 16-in. or 18-in. oven, carbonising in 18 hours, seems to give most satisfactory results. The amount of

heat supplied to the ovens *via* the combustion flues is usually from 850 to 1100 B.Th.U.'s per lb. of coal carbonised, but varies with the speed and temperature of carbonising and with the efficiency of the system. Under average conditions 60 to 65 per cent. of surplus gas is produced. For maximum yield of gas, compound regenerative ovens are built in which the flues may be heated by combustion of preheated producer, water, or blast-furnace gas, the whole of the coal-gas made being available for other use.

Unless the coke-oven gas can be sold for at least 7½*d.* per 1,000 cub. ft., it does not pay to heat the ovens with producer-gas and liberate for other uses a greater quantity of coke-oven gas.

Coke.

This varies in characteristics according to the coal used and carbonising procedure. Size is dependent on the thickness of the charge carbonised. In beehive practice the largest pieces are 30 ins. to 36 ins. long, approximating to the depth of coal in the ovens. With by-product coke the largest pieces are slightly less than half the oven width in length. Typical characteristics are :—

	True Sp. Gr.	Apparent Sp. Gr.	True Porosity. %	Apparent Porosity. %
Beehive coke	1·88–1·98	0·87–0·90	52–56	45–50
By-product coke	1·90–2·00	0·95–1·10	42–52	38–45

Crushing strength varies from 1,000 to 3,500 lbs. per sq. in., and volatile matter from 0·5 to 3 or 4 per cent. The volatile matter is greatest in high-speed practice where no over-coking takes place. Most of the coke made is used in metallurgical furnaces, and from 85 to 95 per cent. of the product of a coke works is in pieces large enough for such purposes, the remainder being in the form of coke nuts down to ⅝ in. size and coke ballast below this size.

For smelting use a hard dense coke is required strong enough to resist the severe crushing and abrasion it receives Beehive coke is still preferred by some foundry managers on account of its size and bulkiness, although equally good results are obtained from properly sized by-product coke. In British blast-furnaces the greater part of the coke used is the over-coked variety made in pre-war by-product plants, and screened to eliminate sizes below 2 ins. or 3 ins., but American blast-furnacemen appear to obtain greater efficiency by using the smaller but evenly sized and uniform coke which is produced by high-speed ovens.

Correct sizing and efficient screening is established as a means of obtaining greater efficiency in its use as a fuel. Structure and porosity have a definite bearing on the combustibility, while volatile content governs the ignition temperature, so that there are great possibilities in adapting oven conditions for various types of coke production. Screened coke nuts are to some extent used in domestic applications. A small uniform coke with low ash, up to 6 per cent. volatile matter and an open but strong structure is desirable, so that satisfactory ignition and combustion results under the feeble draught conditions of open ranges and fire grates. A new and increasing use of coke nuts is in the synthetic chemical industry where, as producer fuel, they supply the hydrogen and carbon monoxide required for ammonia and methanol syntheses. Other uses are in lime-kilns and for steam-raising. Coke ballast under ⅝ in. size is usually consumed under boilers by means of mechanical stokers, chiefly to supply steam at the coke works and adjacent plants.

4½ to 5 lbs. of steam can be raised per lb. of coke ballast.

By-Product Recovery.

This follows the main lines of gasworks recovery, with the following exceptions. Individual ascension pipes are not liquid sealed in the collecting main, but are shut off by means of valves. The gas-collecting main is kept clear by a flush of tar or ammoniacal liquor. In some cases, cold liquor is sprayed into the collecting main at the junction with each ascension pipe and gives additional gas cooling.

In coke-oven practice ammonia recovery has reached a higher stage of efficiency than in gas-works practice, and benzole is always recovered. Actual yields depend on the coal, and also on the extent of degradation of volatile products in the ovens caused by contact with the hot walls and coke. Ovens are designed with a view to keeping the tops reasonably cool and to allow the rapid removal of gaseous products in order to reduce the time of contact with heated surfaces.

	Average Gas Temperatures.
Gas leaving ovens	600°–700° C.
„ entering collecting main	300°–400° C.
„ leaving collecting main	150°–200° C.
„ entering by-product coolers	70°– 80° C.

Tar.

This is removed partly by condensation from the gas in various parts of the coolers, and is completely removed by passage through tar extractors before the ammonia recovery plant. Three types of extractors are in common use—(*a*) the impact type, in which tar mist is precipitated by contact with metal screens ; (*b*) the cyclone type, in which gas is constrained to follow a rapid spiral

course, and tar mist is separated centrifugally ; (*c*) the direct type, in which tar is precipitated by means of high-pressure ammoniacal liquor sprays.

Composition of Crude Coke-Oven Tar.

Ammoniacal liquor	2·5 – 5·0%	Free carbon in pitch, 6%–15%.
Naphthas	Trace – 0·5%	
Light oils (to 180° C.)	1·0 – 2·0%	Tar acids in carbolic oils, 1%–2·5%.
Carbolic oils (180°–230° C.)	6·0 – 8·0%	Naphthalene in carbolic and creosote oils, 5%–10%.
Creosote oils (230°–270° C.)	8·0 –11·0%	
Anthracene oils (270°–360° C.)	16·0 –22·0%	
Pitch	50·0 –63·0%	
Sp. Gr. at 60° F.	1·150– 1·205	

Ammonia Recovery.

Three systems are used :—

1. *Indirect System.*—Gas is cooled to atmospheric temperatures and sprayed with water. The resulting liquor mixed with liquor condensates from the gas-coolers has a concentration of about 1 per cent. ammonia, of which only 0·1 to 0·2 per cent. is fixed ammonia. The liquor is distilled with live steam and a little milk of lime in a continuous still and passed through a saturator containing hot mother liquor and 5–10 per cent. free sulphuric acid. Ammonium sulphate is formed and salts out, being removed by steam or air blowers at intervals. Draining and centrifuging reduces the moisture in the salt to about 1½ per cent. and the acidity to 0·3–0·5 per cent. Complete drying and neutralisation of the salt is performed in a separate plant. The indirect system is confined to early coke works. It is flexible and can be readily turned over to the manufacture of concentrated ammonia liquor should the sulphate market be unprofitable, but results in the formation of about 9,000 gals. of noxious waste liquor per ton of sulphate, which is often disposed of with difficulty. The steam consumption is about 9 lbs. per lb. of sulphate.

2. *Direct System.*—Gas is cooled to a temperature of 75°–80° C., that is, just above its dew-point, to avoid condensation of ammoniacal liquor. After tar extraction the whole of the gas is passed through a closed saturator for ammonia recovery. Heat of reaction between the ammonia and the acid causes so much evaporation in the saturator that, theoretically, the process uses no steam and makes no waste effluent. Actually a small amount of fixed liquor is condensed from the gas and must be distilled into the saturator, or else evaporated to give crude ammonium chloride. This system followed the indirect system, but it is rather difficult to work for complete tar extraction and elimination of liquor condensation, and is not now built into new plants.

3. *Semi-direct System.*—This embodies most of the advantages of previous systems, and is generally used in modern practice. Gas is cooled to 40°–50° C. with complete tar separation and partial liquor condensation. The remainder of the ammonia is recovered by passage of the gas through the saturator into which the previously condensed liquor is also distilled. Approximately 3–3½ lbs. of steam are required per lb. of sulphate, and the amount of waste liquor formed is only one-quarter of that of the indirect method.

Benzole Recovery.

Oil scrubbing of the gas at 20° C. is used to remove hydrocarbons of the benzene series, the benzolated oil being stripped by live steam to give a crude benzole before being cooled and returned to the scrubbers. The crude benzole, of which approximately 65 per cent. distils at 120° C., is redistilled to eliminate any wash oil, washed with concentrated sulphuric acid, neutralised and then fractionated into various products, motor benzole, pure benzole, toluole, xylene, naphtha, and so on, as required. Typical analyses of oils used for scrubbing, taken from the 1928 Report of the Research Committee of The National Benzole Association, are :—

Oil.	Absorption Capacity.	Viscosity (20° C. Redwood).	Sp. Gr. 20° C.	Drop Point.	Distillation Range.
Light creosote	4·8–4·5	34·6	1·013	200° C.	95% at 300° C.
Medium creosote	4·5–4·0	37·6	1·031	200° C.	„ „ 350° C.
Washed blast-furnace creosote	4·0	39·8	0·935	210° C.	„ „ 340° C.
Green oil (anthracene)	3·75	69·9	1·088	250° C.	„ „ 385° C.
Gas oil, American petroleum	3·0–2·8	40·0	0·864	210° C.	„ „ 363° C.

(The absorption capacity is the per cent. volume concentration of benzole in an oil solution in equilibrium with coal-gas containing 2·4 gals. of benzole per 12,000 cub. ft.)

A circulation of 80–120 gals. of oil through the scrubbers is required per ton of coal carbonised. Creosote oils are most generally used on account of their high absorption powers, but thicken quickly in use and lose this desirable property. They are also rather volatile, so that stripping

results in the loss of up to 6 gals. of oil per 100 gals. of benzole made. Blast-furnace creosote is used in Scotland and retains its fluidity well, but tends to give troublesome sludges in the oil coolers and heat exchangers. Gas oil, though of lower initial absorption power than creosote, is very satisfactory as it retains its fluidity, and on account of its low volatility loses little in stripping. Its low specific gravity makes it easily separable from water in the stripping stills and avoids troublesome emulsions. However, its paraffinoid nature causes contamination of the benzole. This is of little consequence in the manufacture of motor spirit, but it is undesirable when the products are to be used in chemical processes. Other methods tried for benzole recovery are absorption in absorbent charcoal or silica gel, but these have not yet proved commercially successful.

Coke-Oven Gas.

This is practically identical with coal-gas from gasworks' retorts, a typical analysis after stripping of tar and benzole being :—

CO_2. %	CnHm. %	O_2. %	CO. %	CH_2. %	H_2. %	N_2. %	Gross Calorific Value. (60° F. and 30 ins. pressure.)
1·1	2·4	Nil	5·2	26·2	58·4	6·2	524 B.Th.U.'s per cu. ft.

A surplus of roughly 60,000 to 65,000 million cu. ft. is made annually. Of this a small but increasing proportion is sold to gasworks for domestic supply, the amount in 1929 being 10,948,241,000 cu. ft.

In favourable circumstances the gas is used mixed with producer or blast-furnace gas in steel melting and reheating furnaces, but the largest use at present is for steam-raising and generation of electricity.

Low-Temperature Distillation of Coal.

This consists in the gradual heating of bituminous coal to a comparatively low maximum temperature (500° to 600° C.). The retorting vessels employed are designed in such a way as to ensure the rapid removal of the volatile products. By such a process a low yield of very rich gas is obtained, and a high yield of thin tar. The tar is richer in low boiling-point fractions than the tars produced by the gasworks or coke-oven plants. The residual coke contains approximately 10 per cent. of volatile matter, and may be marketed for use in domestic fires, for which purpose it is claimed to be easily ignitable, and at the same time to give off the major portion of its heat as radiant heat, and to burn without generating smoke. Until recently the process has not met with success, largely on account of mechanical difficulties in the operation of the retorts; these difficulties, however, appear to be now overcome by 'Low-temperature Carbonisation, Ltd.,' in their production of 'Coalite.'

Coalite.

The following results were obtained in a test by the Government Fuel Research Board * :

The coal used in the test was a good average Yorkshire coal, and one which has been frequently tested in every way at the Fuel Research Station.

The yield of products per ton of coal carbonised was as follows :—

'Coalite'	13·92 cwts.
Gas	5,620 cu. ft., or 39·6 therms, after stripping of motor spirit. (See †.)
'Coalite' crude oil	18·62 gals.
Ammonia liquor	26·00 gals.
Crude motor spirit from scrubbing the gas	1·78 gals.
Equivalent ammonium sulphate	13·55 lbs.

The 'Coalite' produced was of a very suitable size (1 to 3-in. pieces), containing only 4·6 per cent. of breeze, and was quite suitable to withstand the rough handling natural to rail or road transport. Analysis of this fuel showed a slightly lower percentage of volatile matter than usual, but when burnt in a household grate it readily ignited and gave a good hot fire.

The yield of crude oil was high, showing 68 per cent. of that obtained in the standard assay apparatus developed by the Fuel Research Board, and upon examination proved to be a normal low-temperature coal oil.

The yield of gas was greater than that anticipated from this particular coal, and averaged

$$\left(\frac{39{\cdot}6 \times 100{,}000}{5{,}620}\right)^{\dagger} = 705 \text{ B.Th.U. per cubic foot after being stripped of its crude motor spirit.}$$

The motor spirit obtained by scrubbing the gas was 1·78 gals per ton, but as the crude oil also contained 1·09 gals., the total yield of this product amounted to 2·87 gals. per ton; a most satisfactory result.

The ammonia was also higher than expected, and, when converted into ammonium sulphate, yielded 13·55 lbs.

* Report published by H.M. Stationery Office, Kingsway, London, W.C. 2, price 9*d*.

YIELD FROM ONE TON OF AVERAGE COAL (say 25-30 per cent. volatile matter).

	Low-temperature Carbonisation.	High-temperature Carbonisation.	
		Gasworks.	Coke Ovens.
Temperature of carbonisation	1,000° F.	About 1,800° F.	About 1,800° F.
Gas	6,000-6,500 cubic feet of rich gas, 700-750 B.Th.U. per cubic foot.	12,000 cubic feet of medium quality (town's) gas, 550 B.Th.U. per cubic foot.	11,500 cubic feet of poor quality coke-oven gas, 450 B.Th.U. per cubic foot.
Liquid	20 gallons coalite oil (fractionated to, say, 3 galls. motor spirit, 8-9 galls. Diesel or fuel oil, and 8-9 galls. lubricating oil).	10 gallons coal tar. (Fractionated to about half-gallon motor spirit, carbolic acid, a large amount of naphthalene, fuel oil, &c.)	8 gallons coal tar.
Sulphate of ammonia (from the ammonia)	15 lbs.	25 lbs.	28 lbs.
Residue in retort	14 cwt. of smokeless fuel coalite containing about 9-10 per cent. volatile matter.	13½ cwt. of soft coke, containing about 1 per cent. volatile matter.	14-14½ cwt. of hard coke, containing less than ½ per cent. volatile matter.

(*David Brownlie, A.I.Mech.E.*)

From one ton (American, 2,000 lbs.) of bituminous coal, the Colorado Fuel and Iron Company of Denver, U.S.A., obtains in actual practice the following products, viz.:

Coke	1,400 lbs.	Pure benzol	1¼ gals.
Coke breeze	60 lbs.	Toluol	¼ gal.
Gas	7,500 cu. ft.	Zylol	2/10 gal.
Ammonium sulphate	25 lbs.	Pitch	5 lbs.
Tar	10 gals.	Naphthalene	½ lb.
Light oil	3½ gals.	Creosote	1 qt.
Motor benzol	2¼ gals.	Paint	1 qt.

[Annual capacity of ovens, 540,000 tons (American) coke.]

Coke as a Boiler Fuel.

(*Contributed by E. W. L. Nicol, M.I.Mar.E., A.M.I.E.E.*)

With a view to cheapening the cost of steam raising by improving steam-boiler efficiency, and to eliminate the emission of visible smoke, gas coke is now largely used as fuel in lieu of crude coal. In hand-fired boilers, coke exclusively is used under ordinary natural draught conditions. With a draught of 0·25 in. W.G. over the fire, the average rate of combustion is 12 lbs. to 14 lbs. of suitably graded coke per sq. ft. of grate area per hour. Some form of impelled draught is necessary if this rate is insufficient. The forced draught apparatus usually employed is some form of steam-jet blower applied to the enclosed ashpit of the boiler, and used to maintain a 'balanced' draught over the fire (fig. 8). The steam consumption of the jets should not exceed 3 per cent. of the total steam generated when burning graded coke at a rate of 20 lbs. per grate-foot-hour. For hand-fired boilers the minimum allowance of grate area should be 1 sq. ft. per 22 to 25 lbs. of coke consumed per hour. In practice it is found that this rate can be exceeded only at the expense of efficiency.

Unlike coal, the combustion of coke is practically completed on the grate, a supply of secondary air over the fire being unnecessary. This tends to localise the heating effect to the boiler furnace area. The introduction of a circulator, *b*, tends to neutralise this effect and set up active circulation of the water in the boiler. The operation of cleaning fires, and the losses incidental thereto, due to inrush of cold air and consequent loss of steam pressure, are minimised by the use of the Gallagher Crompton baffle bridge *a*, also shown in the figure. During the cleaning operation the live fuel is heaped up on the baffle bridge.

In mechanically-stoked boilers fitted with both forced and induced draught, average rates of combustion exceeding 40 lbs. of graded coke per grate-foot-hour are maintained. Types of

mechanical stokers specially adapted for use with coke or coke breeze include the 'Underfeed travelling grate' and the 'Babcock balanced draught chain grate.' Existing chain grate

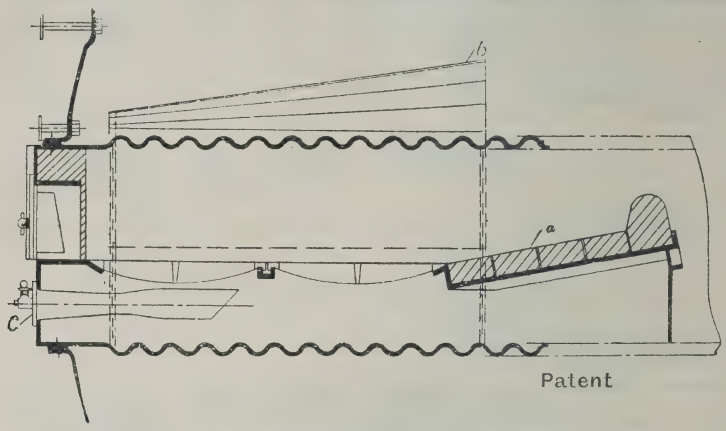

FIG. 8.—*a*, Gallagher Crompton baffle bridge; *b*, Ross Schofield circulator; *c*, Steam Jet forced draught.

mechanical stokers have largely been adapted to use admixtures of coke or breeze up to 75 per cent. at full normal rates under ordinary natural draught conditions, by means of the patent 'Sandwich' system (fig. 9), which is designed to feed, from a double hopper, well-defined layers

of coal slack and suitably graded coke of any desired thickness, the coal being uppermost. Using this system at the L.C.C. Greenwich Power Station, the General Manager gives the following data relating to the year 1919–1920 :—

Tons of fuel burnt	176,400	Average percentage of ash	10·0
Average price for coal	41*s.* 11·3*d.*	,, calorific value of breeze	9,000 B.Th.U.
,, calorific value	10,780 B.Th.U.	,, percentage of ash	18 to 20
,, percentage of ash	14·59	Coke and breeze consumed	25,000 tons
,, calorific value of coke	11,500 B.Th.U.		

With coal at 42*s.* per ton, and coke breeze at 22*s.* 6*d.* per ton, the fuel cost per 1,000 gallons evaporated was 19*s.* 6*d.* with equal quantities of each fuel, as against 23*s.* 2*d.* with Scotch nuts alone, a saving of about 16 per cent. The official report says: 'Apart from the saving in money, low grade classes of fuel can be dealt with on the Sandwich system at a much higher efficiency than would be the case if burnt separately. The results have been extremely satisfactory and a saving of about £8,000 a year can be effected.' Average evaporation obtained with 50 per cent. mixture of coal and breeze, 7·25 lbs.; with coal and coke 9 lbs. from and at 212° Fahr. Gas coke is also used extensively as fuel for road transport vehicles of both the under-type ('Sentinel,' 'Leyland,' and 'Atkinson') and the over-type wagon ('Foden' and 'Garrett,' etc.). The following table shows the fuel cost of evaporation from and at 212° Fahr. with common solid fuels at varying prices:—

APPROXIMATE FUEL COST OF EVAPORATION FROM AND AT 212° FAHR.

Anthracite.

(*Contributed by A. Leonard Summers, Author of 'The Anthracite Industry,' &c.*)

The bulk of the anthracite produced in Great Britain is mined in the western portion of the South Wales coalfield, the best qualities in Carmarthenshire and Glamorganshire. It consists virtually of carbon—as much as 94 per cent. in the better qualities—with only a small proportion of the constituents of bitumen. It is jet-black, with a metallic lustre, very hard, slow burning, absolutely smokeless, gives intense heat, and burns with a bright red glow. These qualities fit it for many purposes. It is used largely for smelting; in the burning of lime and brick; for the generation of steam; and in the United States and on the Continent of Europe extensively for domestic heating and cooking. For malting and horticultural purposes, owing to its purity and

freedom from arsenic, etc., it is in immense demand; while in Norway, Sweden, and Italy, Welsh anthracite is used for making carbide of calcium.

The American coalfield (Pennsylvania) produces the largest amount of anthracite—about 100 million tons per annum—the Welsh output being only about 5,000,000 tons a year at present, though capable of a much greater yield, the major part of the field being still untouched.

One ton of anthracite used in a pressure or suction-gas plant will give power equal to 10 tons of the best steam coal used under boilers. Some typical figures for a suction-gas plant using anthracite were produced by a test carried out at the Metropolitan Reservoirs, Chingford, under the direction of their chief engineer. A guarantee had been given that the consumption would not exceed 1·1 lb. of anthracite per actual b.h.p. hour, and in the report it was stated that the average fuel consumption for the four main pumps was 0·913 lb. per b.h.p. hour, whilst the small pump gave the figure of 0·8 lb. of anthracite. The general average for the whole of the pumps was 0·904 lb. of anthracite per actual b.h.p. hour, and the guarantee lift of the pumps was exceeded by almost 20 per cent. The producer tests showed that 1 lb. of anthracite yields 82·1 cu. ft. of gas at standard temperature and pressure, the net calorific value being 146·3 B.Th.U. per cu. ft., giving a yield of 12,011 B.Th.U. per lb. of anthracite. The calorific value of the anthracite supplied was 14,600 B.Th.U. The fuel used under the boilers which supplied steam for the producer was taken into account.

A ton of Welsh anthracite will produce from 170,000 to 220,000 cu. ft. of gas for power purposes. The following is a typical analysis of good Welsh anthracite:

Carbon	92·73	per cent.
Hydrogen	3·37	,,
Oxygen and nitrogen	2·69	,,
Sulphur	0·45	,,
Ash	0·76	,,
	100·00	,,

In furnace installations where crude gas can be used bituminous fuels are generally used, as the gas is supplied direct to the furnace along with the tar and soot. In small furnaces, where small burners are used, or where necessary to convey gas a long distance, it is generally not possible to use crude gas, and anthracite is more convenient than bituminous coal. The average consumption in a pressure gas-producer is about 13 lbs. of anthracite per 1,000 cu. ft. of gas, and at normal prices this would work out between 2*d.* and 3*d.* per 1,000 cu. ft. of gas, and the overall consumption for producer and engine should be about 1 lb. of anthracite per b.h.p. hour.

The principal anthracite collieries are equipped with electrical and other machinery, the preparation of the coal being very elaborate—breaking, screening, washing, etc. A revolving breaker deals with the large coal; this coal travels to the various 'screens' for sizing. These sizing screens are placed one above another at an angle and worked on a shaking principle. Thus the coal is kept steadily on the move to obviate congestion. The large collieries break and screen their product into at least eleven different sizes. The screens are perforated with round holes, through or over which the coal passes in sizes from 2½ ins. by 4 ins. (the largest cobbles) to ¼ in. by ¼ in. ('grains'). Similar moving belts, but not perforated, convey the screened coal to the pickers, who remove by hand whatever shale it may contain. Impurities are picked from the cobbles and large coal prior to the coal going to the breaker. These picking belts also load the coal into the railway trucks, but only convey the larger sizes, viz. machine-made cobbles and machine-made 'French' nuts. Sizes below the French nut cannot be conveniently picked and sorted by hand, and are therefore transferred to a washer. The 'washery' belts work with the same shaking movement, carrying the small coals, such as stove nuts, peas, beans, pea-nuts, etc., through tanks of water to remove the small particles of stone. To ensure the maintenance of a maximum standard of quality, a coal examiner usually twice daily takes and tests samples of coal from the screens and washery, and the percentage of waste material detected rarely exceeds 1 per cent.

What is known in the trade as 'rubbly culm' is the rough small coal which passes between longitudinal bars 1¼ in. apart. It is used principally for lime-burning and steam-raising.

The 'duff,' or very fine, small anthracite, is used in the manufacture of patent fuel and cement making.

In regard to ordinary boiler furnace utilisation of anthracite not much advance has been made, due to the narrow conception of boiler-house practice, coupled with the question of availability. When anthracite is used for this purpose it must not be disturbed, and should be stoked with a

thin bed, very evenly, and if this minimum attention is given an evaporation of from 8–10 lbs. of water per hour can be easily maintained. Tests made in London in which anthracite peas were used showed an evaporation of 12·2 lbs. of water per lb. of coal in one test, and 11·3 lbs. in another. Sometimes the draught or other conditions render the use of anthracite alone impossible, but its blending with other fuels gives very satisfactory results. Where mechanical stoking is used a larger proportion of anthracite—say 2 to 1—can be used, as distinct from equal quantities where hand-firing is adopted.

An important aspect of anthracite has been the recent utilisation of the large accumulations of duff and washery refuse. Hitherto, anthracite dust could not be satisfactorily burnt on standard furnaces, and considering that this fuel has a calorific value of 12,000 to 13,000, with over 80 per cent. fixed carbon, and about 10 to 12 per cent. of ash, it was obvious that valuable material was lying dormant in the dumps. Therefore a new furnace was introduced, with air spaces subdivided into a large number of small holes, and other modifications. The following results of tests at a Welsh colliery show the great increase made in evaporation :

Test No.	Class of Fuel.	Evaporation in Lbs. Steam per Hour.	Remarks.
1	Duff, good quality . .	3,500	Jet pressure 60 lbs.
2	'Grains' . . .	4,400	,, ,, 30 ,,
3	Duff	3 125	,, ,, 45 ,,
4	Duff	3,000	,, ,, 25–30 ,,
5	'Grains' . . .	5,750	,, ,, 30 ,,
6	Duff	4,250	,, ,, 40–50 ,,
7	Duff	4,875	,, ,, 55–85 ,,

The first four tests were carried out on the old type, and tests 5, 6, and 7 on the newly designed bar-furnace.

Burnt under proper conditions, there is no better coal for steam-raising than Welsh anthracite. At one works using English coal it was necessary to employ two Lancashire boilers 30 ft. by 7 ft. 6 in., but after a patent furnace was fitted and anthracite coal introduced, *one* of these boilers was sufficient to do the work previously done by the two boilers.

Below are the standard sizes of Welsh anthracite :—

Cobbles	$2\frac{1}{2}'' \times 4''$	'Beans'	$\frac{1}{2}'' \times \frac{3}{4}''$
'French' Nuts . .	$1\frac{3}{4}'' \times 2\frac{1}{2}''$	'Peas'	$\frac{1}{4}'' \times \frac{3}{4}''$
Stove nuts . . .	$1'' \times 1\frac{3}{4}''$	'Grains'	$\frac{3}{8}'' \times \frac{1}{4}''$
'Pea-nuts' . . .	$\frac{1}{2}'' \times 1\frac{1}{4}''$		

Lignite.

The composition of lignite, and its properties, lie between those of wood and coal.

Lignite occurs in most European countries and is abundantly found in the Colonies, but does not occur in quantities in the British Isles. Lignites vary widely in composition, but generally between the following limits : carbon 55 to 80 per cent., hydrogen 5 to 7 per cent., oxygen 10 to 35 per cent. (in the dry state). The calorific value is from 9,000 to 13,000 B.Th.U. on dry sample. The high ash and water contents of lignite frequently make it unsuitable for direct combustion, but good grades may be used for steam-raising. Lignite is frequently subjected to destructive distillation, whereby valuable liquid products are obtained. It may also be used for the manufacture of fuel briquettes, or be utilised in gas producers.

Peat.

Large deposits of peat occur within the British Isles, but little use has been made of them hitherto, the high water content (80 to 96 per cent. when in bog, and 30 to 60 per cent. after air drying) being a great drawback to their utilisation. Peat is suitable for use in gas producers and is sometimes carbonised, when peat charcoal is the main fuel product.

Anderson and Dillner (*Jour. Soc. Chem. Ind.*, 1902, 459) give the following calorific powers for peat (in the dry state) :—

Average from bog	8,100 to 11,000* B.Th.U.
Reed grass peat	7,450 to 9,820 „
Mud peat	7,825 to 8,200 „

Wood.

When freshly cut, wood contains up to 50 per cent. of water, but this can be reduced to about 20 per cent. by air drying. The composition of dry wood is about 49·5 per cent. carbon, 6 per cent. hydrogen, 44 per cent. oxygen, and ·5 per cent. ash, and the heat value is generally a little below 9,000 B.Th.U. It only finds use in countries where large forests exist and where coal is not readily obtainable.

Wood Charcoal.

Wood charcoal consists mainly of carbon and possesses a calorific value of 11,000 to 13,500 B.Th.U. (Brame). Its use as a fuel is very limited.

Briquette Fuel.

(*Contributed by Arthur Grounds, B.Sc., A.I.C., Assoc. M.I.Min.E., Consulting Chemist.*)

Briquettes can be used on hand-fired boilers, without the necessity of installing special stokers to deal with the fuel. The composition of the fuel can be varied from an anthracitic fuel, suitable for consumption in domestic grates, and giving a high degree of radiant heat, to a briquette of higher volatile matter, suitable for industrial boiler firing, and giving the long flame necessary for the heating of Lancashire, Cornish, and water-tube boilers. The shape, size, and weight of the briquettes must be suitable for the purpose for which they are to be used, and for the nature and duration of the transport and storage to which they will be subjected. Their degree of cohesion should be at least equal to that of good coal, and the loss by attrition and crumbling during ordinary handling and transport should not exceed 5 per cent. by weight. Their mean specific gravity should not be below 1·24, whilst the ash content of the dry fuel should not exceed 12 per cent., and is preferably below 10 per cent. They should not contain over 5 per cent. of moisture, nor should they absorb water, whilst they should not be affected in physical character by immersion in water over a long period. Their calorific value should be at least equal to that of good coal.

Artificial fuel is made in many sizes and shapes, from the 'boulet' of 30–40 grms. weight (1–1½ ozs.) to the large block of 28 lbs. weight. The latter block is chiefly made for export to the West Indies and Egypt, and to other tropical and sub-tropical countries, as a weight of 28 lbs. corresponds roughly to that which a native labourer or coolie can carry. Between these two sizes of fuel there are the normal ovoid, about the size of a hen's egg, weighing 70–100 grms., and the larger ovoid of 200–250 grms., which has lately been developed. These ovoids are chiefly used for domestic fuel, and are largely anthracitic, whilst for steam raising the block form is most popular, the common size being the 10-lb. block, measuring 10 ins. by 5 ins. by 4 ins. Ovoid fuel has lately been made in the 'boulet' size for use in suction gas producers, and for use with automatic stokers, in place of screened nuts. The blocks are made in various shapes, either as bricks with rounded corners, quadratic flattened cube shape, or grooved in order to facilitate their breaking up in the stokehold. They may be marked with the makers' name, or with some distinguishing mark, or may be quite plain.

Domestic ovoids may be made from anthracite and a binder alone, although this has the disadvantage that, as pitch is the binder generally used, when the fuel is placed on the fire, the pitch burns off very easily at first, and then the anthracite, being a non-caking coal, falls to powder in the fire, and the result is a dull, black-looking mass. To avoid this, these ovoids are generally made from a mixture of about 80 per cent. of anthracite duff, with 10 per cent. of a good coking coal and 10 per cent. of pitch.

When placed on the fire, the pitch at first burns off and the heat of combustion leads to the carbonisation of the bituminous coking coal, which cakes and acts as an agglutinant, binding the non-caking anthracite together, and this burns very slowly and gives out a large amount of radiant heat per unit weight. This is the cheapest form of artificial fuel, as anthracite duff is the cheapest form of raw material and forms 80 per cent. of the total weight of the fuel. The binder generally used for the process is coke-oven or gas-works pitch, the grade used being known in the trade as 'medium-soft coal-tar pitch, suitable for the manufacture of briquettes.' Blast-furnace pitch is used to a certain extent, but it is inferior to coke-oven or gas-works pitch in binding power, and contains a much higher percentage of ash, and, on carbonisation, it gives

* Exceptionally high.

a swollen, instead of a sintered coke. The ash in a good pitch should not exceed 0·5 per cent., whilst that in blast-furnace pitch varies from 5 per cent. to 25 per cent., or even more, according to the dust-catching arrangements at the blast-furnace from which it has been obtained. The volatile organic matter of the pitch is determined by heating 1 grm. of the pitch in a platinum or porcelain crucible over a bunsen flame for seven minutes, the flame being 18 cms. high, and the crucible being held on a triangle of fine wire, about 7 cms. above the mouth of the burner. The crucible is provided with a lid, and is weighed after heating for seven minutes, with subsequent cooling, the loss in weight giving the volatile matter. The ash can be determined by igniting the coke obtained as above until all the combustible matter has been burnt off. The residual coke from the volatile matter estimation should be in the form of a flat button. If the button is not flat, but conical in shape or puffed up, the pitch will not be suitable for the purpose. The twisting point is measured by immersing a bar of pitch, 2 ins. by $\frac{1}{2}$ in. cross section, in water at gradually increasing temperatures for a period of two minutes. The pitch is then withdrawn and a very slight pressure exerted with the fingers in the attempt to twist it round. If the pitch is still too hard, the water is heated again until it has risen in temperature another 5° C., and the pitch is again immersed for two minutes, and then tested to see if it will twist. When this is possible, the temperature of the water is taken, and this temperature is known as the 'twisting point.'

A suitable pitch for briquette manufacture should have a twisting point of 50–60° C. The melting point is determined by immersing a cube of pitch, of $\frac{3}{4}$-in. side, stuck on a No. 12 copper wire, bent horizontally, in a beaker of water. The water is gradually heated so that a rise in temperature of 5° C. or 9° F. per minute is obtained. When the cube of pitch softens and drops to the bottom of the beaker, the temperature is noted, and this is taken as the melting point. For a coke-oven or gas-works pitch of suitable quality, the melting point is usually about 85°–100° C.

The solubility in carbon disulphide is determined by weighing out 0·5 grm. of the pitch into a flask and adding 200 c.c. of carbon disulphide. The flask is heated on a water bath or an electric heater, under a reflux condenser, for an hour, and is then removed and cooled. The free carbon is filtered off through two filter papers, and is well washed with carbon disulphide, the washings being added to the filtrate. The carbon disulphide is then distilled off from the filtrate, which has been caught in a weighed flask, when the increase in weight of the flask gives the amount of matter soluble in carbon disulphide. This figure is a useful indication of the binding power of the pitch, as those pitches which give high solubility figures are generally found to be excellent binders. This figure should be in the region of 66–84 per cent. The difference between the percentage of matter soluble in carbon disulphide and 100 is the 'free carbon.'

Other tests are necessary for special purposes, but those cited are the usual tests adopted. A typical analysis of a suitable pitch would be: Volatile organic matter, 70·4 per cent.; coke, 29·6 per cent.; ash, 0·3 per cent.; fixed carbon, 29·3 per cent.; soluble in carbon disulphide, 75·5 per cent.; free carbon, 24·5 per cent. Twisting point, 56·5° C.; melting point, 97·0° C.

The amount of binder necessary varies with the coals being used, but, generally speaking, it increases with the hardness of the coals being briquetted. Thus, about 10–11 per cent. is necessary for hard anthracites, about 8·5–9 per cent. for steam coals, and 6·5–8·5 per cent. for bituminous coals, according to their volatile matter content. The hardness of the coal is roughly proportional to the volatile matter content of the coal, and the more bituminous coals, with a volatile matter content of 33–40 per cent., can be briquetted fairly easily by fine grinding (97 per cent. of the material should pass a 200-mesh screen) and pressing, taking care that the air is extracted from the fine coal before pressing. The pressure necessary for the production of briquettes made in this way is about 10 tons per sq. in. The cohesion is then about equal to that of a pitch-bound briquette. The fuel is said to stand handling well and to be weather-proof. The fuel can also be made from all coals possessing a volatile matter content of 11–12 per cent. and over, but the more bituminous coals already described are the most suitable for this purpose. Anthracite cannot be briquetted in this way. The great advantage of this process is the elimination of the binder, as the cost of pitch is a very serious item in the fuel-works balance sheet. For example, at the end of 1920, the cost of pitch had risen to £12 per ton, and assuming the pitch content of fuel to be 10 per cent., the cost of *pitch alone* in 1 ton of the fuel would be £1 4*s*. In the manufacture of the usual briquettes, with pitch as a binder, creosote and anthracene oil fractions are frequently used for the purpose of obtaining the optimum binding power of the pitch. The oil is mixed with the pitch in the pug mill in which the materials are mixed thoroughly, and the oil dissolves the pitch, which then flows more evenly over the grains of coal and coats them evenly without undue waste. By this means it is possible to cut down the pitch consumption by about 10–15 per cent., a very considerable amount when cost is taken into account.

As already mentioned, anthracitic fuel would not be suitable for steam-raising, and the coals most generally used for the manufacture of fuel intended for this purpose are blends of bituminous, anthracite, and steam coals. The following table shows the analysis of these coals, from which it will be seen that the steam coals contain more volatile matter than anthracite, whilst the bituminous coals contain still more volatile matter than the steam coals.

Fuel.	Moisture.*	On Dry Coal.			
		Volatile Organic Matter.	Coke.	Fixed Carbon.	Ash.
	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Anthracite . . .	0·2– 3·5	5·0–10·0	90·0–95·0	83·0–92·0	3–7

A good mixture for the manufacture of briquettes for steam-raising would consist of 50 per cent. steam coal, 20 per cent. bituminous coal, and 20 per cent. of anthracite duff with 10 per cent. of pitch as a binder. This would give a finished fuel of approximately the following composition :—Volatile organic matter, 21·0 per cent.; coke, 79·0 per cent.; fixed carbon, 73·0 per cent.; ash, 6·0 per cent. This is assuming that clean coals had been used in its manufacture, and such coals could be produced by washing the small coals in one or other of the washers on the market, snch as the Draper, Hoyle, British Baum, Notanos, or other plant.

Briquettes can easily be prepared to specification by varying the percentages of the constituent coals used for any particular purpose. Thus, if a briquette is desired for furnace or other purposes which shall give a long flame, this can be obtained by putting in an extra large percentage of bituminous coal, whilst we have seen that for domestic fuel anthracite is introduced in order to make the fuel burn slowly and to give radiant heat, instead of throwing a large number of B.Th.U.'s up the chimney in the form of volatile constituents. Resin is sometimes used as a binder, in addition to pitch, and this substance has, roughly, twice the binding power of medium soft pitch, but briquettes made with resin alone fall and soften in the fire and are therefore unsuitable.

A large number of inorganic binders have been tried with varying degrees of success, but these are objectionable on account of the fact that they introduce still more ash into the fuel than is due to the coal alone. Such materials are Portland cement, silicate of soda, lime, clay, spent tanning materials, and sulphite cellulose liquor. Coal tar has also been used, but the resultant briquette is too weak and softens in tropical countries. Various organic materials have also been tried, such as molasses and sugar residues, jelly from Irish moss, mucilage, waste starch, etc., but the only satisfactory binder seems to be pitch.

In the manufacture of blocks, the coal is generally crushed in a disintegrator of the squirrel-cage type, whilst the pitch is broken up in a pitch-cracker, falling on to a grating provided with longitudinal slots, through which revolving arms protrude, which arms carry the pitch forward and crush it against the breaker plate. The mixture of coal and pitch is sometimes subjected to a crushing either in a second disintegrator or in a mill of the Jeffrey swing-hammer, or fixed beater type, such as the Alexander Pulvergrinder, made by Messrs. Briquette Machinery Ltd., of Leeds. The coal should not be too finely ground, as a large amount of fine coal leads to the breaking down of the binding power of the pitch. The pitch, however, should be ground to as fine a degree as possible, so as to obtain the maximum spreading effect with the least possible quantity. The coal and pitch mixture is elevated into a pug, or cooking chamber, above the press, where it is thoroughly admixed, steam being blown in at the same time. Using steam at 400° F., the steam consumption for a press turning out 17–20 tons per hour of briquettes is about 2,200 lbs. Such a press absorbs about 45–50 B.H.P., and runs at 30–40 strokes per minute. The pressure necessary for briquetting steam and bituminous coal mixtures with 9–10 per cent. pitch is about 30–35 cwt. per sq. in. Ovoid fuel is made in roll presses, the fuel mixture being fed between the rolls, after cooking, at a temperature just above that of the twisting point of the pitch used, *i.e.*, about 60–70° C., with a normal pitch. The ovoids are caught on a shaker screen as they emerge from the press, so that all fines are removed, and are then loaded direct into either wagons or ships, provision being made for cooling, to prevent sticking of the fuel, and possible fusion into a solid mass.

* The moisture varies according to the amount of exposure to which the coal has been subjected and to the degree of humidity of the atmosphere, but the above are given as the average of a large number of results. The ash content in general increases with increase of volatile matter content.

In some of the processes recently devised for the purpose of low-temperature carbonisation, the low-temperature coke is fed direct from the retort to a press and is briquetted without the addition of any further binder.

The Smith continuous system of carbonisation, which produces 'Carbocoal,' is a combination of low- and high-temperature carbonisation with briquetting. The coal, sized to pass a $\frac{3}{8}$-in. mesh screen, is subjected to carbonisation at 480° C., the resulting product being a friable residue called semi-carbocoal, which contains 7–10 per cent. of volatile matter. This process takes some two to three hours for completion, but is continuous. The semi-carbocoal is reground, mixed with pitch, and briquetted. The briquettes contain about 15 per cent. volatile matter, and these are carbonised at 1,000–1,100° C., the residue being a hard coke containing 3–4 per cent. volatile matter. The tar yield from the primary carbonisation contains the products usually obtained from low-temperature processes, *i.e.*, paraffin bodies predominate, whilst the tar yield from the high-temperature process gives heavy oils and pitch, with an increased yield of ammonium sulphate. The gas yield from the first stage is 5,000–6,700 cub. ft. per ton, with a calorific value of 650–700 B.Th.U.'s. per cub. ft. whilst from the second stage there are obtained 4,480 cub. ft. of gas of calorific value 350–400 B.Th.U.'s. per cub. ft. The average yield is therefore about 10,630 cub. ft. of gas of calorific value 584 B.Th.U.'s per cub. ft.

Other processes merely briquette the low-temperature coke whilst hot, and either recarbonise at high temperature or sell the product as a smokeless fuel for domestic purposes.

A great amount of work has been done of late in Canada by the Lignite Utilisation Board on the briquetting of lignite. The Souris lignites are of very low grade in the raw state, but by carbonising at 600° C. a residue is obtained which resembles charcoal and which produces an excellent briquette on binding with pitch and pressing in a roll press. The size of the lignite used is under 1/10-in. mesh, 60 per cent. of the material sizing between 1/10 and 1/20-in. mesh. The binders used are coal-tar and petroleum pitches, with sulphite liquor and various waste flour residues as subsidiary bodies. The quantity of binder required, however, is much higher than that which is necessary for the production of ovoids from anthracite fines, and this would seem to be a critical factor where the cost of pitch is high. It was found that 13 per cent. of coal-tar pitch was necessary to produce a sound fuel.

The strength of fuel is generally measured in an empirical way by the 'cohesion test.' This is carried out by revolving 100 lbs. of the fuel in a horizontal cylindrical drum, 3 ft. long and 2 ft. 6 ins. diameter, provided with three internal ribs of angle iron 6 ins. deep, for two and a half minutes at 28 revolutions per minute. The fuel is sawn out of the solid block into pieces 1 lb. in weight, and after the test is completed the residue in the drum is screened over a sieve of $1\frac{1}{2}$-in. mesh, and the portion remaining on the sieve is weighed. This weight, in lbs., is called the 'cohesion' value of the fuel. The revolution of the drum is supposed to represent the rolling of the ship, the attrition in the drum corresponding to the attrition in the ship due to projecting girders, baulks, etc. The cohesion value should not be less than 55 per cent., and a good fuel will often average over a long period 72–82 per cent.

The chemical tests on fuel are the same as are carried out on coal, and these will be found in any book on the evaluation of coal, such as 'Fuel,' by Coste and Andrews, or 'The Analysis of Coal and its By-Products,' by S. R. Illingworth.

Firebars.

The following proportions are for the usual cast-iron bars :—

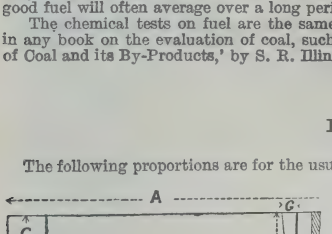

FIG. 10.

A.	B.	C.	D.	E.	F.	G.	H.
Ft. Ins.	Ins.	Ins.	Ins.	Ins.	Ins.	Ins.	Ins.
2 0	$3\frac{1}{4}$	$1\frac{5}{8}$	$1\frac{3}{4}$	$1\frac{1}{4}$	$\frac{3}{4}$	$\frac{3}{8}$	$\frac{3}{8}$
2 6	$3\frac{5}{8}$	$1\frac{3}{4}$	$1\frac{3}{4}$	$1\frac{1}{4}$	$\frac{3}{4}$	$\frac{3}{8}$	$\frac{3}{8}$
3 0	$3\frac{5}{8}$	$1\frac{3}{4}$	2	$1\frac{1}{4}$	$\frac{3}{4}$	$\frac{3}{8}$	$\frac{3}{8}$
3 6	$3\frac{3}{8}$	2	2	$1\frac{1}{4}$	$\frac{7}{8}$	$\frac{3}{8}$	$\frac{1}{2}$
4 0	$4\frac{1}{4}$	2	$2\frac{1}{4}$	$1\frac{1}{4}$	$\frac{7}{8}$	$\frac{3}{8}$	$\frac{1}{2}$
4 3	$4\frac{3}{4}$	2	$2\frac{1}{4}$	$1\frac{1}{4}$	$\frac{7}{8}$	$\frac{3}{8}$	$\frac{1}{2}$
4 6	5	$2\frac{1}{4}$	$2\frac{1}{4}$	$1\frac{1}{4}$	1	$\frac{3}{8}$	$\frac{1}{2}$
4 9	$5\frac{1}{4}$	$2\frac{1}{4}$	$2\frac{1}{2}$	$1\frac{1}{4}$	1	$\frac{3}{8}$	$\frac{1}{2}$
5 0	$5\frac{1}{4}$	$2\frac{1}{4}$	$2\frac{1}{2}$	$1\frac{1}{4}$	$1\frac{1}{8}$	$\frac{3}{8}$	$\frac{1}{2}$

Firebars require to be suited to the fuel. Clean riddled coal-nuts or cobbles may be burned on a $\frac{1}{4}$-in. bar with $\frac{1}{4}$ in. to $\frac{1}{2}$ in. spaces, but slack coal requires wider bars and narrow spaces. Bars are often made with projecting fingers or corrugations in plan, thus increasing the length of air space considerably, though reducing it in respect of the increased width of the bar body. Such bars are made to rock for the purpose of shaking the ashes out of the fire and of breaking up clinker. Air, to supply a secondary demand behind the bridge for the combustion of the gases, is often admitted through hollow bars which heat the air and keep themselves cooler thereby, and under suitable conditions good results may be obtained.

Some firegrates are built up of short bars or links pinned together to form a side travelling band or chain; such grates are self-cleaning and are much used in mechanical stokers, and are good, if provided with suitable air control damper plates below. Other firegrates have a somewhat steeply inclined surface, and may be built up either of longitudinal bars or of transverse bars, in which latter case they form the so-called 'step' grate. Such grates may have a creeping or a shaking movement of the bars in order to assist gravity to lower the burning fuel down hill to make up at the foot of the slope the vacant space left as the fuel burns away. The fuel is mechanically fed in, above, or at the head of the sloping grate surface, and gradually descends under the combined influence of gravity and the moving bars. A dumping device is often added at the foot of the slope by means of which the ash and refuse may be cleared from the furnace by movement of a lever.

Grates for anthracite coal, which develops an intense heat in the fire—not sending off much gas by the heat-absorbing process of distillation—are often made in the form of flat plates with a number of perforated nipples or little mounds raised half an inch above the general surface. The space between the air mounds fills level with dust and preserves the iron surface from heat and checks the adherence of clinker.

Firegrate bearers must never be rested upon the actual plates of furnace tubes of internally fired boilers, but must rest on angle bracket pieces riveted to the plates by not less than two rivets each. For convenience in handling it is usual to employ two or three bars in the length of a 6-ft. grate.

Hollow bars are necessarily (or more conveniently) made in one length; this, however, makes them cumbersome, and is one cause of their being sometimes unpopular, for they are heavy to remove and replace when cleaning; but where conditions are favourable, hollow bars with outlets to the surface and a steam-impelled supply of air through the bars will beget economy, by enabling a cheaper grade of fuel to be employed.

Coal Combustion and Smoke.

Bituminous coal cannot be burned smokelessly except under certain proper conditions. These are that the whole of the products of combustion must be allowed to travel over the full length of the fire towards the bridge; that additional air must be admitted in fine streams above the fire after each fresh charge of fuel. The fresh air thus admitted mingles with the gases from the fuel, and the mixture must be hot enough to burn at the bridge, beyond which point there must be a clear space in which combustion may complete itself. The combustion chamber may with advantage be wholly or partially brick-lined. The draught necessary should be not less than 30 ft. per sec. To compel air to enter over the fire, dampers are sometimes fitted to the ash pits.

The most satisfactory results in coal combustion are obtained with the thickest possible fires, but the thickness of a fire depends on the draught and on the size of the fuel. The largest fuel will bear the thickest fire and the strongest draught. The three factors are interdependent.

The combustion space should be at least in a good red heat so as to ensure burning all the combustible into carbon dioxide and water, which would give smokeless operation. Although about 14 lbs. of air is required to burn one pound of soft coal completely, only half this amount should be admitted through the grate; the remainder should be supplied over the fuel bed. If this can be well preheated, smokeless combustion is practically assured.

Leaving the door open a short interval after feeding fresh coal, supplies an extra quantity of this secondary air when most needed. Poor draft always causes smoke and lowered efficiency. Ample combustion space, involving high settings on boilers, is required with such fuels as Indiana bituminous, pulverised coal, or oil.

There are two general ways of firing bituminous coal. One is to place a thick bed of coal on the front grates. Here it will coke, and the gases given off will pass over incandescent fuel and be consumed, the coked fuel then being pushed over the remaining grate area. This is well adapted to return tubular boilers.

The second method is that of spreading the new coal evenly over the grate in small quantities at a time through alternate doors. One-half of the fuel bed is kept incandescent. A uniform size of coal, neither coarse nor fine, gives best results. High-volatile coals require a bed of four to six inches, and those with less volatile somewhat thicker beds.

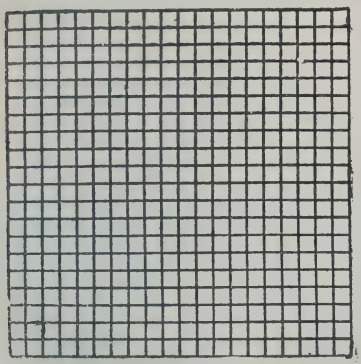
Where gases rise directly upwards from a grate amongst water tubes without the admixture by travel pointed out above, smoke is inevitable.

Fine dust fuel can now be burned at the rate of 40 lbs. per sq. ft. of furnace area per hour. Given furnace room, the cheapest fuel is usually the most economical. In practice the best economy is that due to the use of the cheapest fuel which can be employed to raise the steam necessary.

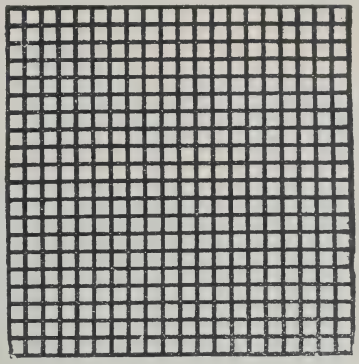
The foregoing, of course, is qualified by the amount of ash in the coal where the extreme of removal is great.

With externally fired boilers which permit of a liberal design of furnace with suitably disposed firebrick, smoke can readily be prevented. It is less easy to secure perfect combustion with internally fired boilers, because of the difficulty of applying durable firebrick linings. But the question of smoke prevention is wholly one of air mixture and temperature. The burning gases must not too soon be brought into contact with cold plates or tubes.

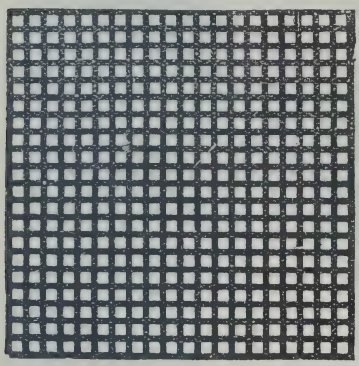
In burning bituminous coal only a part of the total heat is generated at the grate. Part of the heat of the fuel is absorbed in driving off the volatile parts of the coal in gaseous form. This heat becomes latent and very materially reduces the furnace temperature. The gases pass off, containing a third of the total heat capacity of the coal, as well as the heat of gasification. Unless mixed with air and burned later, these gases may be totally lost. To burn bituminous coal not only demands thorough air mixture, but also a sufficient temperature, and the heat of the burning gases must not be abstracted by too early bringing them into contact with the cool surfaces of the boiler. Sufficient length and clear space must be afforded for combustion to complete itself,



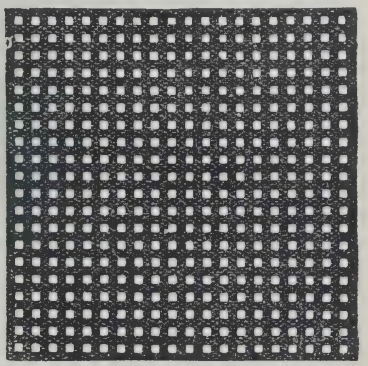
2. Light grey smoke.



3. Darker grey smoke.



4. Very dark grey smoke.



5. Black smoke.

FIG. 11.

or black smoke will be formed. The furnace arrangements of the Lancashire boiler are correct in form, but the water-cooled plates are a hindrance to certain combustion in the case of hand-firing; when high temperature mechanical-stoker conditions are obtained, however, it is much easier to prevent smoke with bituminous coal in a Lancashire boiler than it is in a water-tube boiler.

Water-tube boilers require a special setting to enable them to burn coal smokelessly. No furnace can be smokeless where the gases from the fire rise vertically and pass amongst cold-water tubes. Bituminous fuel can rarely be burned satisfactorily unless there is some extent of firebrick lining to protect the gases from too early chilling. Cross water-pipes in the inner flues of the Lancashire or Cornish boiler are bad, and will seriously hinder perfect combustion and produce black smoke.

Colour of Smoke.

The colour of smoke is best indicated by Ringelmann's smoke charts, which are numbered from No. 1, all white, to No. 6, all black. In fig. 11 intermediate sizes 2, 3, 4, 5, are shown, the ratio of line to space breadth being respectively, 10 : 90 ; 23 : 77 ; 37 : 63 ; and 55 : 45. Large charts drawn to these proportions and hung about 50 feet from the observer where the chimney top can be seen simultaneously, if possible, are very great aids in correctly estimating the relative blackness of smoke.

The four scales of the figure are called light grey, darker grey, very dark grey, and black, the extreme all white or all black being respectively no smoke or dense black.

MECHANICAL STOKERS.

There are several types of mechanical stokers ; for internally fired boilers (such as the Lancashire), the underfeed coking and sprinkler, and, for water-tube boilers, the travelling grate, the single horizontal retort, and the multiple inclined retort.

With regard to the internally fired boilers, by reason of their construction a stoker of the self-cleaning type is not possible, and for this reason the efficiency of such boilers can never be as good as that of the water-tube boilers. In the underfeed stoker the coal is forced onwards and upwards in a central trough by a helix conveyor, the hydro-carbons being distilled while the fuel is rising from the trough, and burnt while passing through the incandescent fuel bed, thus removing the possibility of smoke ; and the coke is burnt while passing over the side grates, so that the ash and clinker collect at the extreme sides of the furnace, from which position they can be conveniently removed. In the coking stokers, the fuel is usually fed on to the front of a moving grate, the volatile portion being expelled and burnt near the front, and the coke burning while travelling towards the back of the fire under the influence of the moving grate surface. In the sprinkler stokers the fuel is thrown on to the grate surface by means of a throwing shovel or similar device. All three types of stoker are capable of burning the fuel efficiently, but the underfeed type has the advantage as regards smokeless combustion.

The single retort machine is quite satisfactory for small boilers, and has the advantage that it is driven by a self-contained steam motor. The multiple retort type of stoker gives satisfactory results with many kinds of coal.

The travelling grate stoker is highly efficient and is capable of dealing with a wide variety of fuels; it has the advantage that each portion of the grate is in the furnace only one-third of each complete revolution, so that it may be adequately cooled and repaired, if necessary, without shutting down the boiler; the ash is discharged automatically over the back end of the grate.

In its original form it had the disadvantage that the fuel bed tapered from full thickness at the front to nothing at the back and thus offered a diminishing resistance to the air supply, the majority of which passed through the thinner fuel layer. In plants subject to varying loads this led to excessive amounts of excess air to secure smokeless combustion and limiting the power of the stoker. It has now been improved by dividing the wind box into a number of compartments provided with suitable regulating dampers so as to secure regular combustion under all load conditions, and this has resulted in greater outputs and considerably increased thermal efficiency.

It is necessary to study carefully the position, size and arrangement of the 'ignition arch' used with such stokers to suit the particular class of fuel to be used if ready ignition and even and smokeless combustion is to be attained.

The Babcock and Wilcox Patent Improved Mechanical Chain Grate Stoker.

The grate of this stoker (*Babcock & Wilcox, Ltd.*), as illustrated on page 1597, consists of an endless chain of short interlocking cast-iron grate bars, linked together, running on angle irons and rollers, and driven by a revolving shaft and sprocket wheels at the front end of the stoker. The necessary power to drive the revolving drum is transmitted through a link chain and sprocket wheels from a shaft arranged either overhead or underground. The starting or stopping of the stoker, or the variation of speed, is effected through the Babcock & Wilcox patent gear box, which can be driven at varying speeds. This box forms an oil bath in which the gear runs, and also contains an efficient clutch for putting the driving gear out of action should any unusual strain arise from an obstruction on the grate. Any small repair, such as replacing a link, can be carried out with the stoker in place under the boiler ; but in case of need the whole stoker can be brought out clear of the boiler, the frames being provided with wheels running on rails placed at the sides of the ashpit. The slack of the chain can be taken up from the front end of the stoker, thus avoiding the necessity for obtaining access to the back end for tightening the grate. The grate bars or links are of a special interlocking pattern, which allow the smallest coals to be used, and, while providing for an ample supply of air for the combustion of the fuel, prevent the influx of cold air at the back of the grate. The coal is fed over the whole width of the grate, and the depth of the fire is regulated by the adjustment of the vertically lifting fire-door.

The feed of the coal is slow, and the gas evolved from the fresh fuel as it drops on to the grate readily perfects its combustion by passing over the incandescent fuel farther on. The depth of the fire being regulated by a vertically lifting fire-door, the stoker can be adjusted in

a moment to suit the class of fuel to be consumed and varying demands for steam, both by the depth of the fire and the speed of the grate. Where the special requirements of the work make it desirable, the stoker can be fitted with an arrangement of vanes for cutting off the air supply to a portion of the grate during periods of light load, thus enabling the general efficiency to be kept up under all conditions of work.

Babcock & Wilcox also manufacture forced draught chain grate stokers of both the compartmental and the boxed-in type, for efficiently burning low-grade and other difficult fuels. When average quality coal is used forced draught is not necessary, and by simply opening the two front ashpit doors—an operation occupying only a few minutes—the stoker can be used as an ordinary natural draught plant.

Bennis Stokers.

(*Ed. Bennis & Co. Ltd., Little Hulton, Bolton.*)

The Bennis Sprinkler Stoker.

This apparatus, fig. 12, affords a perfectly regular output of steam under the most trying conditions; its flexibility permits a rapid response to urgent demands for increased steam. Minimum labour costs, low fuel bills, and smokelessness are a few of the leading advantages

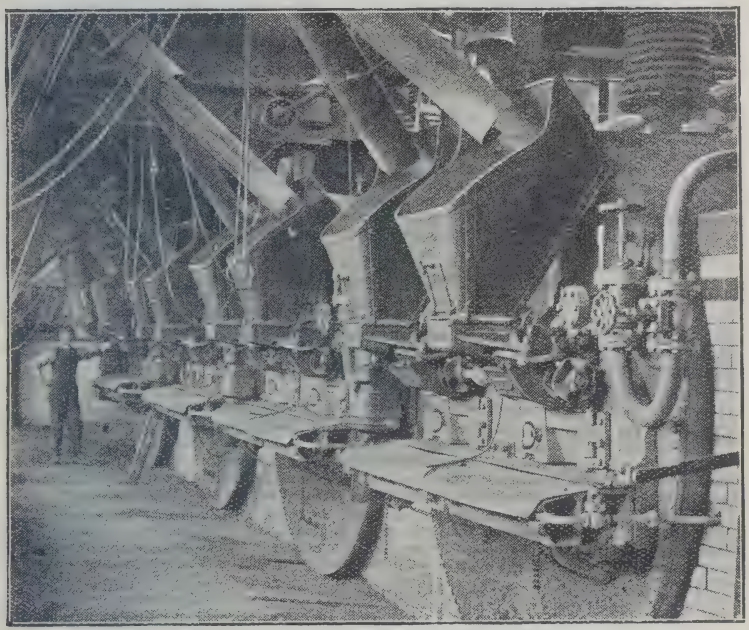


Fig. 12.

that accrue where the sprinkler stoker is in operation. The fuel fed into the hopper of the stoker—preferably mechanically fed—is led to the front of the pusher plate where it is evenly pushed over a ledge formed by the base of the feeding-box. The weight of fuel pushed is regulated, the fuel being deposited on to a flat plate called the shovel box, and then projected into the fire at intervals by an angular shovel actuated by patent pneumatic gear and effectually scattered over different portions of the grate where and as the fire requires it.

The pneumatic gear actuating the shovel, which includes an air cushion to obviate the possibility of shock or jar on the boiler front, is noiseless in operation.

An integral portion of the sprinkler stoker is the self-cleaning compressed air furnace, which prevents clinkering, and ensures perfectly clean fire-bars.

THE BENNIS SELF-CLEANING COMPRESSED AIR FURNACE ARRANGED FOR HAND-FIRING IN COLLIERIES.

This furnace, fig. 13, thus arranged burns any class of fuel, large or small, and burns with special advantage poor quality and refuse fuels, pond settlings, coal pickings, large lumps or small, coke dust, shale, or material which contains a large percentage of ash or clinker. With such refuse it is stated to be able to generate steam as quickly as furnaces fitted with stationary bars burning a higher grade coal. The furnace consists of a strong cast-iron front lined with fire-brick, and fitted with a door of ample size for hand-firing.

THE BENNIS PATENT CHAIN GRATE STOKER.

This arrangement, fig. 14, is applicable to any water-tube boiler or to return-tube boilers—where the fire is under the boiler shell and the flame returns through the tubes—to brewers' coppers and similar furnaces. One of the principal advantages claimed for this particular chain grate is that a larger grate area can be obtained under the boiler than with those of other makes. The Bennis chain grate with the patent halved link was the first chain grate capable of satisfactorily burning fine slack coals. There are many improvements connected with this grate, in addition to the central improvement which gives to the grate its distinction.

The Bennis patent link can be easily fitted to chain grates of other makes, and many successful replacements have been carried out, with the result that considerable economies have been effected by using cheaper coal.

THE BENNIS COKING STOKER.

This stoker, fig. 15, is an improvement on the ordinary type of coker, as it ignites the fuel and cokes it at a more rapid rate than is possible with other types. It is claimed that the immediate result is a higher evaporative boiler duty and greater economical efficiency. It consists of a machine supplied with hoppers into which the fuel is fed. Beneath the hoppers are duplicate feed-boxes with reciprocating feeder rams which feed the coal into the furnace intermittently. A sight hole situated between the feed-boxes makes it easily possible to ascertain the state of the fire at any moment. The feeder rams are worked by means of levers. The rate of the coal feed is easily adjustable. Large air-cooled fire doors are provided beneath the feeder-boxes, their object being to pass cool air into the protection plates fitted immediately round the stoker front on the fireside, thereby preventing damage to the stoker front and also to the boiler.

The Illinois Patent Chain Grate Stokers.

(Vickers Boiler Co., Ltd.)

The Illinois patent Chain Grate Stokers, for forced draught, natural draught, and induced draught, are made under licence by Vickers Boiler Co., Ltd., who hold the sole manufacturing and selling rights in all countries outside the United States.

Broadly, the stoker is of two standard types, viz.:

Type 'A' for natural or induced draught, fitted with air control dampers, and

Type 'G' for forced draught fitted with cast-iron air compartments, hopper bottoms, and device for the discharge of riddlings.

These stokers are of heavy and substantial construction, the frames are of heavy section, well braced and ribbed. The side frames, which, owing to their position inside the casing, are subjected to high temperatures, are independent of the head frames which are outside the setting.

Adjustable ledge plates are arranged at the top of the stoker side frames to prevent leakage of air between these and the chain, and also to prevent the riddling of fine coal. These ledge plates are so set that the distance between them gradually increases towards the rear of the stoker to permit of expansion of the grate and prevent the possibility of the chain binding between the frames.

Drive.

The grates are driven from the front by uniformly spaced driving sprockets which engage on loose rollers on the chain rods, and not on the links or rods, thus minimising frictional loss and reducing the power required, as also the maintenance. The arrangement also ensures a uniform distribution of the driving power over the whole width of the grate.

Idler drums are used on the rear shaft.

The advantages of driving the grate from the front are:

(*a*) The links are in compression, and consequently their strength is greatly increased over that of cast iron in tension.

(*b*) The spaces between the top links are kept closed, and therefore the riddling of fine coal is prevented.

(*c*) The driving sprockets are accessible through inspection doors in the head frame.

(*Continued on p.* 2117.)

BENNIS STOKERS.

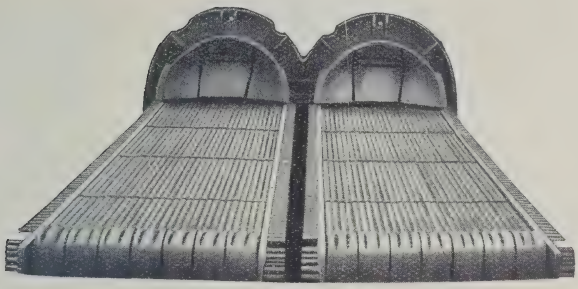

FIG. 13.—BACK VIEW OF THE BENNIS COMPRESSED AIR FURNACE.

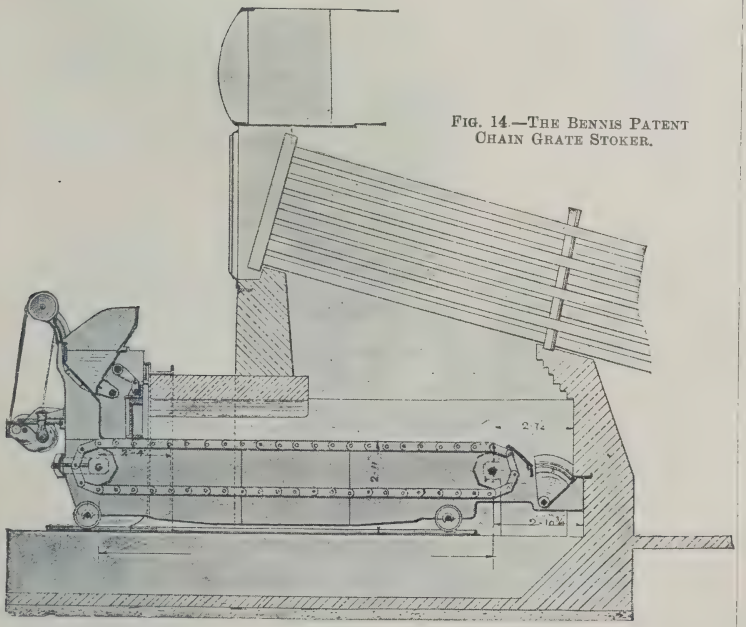

FIG. 14.—THE BENNIS PATENT CHAIN GRATE STOKER.

Bennis Stokers.

The Bennis High Temperature Smokeless and Gritless Coking Stoker.

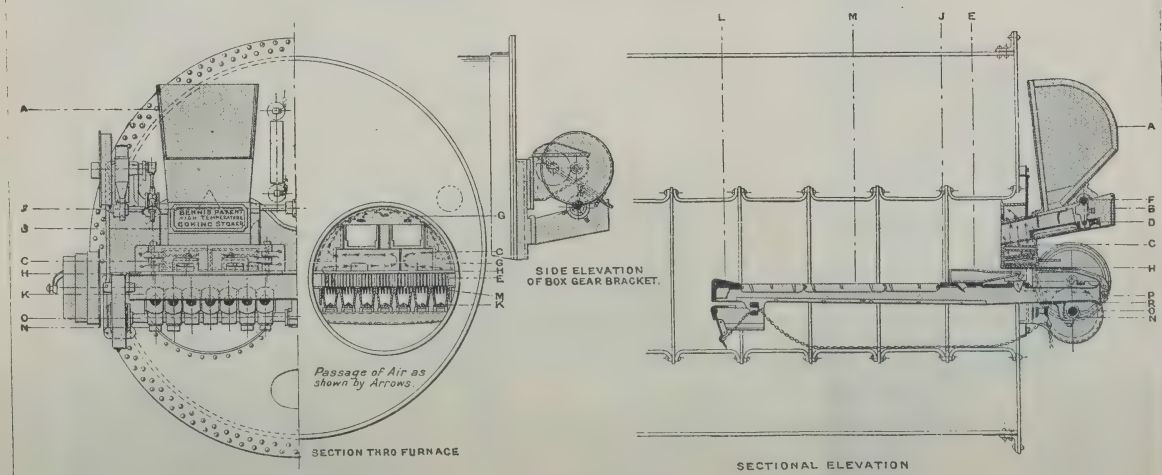

Fig. 15.

THE ILLINOIS PATENT CHAIN GRATE STOKER—*cont.*

The Grate.

The grate is composed of a number of links connected by means of twisted chain rods; the use of these rods prevents the accumulation of dust, rust, and ashes between the rods and links, with a consequent reduction in power consumption and maintenance cost.

The grate tension can be adjusted at any time while the stoker is in operation.

Special repair links are made and supplied for expeditious maintenance under running conditions.

Grate Support.

Chain skids are used instead of the roller construction.

The stokers are made up to 24 ft. in width in a single stoker, which necessitates the use of suspended arches.

Illinois Stokers are in use in this country at the present time up to a width of 18 ft. 6 ins., and stokers up to a width of 24 ft. are in hand.

The forced-draught stoker 'G' is of the compartment type.

The air is delivered from the main air supply duct to a wind box in the side wall extending the full length of the grate.

Stokers of medium width are supplied with air on the one side only; the wider stokers are provided with a wind box on each side.

The whole length of the active grate surface is divided into a number of compartments. Each compartment has its own opening into the wind box controlled by a circular plate damper. These dampers can be locked in any desired position by means of an operating lever and lock placed outside the wind box.

When the stoker has a wind box on both sides, dampers are provided on each wind box. The compartments are constructed of cast iron with hopper bottom and riddling discharging device.

For the burning of anthracite coal, coke breeze, lignite, or other high-moisture or low-volatile fuels, mechanical ignition is provided by means of a mechanical ignition zone at the front end of the stoker, comprising a small compartment running across the entire width of the stoker; in this compartment a suction is maintained whereby a small portion of the hot furnace gases are drawn down through the incoming green coal, causing the fuel to be completely ignited for its entire depth.

The stoker throughout is of robust construction, with a view to ensuring continuity of operation, freedom from trouble, and low maintenance cost.

THE ERITH-ROE STOKERS.

(*Erith's Engineering Co., Ltd.*)

These stokers, for water-tube boilers, figs. 16 and 17, are of the inclined multiple retort underfeed type, in which the fuel is fed from the bottom of the stoker hoppers into a series of retort units, from which it gradually rises to the surface of the fuel-bed and passes down an inclined plane, so that the ash and clinker finally fall into the ash hoppers in a continuous manner, without manual labour.

A heavy fuel-bed is carried, and the *surface* of the fire is maintained in an incandescent condition, so that the heat radiates direct to the boiler tubes; coking arches being entirely dispensed with, their cost and upkeep is eliminated.

The upkeep cost of the stoker is low, due to the metal being kept covered with the incoming fuel that has not risen into the zone of high-temperature furnace combustion.

A regulated supply of air from a fan is furnished to the air chamber below the stoker, and is suitably distributed through the retort tuyeres, etc., at the requisite pressure to secure 'balanced draught' conditions. A special baffle in the air chamber (which forms the subject of an additional patent) has been found of considerable value in improving the air distribution, so that the minimum of excess air, combined with a very high percentage of CO_2, can be maintained in regular service. Under these regulated and controlled conditions, low-grade slack and other fine coal of, say, 10,000 B.Th.U.'s per lb., or less, can now be burned with a thermal efficiency nearly equal to that obtainable with high-grade fuel.

The robust and simple operating mechanism of the stoker consists of a slow-moving crankshaft, which is normally run at about one revolution per minute; it operates, in series, the coal-feeding rams and distributing pushers within each retort, together with the stepped slicing bars reciprocating between each retort (which automatically slice the fires and keep them open and porous) as well as the reciprocating extension grates over which the refuse passes before it finally falls into the ash hoppers at the rear.

In the Erith-Roe stoker provision is made for the immediate and *independent* adjustment of the levers controlling the movement of the fuel-bed, which experience has shown to be essential for

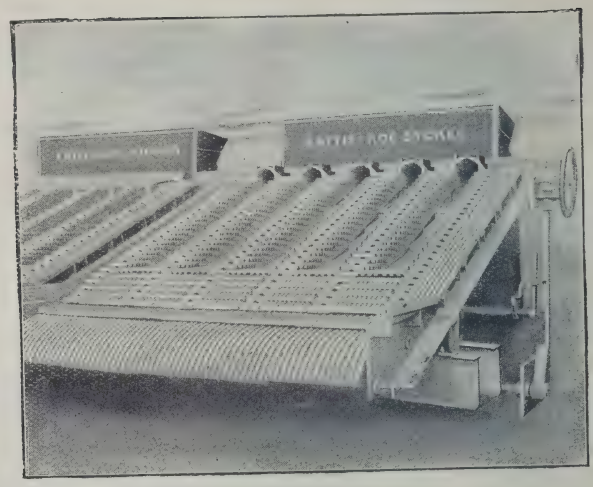

FIG. 16.

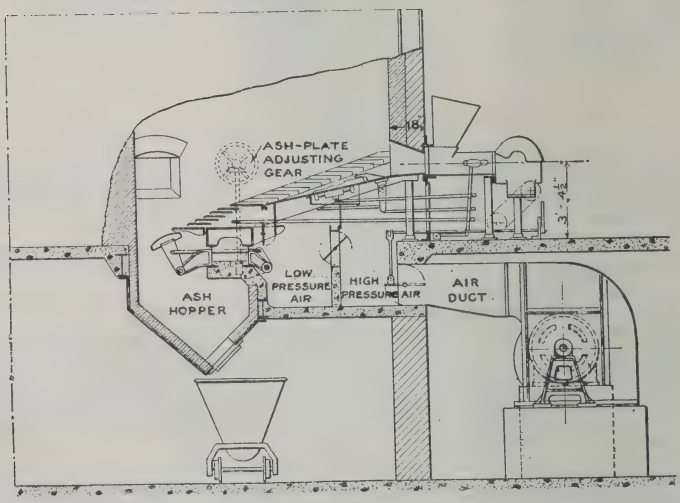

FIG. 17.

burning the widest range of fuels to the best advantage. No alteration from the original adjustment is, however, required, unless the conditions are materially altered through the coal being changed, etc. The Erith-Roe stoker is a British invention, and is being increasingly adopted for central station and industrial service at home and in the Colonies.

The Underfeed Stoker Co.'s Stokers.

(The Underfeed Stoker Co., Ltd.)

Type 'L' travelling grate stoker for water-tube boilers.

This arrangement, which is the outcome of over twenty years' experience with the well-known 'A' type, and of years of research, has been developed to meet the demand for a stoker which can be made in such size that only one machine is necessary for each boiler instead of two, three, or four separate machines having division walls between them in the furnace. Type 'L' stoker can be made in single units up to 700 sq. ft. grate area.

The two most important features of any travelling grate stokers are :—

(1) The construction of the grate surface.

(2) The method of air distribution.

The grate surface employed on the type 'L' machine represents a great advance in design as regards durability, tendency to make riddlings, and resistance to adhesion of clinker which, in many forms of grate, tend to clog the air spaces.

Referring to figs. 18 and 19, showing sectional views of the grate, it should be explained that the grate bars are arranged transversely. They are supported at their ends on steel tension chains, which occur at frequent intervals across the width of the stoker, and are sloped downwards in the direction of travel, lying upon each other in the direction of louvres. The bottom edges of the bars are turned upwards to form troughs, into which fall the riddlings, which find their way through the air spaces between the bars.

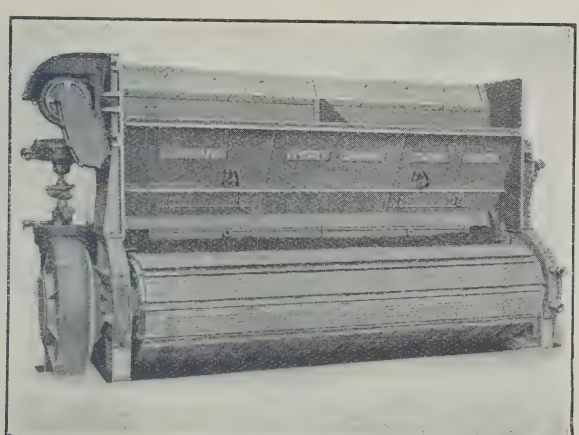

Fig. 18.

The steel tension chains or carrier chains are spaced equally by means of the tie rods having pipe ferrules threaded upon them, and the grate is carried on its journey through the furnace on rollers, which are threaded on to the transverse tie rods and run upon skids of very large area. As the grate passes around the rear drum, the firebars overbalance on the pivots, which are cast on their ends, as shown in fig. 19, and so empty the riddlings from the troughs, at the same time cleaning the grate surface of any clinker adhering thereto.

The following advantages are claimed for the grate surface :—

(*a*) The grate is non-riddling. The actual quantity of dust which is deposited inside the main air chamber, measured over a period of months, averages 1 lb. for each ton of coal burnt on the stoker. This quantity is so small as to eliminate the necessity for any mechanical means for removing the dust from the air chamber. It is quite sufficient if the air chamber is cleaned out once per week, and this can be accomplished either by raking from the access doors or by blowing dust to the rear end and through grids arranged in the bottom of the air chamber.

(*b*) The grate is self-cleaning, due to the movement between individual bars of the grate as they pass around the rear drum. This increases the life of the grate surface, owing to the air space being kept free from clinker.

(*c*) Any part of the grate surface may be renewed without shutting down the boiler and without disconnecting the tension chains. This operation is best accomplished as the grate is passing around the front drum.

(*d*) Owing to the angular disposition of the grate bars, the thickness of each bar is considerably less than the pitch of the bars, measured in the direction of travel, and on this account considerable growth may occur on the surface of the bars without reducing the widths of the air spaces.

(*e*) Due to the 'trailing' progression of the grate bars the possibility of jamming, due to the grate fouling stationary objects, such as clinker dams, etc., is reduced to a minimum.

(*f*) Those parts of the moving chain which are subjected to stress are completely shielded from the heat of the fire.

(*g*) Should one firebar become broken and fall out of position, the space is immediately filled by the preceding bars falling backward and closing the gap.

(*h*) The whole grate is flexible, and therefore unlikely to suffer severe damage in the event of a jam taking place.

Referring to the second important feature, viz. air distribution, this is also quite a novel feature of the type 'L' stoker. Instead of distributing air from side air supply boxes built into the furnace side-walls, and communicating with separate transverse air compartments, the air is admitted into a large air chamber or reservoir which extends the full width and length of the stoker, the height of which is approximately 2 ft. In order to distribute this air to the various combustion zones in the length of the stoker, valves are arranged immediately below the grate. The arrangement of the valve is shown in fig. 16, and the valves in each row are operated simultaneously and independently of all the other rows. There are no divisions in the main air chamber. The advantages of this construction are as follows:—

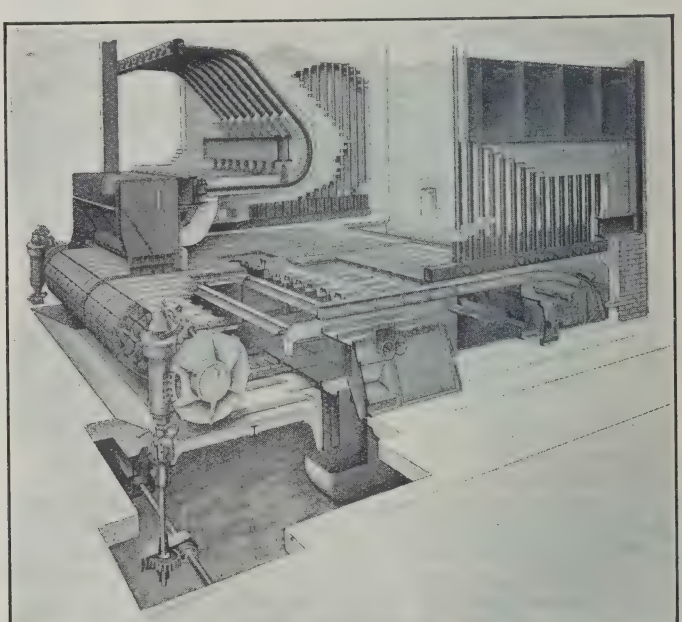

FIG. 19.

(*a*) The volume of the main air chamber is sufficiently large to allow the air to dissipate its velocity, and therefore the pressure over the width of the stoker is uniform.

(*b*) Combustion is under perfect control, and different combinations of air-valve settings may be obtained for the purpose of dealing with different quality of fuel without the need for any change in the stoker itself, as the amount of air passing to each zone of the furnace may be controlled with precision.

(*c*) The whole of the framework of the stoker is kept cool in all circumstances by the movement of air. Even if the rear air valves are completely closed so that no air is passing through that part of the grate, the air is all the time circulating, and thus preventing overheating of the machine.

(*d*) The interior of the stoker is fully accessible. Large doors are arranged through the furnace side walls giving access to the main air chamber, and from the main air chamber to the whole of the return chains and the front sprockets. All the air control valves and their mechanism are immediately accessible from the inside of the main air chamber.

Type 'L' Stoker in widths up to and including 13 ft. 9 ins. are made in the form of single grates, but machines exceeding this width have their grates divided in the middle, the space between the adjacent grates being 5 ins. This space inside the furnace is filled by an air-cooled cast-iron dead plate and no brickwork is necessary. Each half of the stoker is driven and controlled separately, so that in the event of half of the grate going out of commission the boiler may be kept steaming by the other half until a further unit can be brought up on the line. It is claimed for the twin grate that it has all the advantages of the single wide grate and also of the double grate.

The type 'L' Stoker may be driven in a manner similar to the standard 'A' Type Stoker—that is, by means of a line shaft operated from a motor and worm reduction gear, or it may be driven by a motor and gear supported directly on the coal-hopper side-plate. In the case of the Twin Stoker, two self-contained gears are necessary—one for each half of the grate. The self-contained gear is recommended in all cases where electric current is available, as by this means it is possible to avoid all shafting, brackets, bolts, etc., which are objectionable in a boiler-house Apart from this, each driving gear is independent of the other, so that in the event of one going out of commission the other gears are not affected.

THE 'B' TYPE STOKER FOR LANCASHIRE BOILERS.

In this stoker the fresh fuel for the maintenance of the combustion is continuously supplied from *below* the level of the fire and gradually advanced upward to the zone of combustion by the arrangement shown by fig. 20.

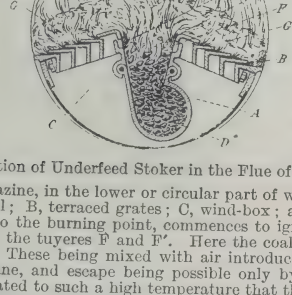

FIG. 20.—Cross-Section of Underfeed Stoker in the Flue of a Lancashire Boiler.

A is a retort or fuel magazine, in the lower or circular part of which revolves a taper-feeding worm which conveys the coal; B, terraced grates; C, wind-box; and D, green coal; the latter being gradually pushed up to the burning point, commences to ignite at the point E, where it meets the incoming air from the tuyeres F and F'. Here the coal is coked, i.e. deprived of its volatile hydrocarbon gases. These being mixed with air introduced at this point through the air inlets of the fuel magazine, and escape being possible only by rising through the glowing coke above, the gases are heated to such a high temperature that they are completely consumed without smoke, while the combustion of the fixed carbon of the coal is completed by the air introduced through the apertures in the sides of the terraced grates B.

The effect of this method of underfeeding is to consume the hydrocarbon gases, so giving a clear fire; it is claimed that at no time, however varying the load, is there the slightest sign of smoke. This stoker caters especially for fluctuating loads, and is much used in works where steam is required for process work.

Another special feature of this stoker is that as it has only three moving parts its upkeep costs are very low.

THE 'UNDERFEED' CLASS 'E' STOKER, FOR WATER-TUBE BOILERS.

In this stoker (*The Underfeed Stoker Co., Ltd.*) the fuel is deposited in a large hopper, and conveyed under the fire by means of a reciprocating sliding bottom which runs the full length of the trough. As the coal rises from the trough it is distributed to the sides of the furnace by means of moving bars. These bars are alternately moving and fixed. The moving bars work transversely to the retort. The extent of the movement is from $\frac{1}{2}$ in. to 1 in., depending upon the size of the furnace and other conditions. On the bottom of each moving bar are cast two lugs which engage with the bulb of the longitudinal rocking bars. These rocking bars in turn receive their movement through the agency of two spirals and nuts, which mechanism is entirely outside the furnace. The nuts are bolted to the crosshead and therefore reciprocate with the bottom. The reciprocation of the nuts causes the spiral to rock to and fro.

The coking and burning coal is constantly carried, by the action of the moving bars, to the dumping trays along each side wall, where the resulting clinker and ash are deposited. These dumping trays are operated by levers on the outside of the furnace, enabling the ash and clinker to be automatically discharged.

One of the important features of this stoker is the distribution of the air, which, upon entering the wind-box, passes upward along each side of the trough, or retort, and is discharged, partly through holes into the retort. The remaining air passes through the bars, which are made hollow. These bars have no openings in their top surfaces, and no air can find its way into the fire above until it has passed through the aperture at the bottom end of the bar, from which aperture it is discharged into the enclosed air chambers. From here the air rises and passes through the small spaces between the bars into the coked fuel. The action of the air in passing through the bars keeps them cool, thus greatly prolonging their life. The heat taken off the bars in this way raises the temperature of the air in the air chambers to from 350° F. to 400° F. The pressure of air in the chamber varies from zero to $\frac{3}{4}$ of an inch of water.

For marine work a variant of this stoker is very successful, and between March 1923 and October 1928 one steamship line alone has thus equipped no fewer than twenty-seven of its ships.

MECHANICAL DRAUGHT.

Various mechanical methods have been introduced for increasing the draught for boilers; this may be accomplished by an exhausting fan drawing the products of combustion through the flues, or by blowing air into a closed stokehold or an enclosed ashpit, and forcing the air through the fire with the necessary pressure, which varies according to rate of combustion desired. There is also a combination of these mechanical means, termed 'balanced draught,' in which air is forced under pressure into the ashpit by one fan and the gases are drawn off by an exhausting fan so arranged that there is neither pressure nor vacuum above the fire. Another method is the 'ejector draught' system in which the flue gases are drawn up the chimney by a high-speed jet of air.

The advantage of mechanical draught produced by a fan is that the first cost is less than half that of a chimney; also the draught is independent of atmospheric conditions, can be varied instantaneously to suit the demand for steam, permits of economisers, and allows the reduction of the temperature of the waste gases to be carried to the lowest practicable point. It increases the capacity of the boiler, and permits of a more perfect combustion with less excess of air. It allows the use of lower grade and less expensive fuel, and so produces steam more cheaply.

Any desired rate of combustion from the normal of 20 lbs., to 30 or 40 lbs. of coal per square foot of grate area, may be maintained with a mechanical draught plant. The air volume required depends upon the style of boiler, condition of boiler setting, skilful stoking, the kind of coal used, and other factors; in round numbers 250 to 300 cu. ft. of air will be required per lb. of coal; these figures represent about 12 per cent. and 10 per cent. CO_2 respectively.

To drive a fan requires about $\frac{1}{2}$ to 1 per cent. of the total power generated. The full benefits of mechanical draught are only obtained where means are employed to utilise to the fullest extent the heat of the flue gases (by means of superheaters or economisers) before the latter are discharged into the chimney. The cost of installing a fan and engine is very much less than the cost of a chimney, so that mechanical draught is economical in first cost.

Fan draught enables a heated air supply to be employed, and it is said that by heating the air supply to 180° the fire temperature will be raised an additional 360°, owing to better combustion, etc.

The Musgrave System.

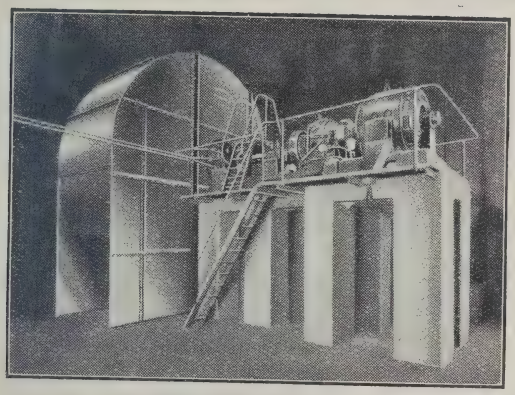
(Musgrave & Co., Ltd., Belfast.)

This is an induced system of mechanical draught. The action of the fan is substantially the same as that of a chimney, the gases being drawn through the furnace and discharged up the stack; this is usually found to be a very convenient and natural method of applying mechanical draught, involving little or no alteration to existing boiler plant, and having a wide range of flexibility. The fact that the draught is set up by suction instead of pressure gives a more uniform flow of air through the fuel, thus reducing the tendency to blowholes through the fire. All leakage being inward, all danger of discharge of flame and smoke at the furnace doors is avoided. In tubular boilers better contact is obtained between the gases and tube surfaces, the tendency with forced draught being for the gases to form a contracted vein at the front end of the tubes, resulting in a consequent loss of heat transmission.

With the induced system the fullest possible use can be made of economisers, either in the form of feed-water or air heaters. There being no necessity to maintain a high gas temperature in the chimney to create draught, as is the case when natural draught is depended on, the whole of the available heat in the gases may theoretically be utilised, and the maximum economy obtained. In actual practice, however, the temperature to which the gases may efficiently be reduced is about 300° F.; to reduce the gas temperature below this figure, the increased cost of economisers or air heaters involved, the additional draught required, and the corrosion due to the condensation of acids from the gases on the cooling surfaces, render further reduction impracticable.

To obtain flexibility and perfect control in a mechanical draught installation, an independent fan drive by steam engine or electric motor is preferable to a drive from a line shaft by means of belt or rope; the speed of the engine or motor can be immediately adjusted to suit the varying draught requirements, and in suitable cases an entirely automatic control can be utilised. The steam

MECHANICAL DRAFT



This Musgrave Induced Draft Fan, one of a pair in an important Power Station, has definitely increased the efficiency of the steam generating plant, and proved a good investment from the economic standpoint.

THE MUSGRAVE SYSTEM of Mechanical Draft gives better combustion, allowing the use of a lower grade fuel; controlled draft securing maintenance of steam pressure. It will pay for itself over and over again in the increased efficiency and economy of your steam-generating plant, while Musgrave Fans are as reliable and trouble free as a chimney.

SENT FREE ON APPLICATION.

consumption of the engine will not exceed 1½ or 2 per cent. as a maximum of the total steam generated, while the steam jet type of blower absorbs from 5 to 10 per cent. of this total.

The great loss of heat where chimney draught alone is depended upon puts it out of consideration altogether in modern plants.

To obtain maximum economy the design of the fan must be correctly proportioned to the required duty, so that the air supply necessary for efficient combustion may be obtained with the minimum expenditure of power under all conditions. All flues should be as short and direct as possible, avoiding all unnecessary bends, changes of section, and obstructive dampers.

Musgrave's induced draught fans are constructed both of the multiblade and straight-bladed types, depending upon the duty. The former with their higher rotational speed are more suitable for use with direct-coupled motor or turbine drive, the latter for engine drive.

Where large quantities of dust are entrained in the waste gases, the straight-bladed wheel is better, owing to its freedom from all possibility of clogging.

The casing may be either of the full or three-quarter housing type: in the latter case, the lower portion of the periphery is formed in brickwork or concrete. The shaft carrying the wheel is usually overhung, being adequately supported in two ring oiling bearings of ample size. For normal gas temperatures the bearing adjoining the fan housing is provided with a water-cooling jacket. For particularly high temperatures both bearings are jacketed, and occasionally a forced lubrication system adopted. Reliability is assured by the provision of ample bearing surfaces in engine and fan bearings, and sound scientific and mechanical design throughout.

THE STURTEVANT SYSTEMS.

Figs. 21 to 24 show the various systems installed by the *Sturtevant Engineering Co. Ltd., London*, which are in use in power stations, workshops, factories, warships, passenger and freight steamers, etc.

Induced Draught (fig. 21). This is the most commonly adopted system, as it is generally applicable to an existing boiler installation, and is economical in operation. The products of combustion are drawn through the flues, economisers, etc., by an exhaust fan, and discharged to an existing stack or to a short length of steel chimney built just high enough to carry the gases above surrounding buildings. The fan is fitted with water-cooled bearings.

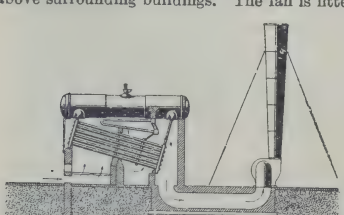

FIG. 21.

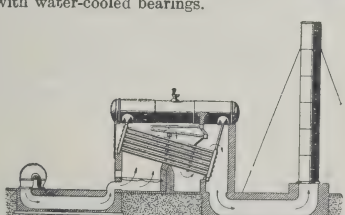

FIG. 22.

Forced Draught (fig 22.) is advantageous for burning small or low-grade fuel. The fan blows air under pressure into the closed ashpit, and the gases are discharged either to existing stack or short steel chimney. For ship use the closed stokehold method is generally used.

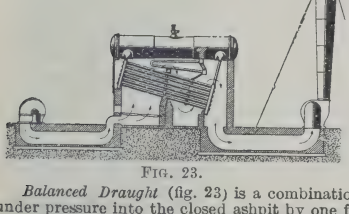

FIG. 23.

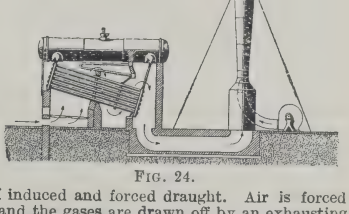

FIG. 24.

Balanced Draught (fig. 23) is a combination of induced and forced draught. Air is forced under pressure into the closed ashpit by one fan, and the gases are drawn off by an exhausting fan so arranged that there is neither pressure nor vacuum above the fire. This is only used in special cases, owing to the cost being much higher than either fig. 21 or fig. 22.

Indirect Induced Draught with Ejector (fig. 24). The combustion gases are drawn up a chimney of special design by the effect of a high speed jet of air, which if desired can be mixed with a portion of hot gases. This system is of special value in cases where the flue gases are corrosive or excessively hot, as they need not pass through the fan. This plant requires very careful designing, otherwise the efficiency is very low indeed.

The Howden Forced Draught System.

The principles on which this system of forced draught (*James Howden & Co., Ltd., Glasgow*) is based are (1) the supplying under pressure of hot air for combustion in quantities suited to the quality of coal used; and (2) the utilisation of the heat in the waste gases for the purpose of raising the temperature of the air for combustion.

Briefly stated, the following are the principal advantages of this method of combustion :—

(1) Great increase in the steaming power of the boilers. (At least 30 per cent. and probably much more over best natural draught conditions. Probably as much as 50 per cent. could be obtained if necessary, though quite such a high rate is not recommended for regular working.)

(2) Unequalled economy in fuel. (At least 10 per cent. and frequently 15 per cent. per lb. of water evaporated over the best natural draught conditions and probably much more.)

(3) Reduced size and weight of boilers for a given power, giving correspondingly additional space available for other purposes.

(4) Complete control of combustion and steam supply under all conditions of the atmosphere. (With this system of draught the volume and pressure of the air for combustion is entirely controlled by the fan and the manipulation of the air valves in the furnace fronts.)

(5) Capability of burning all classes of coal and coke. Low-grade fuel can always be burned satisfactorily where this system of forced draught is applied. Under natural draught conditions this is often difficult and sometimes impossible owing to the inability of supplying the greater volume of air always required where the greater quantity of inferior fuel is used. For the reasons stated in (4) this difficulty is surmounted, the additional quantity and pressure of air necessary being easily obtained by running the fan a little faster.

(6) Preservation of the boilers on account of the more uniform temperature maintained in the furnaces. Boilers fitted with the Howden system of draught are less liable to the leakage and trouble generally present under natural draught conditions; the reasons being that no cold air ever enters the furnace during the period of working, and much greater uniformity of temperature is maintained than under natural draught conditions. Sudden alternations from heat to cold, and the consequent contraction and expansion, have an injurious effect on the internal parts of steam boilers, and such sudden fluctuations in temperature are prevented by the use of this system. When the furnace doors are opened the air pressure in the ashpit immediately ceases, and only the hot air from the upper air supply valve passes into the furnace, first in a direction vertically downwards, thereby forming a hot screen over the furnace mouth and preventing access of cold air. Such conditions when firing or cleaning fires are also conducive to economy. The benefit of the system regarding fluctuations of furnace temperature is most marked and appreciated when it is compared with the working conditions of the closed stokehold system. In the latter a considerable air-pressure is generally used, so that the fluctuation in temperature of furnace is both rapid and violent and puts a severe strain on the boiler structure. This is quite obviated in the Howden system.

(7) Reduction of smoke.

(8) No high chimney required. For land installations a small iron funnel, sufficient to carry off the waste gases clear of the surrounding buildings, is ample for the purpose.

(9) Coolness in boiler-room and ease of working. With this system the air casing, reservoirs, and furnace fronts on the boiler end effectually prevent radiation into the stokehold, which is thereby kept quite cool, making the work easier than with the closed stokehold system, which is very trying for the firemen.

(10) Great reserve power available in case of emergency.

The general arrangement of the Howden system consists of a fan (driven by a steam engine electric motor, or belt), which supplies the air for combustion, discharging it through a conduit into the air-heating chambers. In these air-heating chambers the air circulates round a series of tubes. The waste gases, after leaving the boiler, and before entering the uptake, pass upward through these tubes in the air-heating chambers, or in the Lancashire type of boiler horizontally through tubes in air heaters in the side flues, thus giving up part of their heat to the air, which then passes along passages into air-tight reservoirs or chambers surrounding the furnace fronts. In a recently patented heater developed by this firm, the air is passed through tubes formed by corrugated plates, and the flue gases through spaces between each pair of plates forming the air tubes, and the arrangement is such that a very highly efficient air heater can be accommodated in a moderate amount of space, with a similar arrangement of air reservoirs. From these chambers the air is passed through furnace fronts by valves into the ashpits, and over the fires through air-distributing boxes in proportions exactly suited to the kind of fuel used and the rate of combustion required, thus ensuring a very perfect combustion of fuel.

In the furnace fronts the ashpit air valves are operated by one handle, and a safety locking device is also fitted which prevents the furnace door from being opened until the ashpit air valves are closed. In marine type boilers, retarders are also fitted (one in each boiler tube).

Furnace fronts for powdered fuel have also been developed on the Forced Draught principle, whereby the radiation from the furnace front in general, and the ashpit door in particular, is reduced to a minimum, while simplicity of operation is maintained.

Silley patent smokebox door fastenings form an important adjunct to the forced draught apparatus. These fastenings ensure a thoroughly air-tight smokebox and entirely obviate the trouble usually experienced with buckling, etc., in doors secured by other methods.

At the present time there are about 6,600 installations of the Howden system fitted, and the number is rapidly increasing every year. The aggregate i.h.p. of these is over 24,000,000. They comprise steamers for almost all the principal steamship companies of the world, and a considerable number of installations on land boilers.

PULVERISED COAL.

(Contributed by L. C. Harvey, London.)

General.

Coal in pulverised form was first successfully applied to cement-burning kilns. This method of heating cement kilns has now become universal practice, the steady long flame with its resulting continuous and unvarying heat development inside the rotary kiln being ideal for this work. Moreover, the ash which has always been a source of trouble in other applications forms part of the finished product in this industry.

For cement burning the coal is reduced to a fineness of about 80 per cent. through a 100-mesh screen (10,000 holes to the square inch). It is essential to pulverise to a greater degree of fineness for general applications. A coarser product can be permitted when burning high volatile fuel (30 per cent. V.M. and upwards), or in the case of very large steam-raising units, as now installed in the latest super-power stations in America and elsewhere (see p. 2132), but the American standard of fineness, *i.e.* 85 per cent. through a 200-mesh screen (40,000 holes to the square inch) should be accepted for general boiler firing and for all metallurgical work.

This fine degree of coal-dust, coupled with a low pressure on the air supply, thereby decreasing the velocity of the gases passing through the furnace or boiler, and a wider adaptation of the principle of turbulent mixing of the fuel and air, resulted in the removal of the former troubles due to the formation of ash slag in chequer-work, on metal to be heated, or on boiler tubes.

It is now a recognised and successful practice to apply pulverised coal to all classes of metallurgical furnaces, and in a very marked degree to power-house boilers. (Open-hearth steel furnaces require special consideration.)

The use of pulverised fuel as a means of firing boilers, furnaces, cement kilns, locomotives, public supply, and incidental purposes throughout the world now accounts for a vast quantity of industrial fuel, perhaps 100 million tons per annum.

After the first great reception of this system of burning coal in America the rapid progress which has taken place in the heavy-duty boiler firing has been due to the work of the *International Combustion Engineering Corporation* in bringing the ' Central Mill ' plant to a state of perfection, to the introduction of the water screen in the ash zone, and latterly to the utilisation of Murray Fin Tube and other water-cooled furnace walls and linings, and to ' Turbulent Burners.'

Economy in space, greater flexibility, and reduced first cost of plant have resulted from dispersing the full complement of bunkers, dryers, mills, etc., which constitute the ' Central Mill ' plant into what is now termed by the *International Combustion Engineering Corporation and its Associated Companies*, the ' Direct Firing ' system, *i.e.* one complete and compact plant alongside each boiler.

Advantage has thereby been taken of waste heat from flue gases to dry coal in static dryers instead of fuel utilisation in rotary dryers of ' Central Mill ' plants, and at the same time to eliminate long-distance screw conveyors or pressure transmission systems for the pulverised fuel. ' Self-contained Unit ' mills of small capacity, 200 lbs. per hour, up to relatively large output, 10,000 lbs. per hour, originally established this ' Direct Firing ' system. With these, coal dryers are seldom used though composite types of mills and dryers are in existence. Unit Mills are often designed to draw in heated air or inert gas and thus, in a measure, to dry out moisture in fuel during the process of pulverisation.

Large capacity mills for ' Central Mill ' plants, 5 to 20 ton units, do not operate with coal having more than 5 per cent. free moisture, whereas certain types of ' Self-contained ' mills function quite well with coal containing up to 15 per cent. free moisture.

It is also largely due to the enterprise of makers in bringing the many types of Unit Mills to a stage of relative perfection that pulverised coal firing has been so rapidly extended, the year 1928 crowning their success by the all-important departure in the practical application to marine boilers and the installation of complete ' Unit Mill ' pulverising plant on board ship.

Many important plants are now in operation in France, Belgium, Germany, and other Continental countries. Particular attention is being given to the development of pulverised fuel firing in Europe by *International Combustion Limited*, who have made rapid strides in the development of the ' Lopulco ' system and patents, and have so equipped several power stations in Great Britain (p. 2137).

At the Tennessee Coal, Iron, and Railroad Company's works, and at the Ford Company's works in America, boilers of considerable size are installed for firing either with blast-furnace gas or with pulverised coal. The original practice of using gas and coal together has been discontinued in favour of burning one fuel or the other. It was thought at the outset that the firing of gas in conjunction with pulverised coal prevented the formation of ash clinker, but subsequent improvement in the method of firing pulverised coal has demonstrated that the best results can be obtained when using either one or the other fuel alone, excepting only when pulverised coal must be introduced at times of shortage of blast-furnace gas.

Although chimneys of good height are advisable for large installations, apparatus has been devised to trap much of the dust carried in the flue gases. Tests carried out at Milwaukee show that as little as 15 per cent., and as much as 85 per cent., of the ash in coal passes out at the

chimney top under certain conditions. These conditions are controllable, and whatever may be the amount permitted to escape into the atmosphere, this dust is unlikely to become a nuisance, for it is in such fine particles that the dust rises into space, and its deposition is very widely spread.

Pulverised coal-fired boilers are now guaranteed to give a continuous evaporation of 13 lbs. (from and at 212° F.) of water per sq. ft. of heating surface, at a boiler and furnace efficiency of 81 to 83 per cent. and a peak load evaporation approaching 20 lbs. per sq. ft., with water-tube furnace linings in series with the boiler elements.

As a direct result of high evaporation rates obtained in water-tube protective linings for combustion chambers (the Murray Fin Tubes, etc.), the ' Combustion Steam Generator ' (fig. 25) wherein the main steam generation is effected in a tube-lined combustion chamber has given the first confirmation of the exceptionally high steaming rates, due to radiant transmission of heat, which will be obtainable from these new types of boilers for which refractory linings and external combustion chambers are entirely absent.

In addition to the further progress made in the firing of locomotives with pulverised fuel in Chile, where the ' Fuller ' equipments are in use for the burning of the local lignite, successful trials have been carried out in Austria and Germany and a small number of locomotives so equipped.

Difficulties with the deposit of ash across the tubes at the firebox end have been mainly overcome by methods adopted for the introduction of the fuel to the firebox, turbulent burners, and fine pulverisation.

The use of pulverised fuel for this purpose remains practically dormant, but the statistics relative thereto are retained in view of the possible extension of this method of firing locomotive boilers in various countries, for economies introduced by any successful system will be very important.

For the firing of marine boilers there is every reason to expect that pulverised coal will enter into competition with oil fuel.

Details of Ships in commission and further notes on marine boiler firing and its sequence, ' Lancashire Boiler Firing,' are given below.

The development of low-temperature distillation will be of great influence. The residual fuel is ideal for marine use—soft, friable, readily pulverised, of reasonable volatile and ash content, free from spontaneous combustion tendencies, and therefore safe for storage in ships' bunkers. Semi-coke already pulverised, such as the product of the ' McEwen Runge ' process, offers special advantages. Oil or coal burners, the Peabody, the Buell, etc., are equally suitable for either fuel.

Mill House Plant for Central System.

Fig. 26 shows an outline arrangement of a typical coal-pulverising plant with screen separator mill and rotary coal-fired dryer.

The coal delivered by rail wagon is crushed to ¾-in. cube and passed up the No. 1 elevator to the crushed coal storage bin.

From this bin the crushed coal is fed by gravity into the rotary dryer, wherein the moisture content of the coal is reduced to 1 per cent. This is a necessity for bulk pulverisation, storage, and for conveying the fuel through pipes.

Rotary coal dryers are fitted with furnaces, either hand fired, stoker fired, or arranged for burning powdered coal. The hot gases from the furnace should not pass through the dryer in direct contact with the coal until these gases have been considerably cooled. Some dryers are so designed that the hot gases do not pass over the coal before they have travelled the full length of the dryer through a central tube, when they are diverted into the outer portion of the dryer and pass back to the furnace end in direct contact with the coal. For high volatile coal this type is essential.

The average coal consumption in the dryer is about 20 to 30 lbs. of coal per ton for a reduction of 10 per cent. in the moisture content. When coal is very wet it then becomes necessary to pass the coal twice through the dryer. The final temperature of the coal leaving the dryer should not be above 250° F.

From the dryer the coal passes up No. 2 elevator to the dried coal bin, passing over a magnetic separator pulley in order to remove any pieces of iron from the coal, and is fed by gravity into the pulveriser.

With the static dryer, which has no moving parts, a portion of the waste gases from the boilers, generally about 10 per cent., is forced through the coal, with the result that the coal is thoroughly dried without any loss of the volatile constituents or fine dust.

The stationary type of dryer has been generally adopted for power-house installations. Initial troubles, regarding the flow of coal from the dryer and uneven or over-heating, have been eliminated.

Raw coal can be delivered to the bunker above the dryer, from whence it falls by gravity through the dryer to the pulveriser mill. Thus, the rotary dryer motor, the No. 2 elevator, and, if necessary, the dry coal bunker, shown in fig. 26, are dispensed with, and only in special cases are rotary coal-fired dryers necessary.

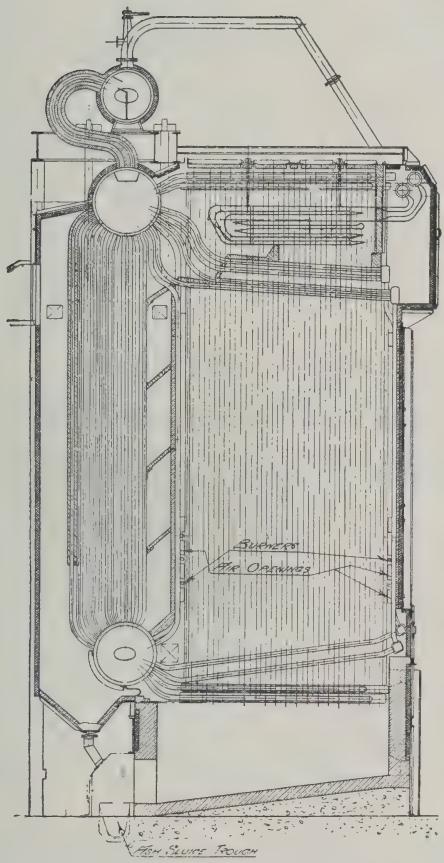

FIG. 25.—Standardised Combustion Steam Generator.
(*International Combustion, Ltd.*)

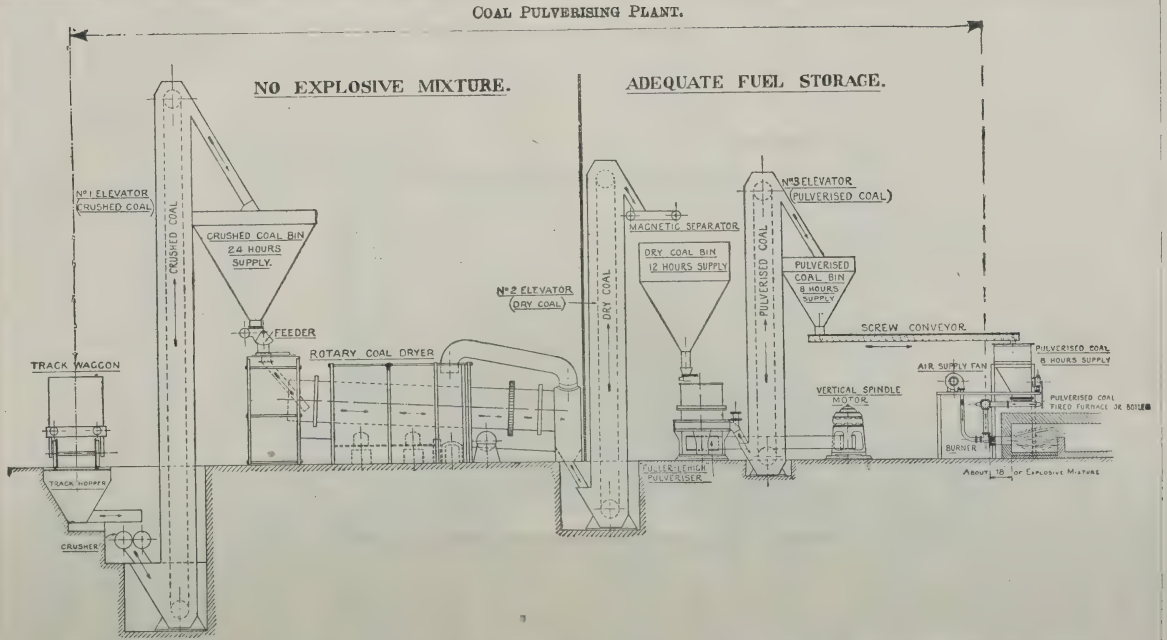

FIG. 26.—General View of 'Central' Pulverised Coa Plant, showing flow of coal from the Track Wagon to the furnaces, and indicating the positions of the Coal Crusher, Elevators, Coal Dryer, Pulveriser Mill, Magnetic Separator, Screw Conveyor, Furnace or Boiler Bin, and Screw Feeder. In place of the Screw Conveyor either the Fuller-Kinyon Pump, Fig. 27 (p. 2130), or the air-pressure system is now generally adopted for long-distance transmission.

The application of this dryer does away with a considerable portion of conveying machinery, for handling both the raw coal and the dry coal at the same time, eliminating expensive plant and fuel used to dry coal. As much as 2 to 3 per cent. of the coal purchased is sometimes employed in drying fuel in revolving dryers, with the static dryer this coal is replaced by waste gases from the boilers. On the Continent the revolving disc, grid, or shelf type of dryer heated by superheated steam is favoured.

Screen separator mills, such as the 'Fuller,' made by the Fuller Lehigh Company, have been used very extensively in the cement industry for pulverising the coal and for grinding the cement clinker. In this type of mill the fine particles of coal are thrown tangentially through the mill screen; the fine product is then raised by means of No. 3 elevator to the powdered coal bin, or it is delivered direct into the screw conveyor or into a Fuller-Kinyon type of pump, for transport to the bins at the furnaces.

In the air-separator type of mill the fine coal-dust is exhausted through a fan and deposited by means of the upward air current into the cyclone collector, whence it is delivered into the powdered coal storage bin, or direct on to the screw conveyor or pump.

The power required for operating a screen separator mill with its pulverised fuel (No. 3) elevator is somewhat less than the power required for operating a screen separator mill and exhaust fan. The wear and tear on the latter may be excessive when abrasive hard coal is pulverised, but the vacuum extraction of the coal-dust from the mill tends towards a cleaner mill-house.

Against the screen separator mill may be placed the occasional damage to the screen by a stray piece of iron. Any perforation of the screen due to this cause permits coarse coal to escape with the pulverised product.

Both types are in general use, and at the present time the advocates of one are as numerous as the advocates of the other.

Hardinge ball mills in conjunction with Hummer screen separation are also in use for pulverised coal production.

Transportation of Pulverised Coal.

The original method of transporting coal-dust was by means of weathertight screw conveyors. This method, fig. 26, although used to some extent for small and compact installations, has given place to air pressure and pump transmission systems for larger plants or greater distance delivery.

The Quigley Furnace Specialities Co. introduced an excellent system of transporting the coal-dust from 'blowing tanks' situate at the mill house. The coal-dust is forced from these tanks by means of compressed air applied to the top of the coal, and the coal is forced through 3-in. or 4-in. pipes to the bins at the furnaces, and over distances up to ½ mile.

Semi-automatic solenoid controlled switch valves are placed at the branches from the main supply pipe. This method of transportation is very compact, convenient, and successful in use.

In the Bonot 'air-transmission system,' the coal-dust is mixed at the mill house with approximately 50 per cent. of the air required for combustion. The mixture is forced through the supply pipes at a velocity of about a mile a minute, and ordinary branch pipes are taken to the furnaces. No furnace bins are therefore needed with this system. Care must be exercised in arranging this system to suit existing conditions, so that danger of accidental explosion taking place in conveyor mains may be realised and necessary precautions taken.

The Fraser & Chalmers air and coal-dust conveying system has been adopted for boilers and ranges of furnaces; its application to Lancashire boilers is illustrated under that heading.

The Fuller-Kinyon system of pumping powdered coal through supply pipes has now been developed by the Fuller Engineering Company, whereby a small quantity of air delivered by a pressure blower is pumped into the powdered coal to prevent 'packing,' so that the fuel can be transported long distances with a minimum of power. Ordinary pipes are used which can be laid underground or placed overhead in the same way as for water pipes.

For any one of these methods of conveying pulverised fuel the product must be dry, otherwise packing troubles will occur.

Feeders.

Whenever coal-dust is held in bulk at furnace bins, feeders are attached thereto fitted with screws or worms to introduce the dust into the air-blast as it enters the furnace, or compressed air is used as a means of syphoning out the fuel.

The screw or worm of the feeder is usually operated by means of a variable speed motor.

One of the best types of variable speed feeder-mixers forms the basis of the 'Lopulco' system of applying pulverised coal to boilers and other furnaces.

The Quigley * feeders have adjustable jaws to govern the supply of dust, and in this way constant-speed motors can be used.

---

* The Quigley, the Bonot, the Buell, and the Fuller patents and designs are now associated with Babcock and Wilcox, Ltd.

THE FULLER-KINYON PULVERISED COAL PUMPING SYSTEM

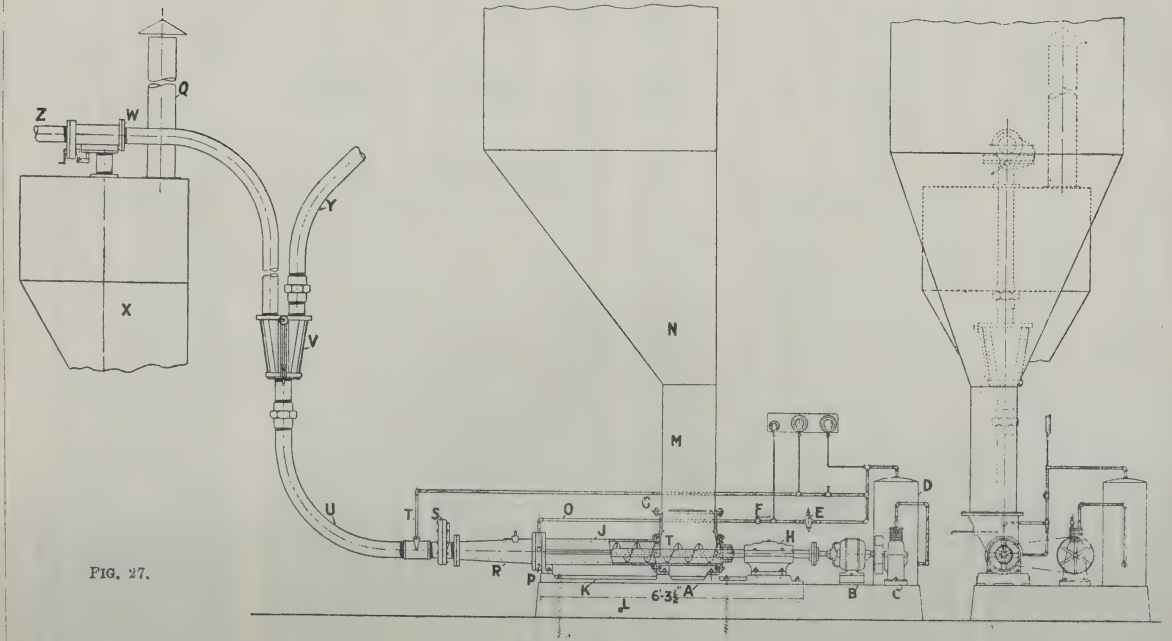

FIG. 27.

T, Conduit Clearing Air Line. U, Convertor Conduit. V, Distributing Valve. W, Double Diverting Valve. X, Receiving Bin. Y, Branch Conveyor. Z, Continuation of Conveyor.

The Simon Carves table feeders have been used with considerable success. This type consists of a horizontal circular table with pockets pierced to take the fuel supply. The rate of rotation is controlled by friction concentric disc drive, and constant speed motors can be employed. On the same principle a single Bailey feeder can be used over a range of 1,000 lbs. to 10,000 lbs. per hour for the supply to any number of burners.

In the 'air-transmission system' no feeders at all are required at the furnaces.

Burners.

The usual type of coal-dust burner met with in general practice has been of very simple construction, merely consisting of an air-carrying supply pipe into which coal dust is fed by the screw feeder. These simple types of burner have given fairly good results, but later practice has established the necessity for a more intimate mixing of the air and powdered coal.

Many special burners have therefore been devised whereby a pre-mixing of coal dust and air is effected before the final stream of air for combustion is introduced.

Exceptionally good results have been recently obtained with the turbulent mixing types of burners, such as the Peabody, the Buell, the Bailey-Tenney, Couch, Fraser & Chalmers, the International Co.'s Type 'R,' and the Clarke Chapman burners, to effect a short diffused flame.

In each type a well-conceived combination of air and coal passages with adjustable or deflection plates or vanes renders it possible to control the direction, length, and intensity of flame.

By reason of the thorough mixture of air and coal, pulverised coal can be applied direct to the fire tubes of Lancashire and Cornish boilers without the use of external combustion chambers, unless high ash coal is used, when it is preferable to collect much of the ash prior to its passage through the boiler tubes. These burners also eliminate the extensive furnace alterations required for long flame burners.

No difficulty is experienced in burning low ash coal (10–15 per cent.) without external combustion chambers.

By reason of wide diffusion of the air and coal-dust mixture, the areas of combustion chambers usually provided for hand or stoker firing are in most cases sufficient.

An actual example of results obtained with the 'Buell' burners, as applied to the stoker settings of a B. & W. boiler of 3,240 sq. ft. of heating surface, without external combustion chambers, is as follows :—

	Stoker Firing.	'Buell' Burner.
Coal—B.Th.U. per lb.	12,562	10,370
„ lbs. per hour	1,792	1,175
Water evaporated from and at 212° F. per hour	13,365	10,552
„ Per lb. of coal	7·4	9·0
Efficiency of boiler and furnace	57 per cent.	83 per cent.

Another method of liberating a very greatly increased number of B.Th.U. in a small combustion area has been developed by the Fuller Engineering Company in their 'Well'-type Burner, which consists of a rectangular chamber with pulverised coal burners at each angle, these producing a high degree of turbulence within the water-cooled burner chamber. (See Combustion Area, p. 2153.)

Power of Motors.

Mill House Plant (for 40 tons per 10 hours).

Preliminary crusher (not required with slack coal)	15 to 20 h.p.
Nos. 1, 2, and 3 elevators	7½ h.p. each.
Dryer	10 to 15 h.p.
Pulveriser mill, screen separation	60 „ 75 h.p.
„ air „	80 „ 100 h.p.

(Mill capacity, 4 to 5 tons per hour.)

Fuel Transportation (say 5 tons per hour, 300 ft. and 40 ft. lift).

*By screw conveyor	15 h.p. (motor).
†By air pressure	75 „ (compressor).
*By air mixture	60 „ (fan mixer)
*By screw pump	20 „ (screw pump and compressor).

* Continuous operation. † Intermittent operation.

(For an approximation of power used, see note on page 2132, 'Progress in America.')

Coal-dust Feeders.

Constant or variable speed motors . . . . . 1 to 3 h.p.
($\frac{1}{2}$ h.p. motors are sometimes used, but are generally unsuitable under mill conditions.)

Air Fans.

No accurate figure can be given for the power required for air fans, as this will depend upon the size of burner used. The total quantity of air per pound of coal allowed is usually 180 cu. ft., 60 to 100 cu. ft. being supplied at a pressure of 3 or 4 ozs. per square inch; the remainder is induced at the burner when furnaces operate under induced or chimney draught.

Pre-Gasification of Coal.

Much of the success obtained in the various applications of pulverised coal has been due to the fine and uniform pulverisation of the coal, and the provision of combustion chambers of considerable cubic area.

Until the advent of the turbulent mixing type of burner, the latter requirement precluded the development of pulverised coal-firing for such purposes as marine boilers, Lancashire boilers, locomotives, and the smaller range of trial furnaces.

A greater measure of success is still to be obtained by subjecting pulverised coal to temperatures n the neighbourhood of 1,000° C. at high velocity, and with an air supply sufficient only to maintain this refractory surface temperature, gas can be generated and delivered direct to furnaces or boiler firing chambers with little loss of the sensible heat.

Developments are now in train for the practical application of pulverised coal in this manner, and a measure of success has already been obtained. Due to the extraction of dust in the pre-gasification chamber, this system lends itself particularly to those applications where dustless conditions on the hearth or in the furnace are essential. Moreover, it will doubtless be possible to utilise such generators or pre-gasifiers with either liquid fuel or pulverised coal.

Progress in America.

The amount of pulverised coal used in the U.S.A. up to 1912, chiefly in the cement industry, was approximately six million tons per annum. In the copper, steel, and iron industries for power-house boilers and all other purposes, including the cement industry, the annual usage of coal in powdered form is now upwards of 50 million tons, following the adoption of pulverised coal-firing at the 200,000 kW. super-power station at Milwaukee. Many other new American power stations have been equipped for pulverised coal-firing, one of the latest stations being the 600,000 kW. station of the Union Electric Supply Co., at 54th Street, New York.

Some super-power stations in America and elsewhere, now operating with, or arranged for, pulverised coal-firing, and equipped with boilers of very considerable size, are tabulated below:

	Approximate Heating Surface of each Boiler. Sq. Ft.
Milwaukee Electric Railway & Light Co., U.S.A.	32,200
Allegheny Steam Heating Co., Pittsburg, U.S.A.	30,800
Ford Company, River Rouge, Detroit, U.S.A.	28,480
Detroit Edison Co. (Marysville), Detroit, U.S.A.	29,800
Detroit Edison Co. (Trenton Tunnel), Detroit (Projector), U.S.A.	28,720
Cleveland Electric Illuminating Co., Cleveland, U.S.A.	30,600
Providence Electric Railway Co., Boston, U.S.A.	12,600
Berlin Electricity Works, Rummelsburg, Germany	17,200
Duquesne Light Co., Brunots Island, U.S.A.	26,500
Western Pennsylvania Power Co., Springdale, U.S.A.	15,300
Metropolitan Edison Co., Middletown, U.S.A.	14,680
Union Electric Light & Power Co., Cahokia, U.S.A.	18,010
Union d'Électricité, Gennevilliers, France	20,200
Union d'Électricité, Vitry, France	16,670
Nippon Electric Co., Tokio, Japan	10,080
Hams Hall, Birmingham, England	20,000
County of London Electric Supply, Barking, England	16,510

At the Cleveland Electric Illuminating Company's plant, the coal, which is of high volatile content (33 per cent.), is pulverised to a fineness of 60 per cent. through a 200 mesh, and 85 per cent. through a 100 mesh screen. Operating power has been determined at 14·5 kW. for production, 1 kW. for screw conveyors, and 4 kW. per ton for feeders and air blowers. Ratio of furnace volume to effective heating surface of boiler is 0·85, or 0·95 to total heating surface, furnace volume being 29,150 cubic ft.

The rating of each boiler is 3,060 h.p., and each boiler operates at 225 per cent. rating on continuous load, and at 300 per cent. rating at peak load.

A special feature of this installation, as at other American power plants, is the automatic control of the fuel and air required for combustion, in direct relation to the load on the boiler, by means of the system perfected by the Bailey Meter Company of Cleveland.

Combustion Area.

The ratio of combustion area to boiler-heating surface at the Cleveland plant is referred to above. The ratio at the Cahokia power station is somewhat less, being 0·635 of the effective heating surface of the boiler.

American practice has established satisfactory results for boiler firing, when burning between 0·6 and 2·0 lbs. of coal (calorific value, 12,500 B.Th.U. per lb.) per hour per cu. ft. of combustion area. At normal steaming this means that in each cu. ft. of combustion area there can be liberated about 18,000 B.Th.U. per hour, and at maximum load about 25,000 B.Th.U.

In Germany, at a special pulverised coal research station, a definite figure for metallurgical high temperature work has been fixed at 33,500 B.Th.U. per hour per cu. ft. of total combustion area. The special Well-type burner recently adopted by the Fuller Engineering Company, referred to under 'Burners' (p. 2131), makes it possible to liberate a much higher number of B.Th.U. per cubic foot of combustion area per hour, and it is claimed that this type of burner, with pulverised coal, has been burned at the rate of upwards of 100,000 B.Th.U. per cu. ft. per hour.

On the above bases of B.Th.U. per cu. ft. of combustion area, calculations can be made for boiler and metallurgical work, for any quality of coal: the higher the ash content, the lower will be the B.Th.U. value per lb., and consequently the larger the combustion area necessary. The greatest obstacle to the general use of pulverised coal for industrial purposes has been the ever-increasing cubic areas of combustion chambers to such a pitch that prices are quoted for the latter which are half the total cost of boilers.

The development of the turbulent mixing types of burners has clearly shown that combustion chambers can be greatly curtailed when using burners giving wide flaring or diffusion effects. (See 'Burners,' p. 2131.) The advent of the 'Wood' boiler may alter the whole design of power-house boiler-house plants, but for ordinary furnaces and boilers the above statistics will still hold good.

Self-contained Pulveriser Units.

Great attention has been given to the perfecting of these small unit mills, which can be placed alongside the boilers or furnaces to be heated. So much progress has been made in design, reduction of power consumption, maintenance costs, etc., that their installation at French and German iron and steel works and at American power houses has been generally accepted. Whereas power consumption was anything up to 30 kW. per ton of coal, these units now operate at 12 to 15 kW. for similar fuel as burned at the furnace, including air supply. These units are also pulverising fuel containing up to 15 per cent. of moisture, but this moist fuel must necessarily be supplied direct to the furnace burners, and not stored in bunkers.

The figures given in the table on p. 2146 represent the capital outlay required for complete mill-house plants of various capacities. The initial cost of same, with transportation system, furnace bins, motors, feeders, etc., necessitates an expenditure which, in many cases, will or can only be contemplated when actual results have proved that the collective advantages and economies thereby introduced render such an investment wholly attractive.

For smaller fuel requirements and for testing pulverised-coal firing upon individual boilers or furnaces, a self-contained pulveriser unit can be conveniently installed. There are now many efficient machines of this type available, and built upon entirely novel principles is the 'Atritor' unit, which embodies the use of eddy currents of air within the grinding zone for the dual purpose of rapid agitation and deflocculation of coal particles and the exposure of maximum surface for driving off moisture. In this unit, therefore, is combined the operation of drying and pulverising.

The French 'Rex' machine is also novel in its provision of carborundum grinding elements, and also in its fuel and air regulation and totalising adjustments. The power consumption with this unit is also exceptionally low; 6 to 10 kW. per ton of bituminous coal.

Coal containing comparatively high percentages of total moisture—20 per cent. or so—can be pulverised in several of the well-known types of units, and through the medium of hot air, up to 500° C.; the resultant fuel powder will be practically bone dry. Coal containing 5 per cent. to 10 per cent. of moisture can be dried and pulverised with air at atmospheric temperature, the resultant degree of fineness depending upon the humidity in the atmosphere at the time of grinding.

By the installation of self-contained units the value of pulverised-coal firing for any specific purpose can be ascertained, so that the question of capital outlay upon a complete mill-house plant and attendant equipment can be based upon the results ascertained in this manner.

The makers of the well-known Bettington sectional water-tube boilers and self-contained pulveriser units have generally improved the construction of both these, so much so that the boiler should find an extended use, and the pulveriser, which is particularly silent and efficient, a useful and general application.

Self-contained pulveriser units have been widely adopted on the Continent, many electric light stations now being fitted with this class of equipment, and some details of the Clarke-Chapman 'Resolutor' Pulveriser unit are given below. This unit is very similar to the French 'Resolutor' unit in general use for boilers and metallurgical furnaces on the Continent. The German B. & W. unit and the Rema Mill are also extensively installed.

The Clarke-Chapman 'Resolutor' Pulveriser.

(Clarke, Chapman & Co., Ltd., Gateshead-on-Tyne.)

This pulveriser, see fig. 28, is a self-contained unit machine and obtains its product by the impact of renewable beaters attached to a rapidly revolving disc. The coal is fed into the machine from a hopper by a belt, the speed of which can be readily controlled. Entering the pulverising chamber the coal is caught up by the high-speed beaters, shattered to an extreme degree of fineness and

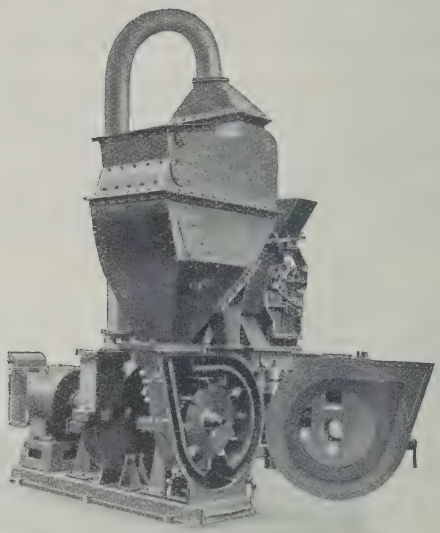

Fig. 28.

drawn up by means of the action of a fan into a separating chamber. In this chamber an adjustable deflector returns any coarse coal for re-pulverisation, whilst the fine material is drawn off into the firing circuit. The 'Resolutor' pulveriser in sizes ranging up to 10 tons per hour is now successfully firing water-tube boilers, Lancashire boilers, marine boilers (seven vessels are now equipped with the 'Resolutor' Pulveriser), and furnaces of all descriptions. This pulveriser is also in use for firing cement kilns and for powdering various materials for industrial purposes.

Marine and Lancashire Boilers.

After years of research and improvements in methods of production and application of pulverised fuel to meet the exacting conditions of firing within the confined areas and chilled surfaces of marine and other fire-tube boilers, these great difficulties have been virtually overcome.

The original tests carried out by the United States Shipping Board and the running of the *Mercer* with the Peabody pulverised coal system as an experimental ship has resulted in serious current attention to marine applications.

PROGRESS OF THE RESOLUTOR PULVERISER

The 'Clarke Chapman' System of Powdered Fuel Firing is making rapid strides. During the last twelve months the results obtained in the firing of Lancashire Boilers, Water-tube Boilers, and Marine Boilers, enable us to definitely state that this method of firing is now established as sound engineering practice, and is no longer in the experimental stage

It has been sufficiently proved that ordinary bunker coal carrying up to 12 per cent. free moisture can be dried and pulverised on board by means of ball mills or impact mills and thereafter evenly distributed to the burners at the furnaces. It is probable that the introduction of small capacity storage bunkers for pulverised coal will be eventually adopted in preference to direct supply from the pulverisers.

The outstanding features of pulverised coal firing are, briefly: maintained speed of ship on full pressure steam by reason of 'no cleaning of fires,' small-grade bunker coal at lower cost, easier application of self-trimming bunkers with small coal, stokehold labour and conditions in every way parallel to oil firing, the lower cost of coal as pulverised and burned as compared with oil.

Excepting only for short sea routes, ferry services, and harbour craft, the question of bunkering pulverised fuel (which requires 30 per cent. increased bunker space) in the form of non-spontaneous or carbonised residue coke, is impracticable and attendant economies have as yet to be demonstrated even for favourable applications.

In the following table certain available data are set out concerning four ships already in service. Others are under consideration.

Special consideration applying to the system	Suitable for usual run-of-mine coal as bunkered for hand-firing at coaling ports	—	—	—

* This ship has been treated largely as a pioneer experimental ship.

The Brand powdered fuel system has been installed in the s.s. *Swiftpool*, and she has completed her maiden voyage, but data are not yet forthcoming as to performance.

The Peabody Engineering Corporation has also equipped the s.s. *Lingan*, which has run twenty trips between Sydney, N.S., and Montreal. A vessel of 4,677 tons. Equipment approximately the same type as used in the s.s. *Mercer*.

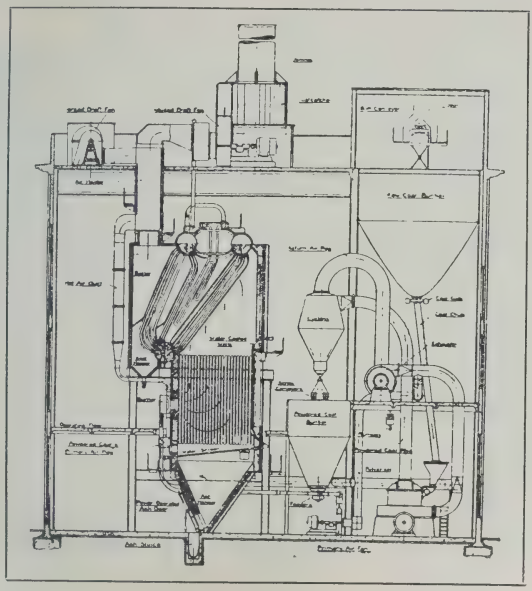
The tug *Tamaqua* was also fitted with this system in April 1929. A vessel of 594 tons. Max. fuel per boiler per hour, 1,000 lbs. 2 S.M., 2 furnace boilers, and 2 impact pulverisers driven by steam turbines.

From now on it will become an increasing practice to fire marine and Lancashire types of boilers in this manner.

The Clarke-Chapman Powdered Fuel system has been installed, after the successful performance of the s.s. *Berwindlea* on two cargo vessels owned by a Liverpool firm. In addition to this the ' Resolutor ' Pulveriser is in successful operation on the Continent on the s.s. *Stassfurt*, the s.s. *Donau*, the tug boat *Metz* and the dredger *Basure de Baas*. An illustration of the *Berwindlea* equipment is given in fig. 29.

The result of the first fourteen months cargo running of the s.s. *Berwindlea* is of importance in that it shows over a period of 57,230 miles an average coal consumption of 1·28 lbs. per i.h.p. per hour and that it reveals an extremely long period in which the powdered fuel plant gave complete satisfaction.

The Clarke-Chapman Ash Ejector Plant ' Woodeson ' patent has been successful in solving the ash problem on several vessels, including the s.s. *Berwindlea*.



THE LOPULCO

System of Pulverised Fuel Firing offers many advantages———

F. 2136

Advantages obtained by installing

THE LOPULCO PULVERISED FUEL SYSTEM

1. Removal of all moving parts from the combustion zone.
2. Increased operating periods without interruption.
3. Greater flexibility of plant.
4. Decreased coal costs per unit of electricity generated.
5. Effective control of combustion conditions.
6. Reduced overall maintenance costs.
7. Higher daily and annual operating efficiencies.
8. Increased evaporative ratings.
9. Rapidity of raising steam to meet sudden demands.

INTERNATIONAL COMBUSTION
LIMITED
ALDWYCH HOUSE, ALDWYCH, LONDON, W.C. 2
WORKS: DERBY

F. 2137

Other types of plants for Lancashire boilers are shown in figs. 34-36, p. 2147. The Fraser & Chalmers systems, air and coal conveyed through a supply main, and direct firing unit mills, are illustrated. As against hand-firing these installations have shown increased steaming 20 per

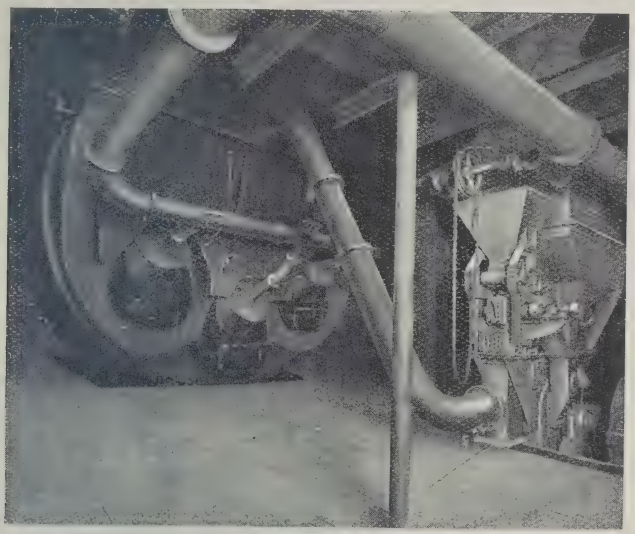


FIG. 29.—View of Stokehold of S.S. *Berwindlea*, showing one of two Marine Boilers fired with Powdered Fuel by 'Resolutor' Pulverisers.

cent., a fuel economy of 20 per cent., steady steaming with inferior coal. Three boilers will supply the steam from four hand-fired boilers. Ash is slagged and run off in the slag pan shown, and ash in the tubes blown out by means of steam jets.

Another method is the pre-gasification system, with which a small external combustion chamber or pre-gasifier is used (see fig. 30); some success has been recorded with this system at a British colliery plant.

THE LOPULCO SYSTEM.

(International Combustion, Ltd., London.)

A typical arrangement of 'Lopulco' Boiler and Pulverised Fuel Plant is shown in fig. 31.

In such a system the raw coal, in pieces of a size which will pass through a 1½-in. diameter ring, is passed through a Raymond Pulveriser which has 4 to 6 pendulum rollers running inside a grinding ring.

The coal is fed by means of a feeder to the grinding chamber, where it is picked up by rotating ploughs and thrown between the rollers and the grinding ring; as soon as it is reduced to the required fineness, it is separated from the coarser particles by a current of air drawn through the pulveriser by an exhauster fan. This air carries the fine particles to a cyclone collector, in which the coal is separated from the air, this latter returning to the pulveriser by way of the exhauster fan.

The degree of fineness is adjusted to suit the amount of volatiles contained in the fuel; thus bituminous coals having a high percentage of volatiles do not require to be ground so fine as semi-anthracite coals, which have low volatiles. A suitable condition of fineness for good bituminous coal is such that 90 per cent. will pass through a 100-mesh sieve, and also that no particles are left on a 40-mesh sieve.

The coal is dried in the mill circuit by means of hot air drawn from the hot air duct of the boiler; the same air is used for extracting the pulverised fuel from the mill. The surplus air from the mill circuit is taken off at a suitable point and supplied (as primary air) for combustion in the boiler by the primary air fan, which delivers it via the feeder to the burner. The burner is of a horizontal type, specially designed to give a turbulent uniform mixture of coal and air to the furnace.

* New boilers. † Old boilers. ‡ Including water-cooling system for side and rear walls.
§ Unit Pulverisers referred to above are the International Type with the exception of Hams Hall, Birmingham, which are Atritor Unit Mills.

The secondary air for combustion is introduced to the burner box direct from the hot air ducts of the boiler and is controlled by means of suitable adjustable dampers around the outside of the burner casting. With the exception of the front burner wall, which is constructed of high-grade refractory material, the combustion chamber walls are constructed of water-cooled tubes of the Murray fin type; these are 4 in. in diameter fitted with a pair of diametrically opposed fins welded on, grouped together and connected to headers at each end, and so coupled to the boiler drums as to be in direct circulation with the boiler unit.

Across the bottom of the combustion chamber there is a screen of water tubes, also forming part of the boiler circulation, which are of seamless steel expanded into forged steel headers. The particles of dust which drop from the flames pass through the tubes and are thus chilled below melting point so that they fall into the ash hopper and are easily removed as fine, dry particles. The following figures give the power required for a 'Lopulco' equipment to deal with 30,000 lbs. of pulverised fuel per hour:

Motor for Raymond Pulveriser	110 kW.
Motor for fan pulveriser	45 kW.
Duplex feeders	4·5 kW.
Motor for primary air fan	32 kW.

This works out at about 15 kW. per ton of pulverised coal burned per hour, which, at ½d. per unit, is 7·5d. per ton; thus, about 1 per cent. of the total steam production is required to work the pulverising plant.

Pulverised Coal for Locomotives.

The advantage for pulverised coal, lignite, etc., as a locomotive fuel are—

30 to 40 per cent. fuel economy as against hand-firing, running mileage and cylinder power of engines increased, cost of firing tools and repairs to fire grating eliminated, no cinders or sparks from the smoke stack, reduction of fire-box strains, firing conditions with pulverised-coal firing analogous to oil-firing with similar fuel-bunkering facilities. Any local fuel within reason can be used.

The following fuels have been and can be used:

	A	B	C	D
Chicago and North-Western Railway.				
	Per Cent.	Per Cent.	Per Cent.	
Illinois bituminous	3·18–15·36	10·00	34·47	10,720–12,400

,, bituminous	0·5	9·0	33·0	13,750

A. Range of moisture. B. Ash. C. Volatile matter.
D. Calorific value. B.Th.U. per lb. (dry).

On the Lehigh Valley Railway a locomotive has been run on a mixture of 55 per cent. raw anthracite silt and 45 per cent. bituminous coal. Full steam pressure is maintained easily at all times, and the anthracite silt contains 38·42 per cent. of ash, and has a B.Th.U. value of 9,675, while the soft coal which is mixed with this has an ash content of 11·6 per cent. and a B.Th.U. value of 12,650. Analyses of these coals are as follows:—

Anthracite Silt.	Per Cent.	Soft Coal.	Per Cent.
Moisture	2·26	Moisture	1·90
Volatile	10·39	Volatile	36·59
F.C.	49·30	F.C.	49·89
Ash	38·42	Ash	11·60

The raw coal and lignite to be burned on locomotives in Italy has the following analysis figures representing the limits in each case are given :—

	Per Cent.		Per Cent.
Moisture .	. 12·52 to 26·80	Volatile .	. 31·5 to 60·94
Ash .	. 11·6 to 32·60	Carbon .	. 35·26 to 68·50
	B.Th.U. values from . . .		3,640 to 10,440

LOCOMOTIVE EQUIPMENT.

A brief specification of the locomotive equipments (Fig. 33) supplied by the Fuller Engineering Company of America is given below:—

Special cast-iron coal hopper base to receive duplex feed screws. Vertical marine-type steam engine for operating same, with intermediate connections, including gears, gear shafts, shafting, etc.

Steam turbine driven fan for conveying the coal dust from the feeder to the tender.

Flexible steam connections between engine and tender, as well as flexible connections for transporting the pulverised coal between engine and tender.

Burner, with necessary dampers and connections for operating same.

3,000° F. pyrometer for indicating fire-box temperatures. Electric revolution counter for indicating speed of engine driving coal-feed screws. Revolution counters for each pair of feed screws, gauges, and valves for operating this equipment.

Mechanism for operating the slag pan or slag pans, as well as mechanism for operating the air dampers in the sides of the combustion chamber beneath the fire-box.

The equipment is started and coal supply commenced with a steam pressure of from 0 to 30 pounds.

Developments in this direction in Germany have been carried out with the 'Bauart' and the 'A.E.G.' patents. The latter embodies a novel burner arrangement in that lateral louvred and water-cooled burners are fitted one on each side of the fire-box. These are clearly shown in fig. 25, p. 623, in 'LOCOMOTIVE' section. Experiments on a freight locomotive have offered sufficient encouragement for the construction of further engines on this principle.

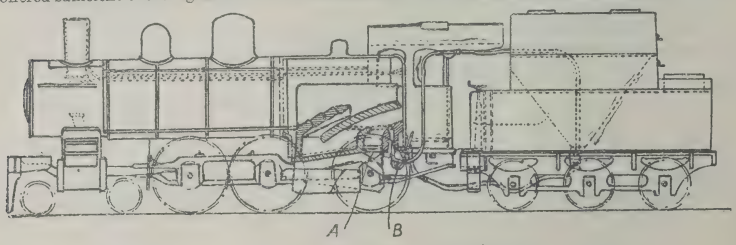

FIG. 32.—Pulverised Peat Fired Locomotive on Swedish Railways.
A. Hand-fired Coal Grate. *B*. Peat and Air Mixture Inlet.

An article by *Bureau Engineer*, Carl Flodin (Centraltryckeriet, publishers, Stockholm, 1916), includes full data regarding tests made with peat-fired eight-coupled freight locomotives: tractive power, 9,000 kg.; weight, 51,000 kg.; tender, 36,000 kg.; water capacity of tender, 14,000 kg.; pulverised peat, 4,000 kg.

It was found on these tests, for equal boiler duty, that 1 kg. of coal was equal to 1·4 kg. of pulverised peat, the coal used having a calorific value of 7,240 cals. and the peat as used 4,400 cals., or approximately 13,000 and 7,900 B.Th U. per lb

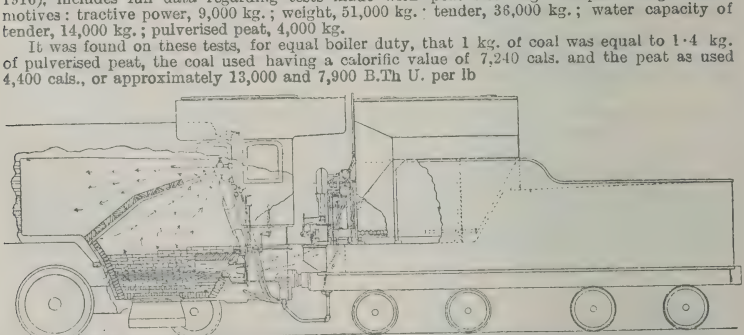

FIG. 33.—Fuller Equipment as fitted to Main Line Freight Locomotive, showing Fuel Hopper, Control Equipment, Burner, and Combustion Chamber.

The arrangement of the firebox setting, fig. 32, allowed for a small grate on which coal was burnt under the incoming mixture of powdered peat and air. On this small hand-fired grate 3 to 4 kgs of coal were consumed per 100 kg. of peat; the analysis of peat and coal was as follows:—

	Powdered Peat. Per Cent.	Coal. Per Cent.
Carbon	47·0	75·5
Hydrogen	4·5	4·4
Oxygen	29·5	8·6
Sulphur	0·5	1·5
Nitrogen	1·1	1·2
Ash	3·2	6·2
Moisture	14·2	4·6
	100·0	100·0

Analogous tests made with coal-fired and powdered peat-fired locomotives gave the following overall boiler efficiencies and fire-box temperature of gases:—

	Efficiency. Per Cent.	Temperature.
Hand coal-fired	65	1,510° F.
Pulverised peat-fired	73	1,670° F.

Recorded and corrected figures for parallel trips with coal- and peat-fired locomotives are given, the following being the more important:—

Parallel Test Run.	Trip Number.	Weight of Loco., Tender and Wagons.	Wagons.	Average Speed, Km. per Hr.	Consumption of Fuel Kg. per 1,000 Kg. Inclusive Loco. and Tender.	Smoke-box Temp.	Kg. Steam per Kg. Fuel.
Service.		Ton per 1000 Kg.	Ton per 1000 Kg.			° F.	
A. Freight	1. Pulverised peat	787	700	29·2	37·5	255	4·47
	2. Coal	782	700	27·5	25·6	290	6·83
B. Freight	3. Coal	782	700	28·7	27·7	312	6·62
	4. Pulverised peat	787	700	27·0	40·7	294	4·56
C. Passenger	5. Pulverised peat	387	300	42·3	56·9	289	4·52
	6. Coal	382	300	41·7	39·0	268	7·0

Many grades of coal (in South Africa, for instance) are considered unsuitable for use on locomotives.

That it is quite possible to eliminate a large quantity, if not the whole, of imported coal, or coal transported long distances by rail, is now being realised in various parts. Brazil has already supplanted imported railway coal to some extent by fuel which hitherto has been considered useless, and continuous extensions in this direction are to be made. The coal used in Brazil is of lower quality than the South African fuels, as the following comparative analyses of Brazilian and South African coals show:—

	Brazilian Coal, as used 'dry' in pulverised form for locomotive fuel.		South African Coal, Undried.		
			Durban.	Kroonstad.	Dundee.
	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Moisture	7·90	1·73	1·60	8·29	0·84
Volatile	28·04	9·50	27·10	31·27	25·30
Fixed carbon	34·73	61·50	60·05	45·32	68·94
Ash	29·33	28·27	11·25	15·12	5·76
Sulphur	3·16	9·10	1·51	1·43	1·53
B.Th.U. per lb.	8,820	10,177	12,950	11,020	14,722
Evap. power	9·20	10·40	13·40	11·40	15·23

The Brazilian coal analysis represents the fuel in pulverised form after treatment in a rotary dryer. The fuel is of friable nature, and the ash of such form that when subjected to heat it flows round the lumps of fuel on a hand-fired grate, rendering it impossible to burn the coal. Kroonstad coal contains about the highest degree of moisture recorded—8·29 per cent.—whereas most South African coal contains but 1 or 2 per cent. of water, and for which drying plant would not be required. This is an important consideration.

Refractory Linings for Combustion Chambers.

The construction and composition of the linings of combustion chambers for pulverised coal fired furnaces are questions of considerable importance.

Although the experience gained of recent years has rendered it possible so to design combustion chambers that the refractory linings are not subjected to the severe destructive action from the flame and ash slag as heretofore, it is still highly desirable under all conditions to have a lining that will not only withstand high temperatures, but will at the same time resist the corrosive chemical action of the ash under these conditions.

In the case of high temperature metallurgical furnaces the factor of corrosion is one that must be carefully considered in view of the presence of metallic oxides introduced through the furnace charge.

Most coal ash consists chiefly of alumina, silica, and iron oxide, together with very much smaller quantities of five or six metallic oxides.

Metallic oxides are of primary importance, in view of the fact that many of them have a marked fluxing action on almost any refractory material. Thus, a fuel ash that contains much iron oxide has in itself a destructive action on furnace linings, irrespective of any of its other constituents.

Apart from this, some fuel ash contains a predominating amount of basic material, whilst in other cases there may be an excess of acid material. When a furnace is to be fired generally or entirely with a fuel containing a basic ash it is highly desirable to provide a basic lining, for by so doing much of the trouble and expense for renewal and repair of furnace linings will be avoided.

Preliminary analysis and investigation in connection with the composition of the coal ash and furnace linings will often save expense and prevent lining troubles during the subsequent operation of the plant.

The more common and cheaper grades of refractory bricks usually contain a more or less equal amount of silica and alumina, and the slight excess of one or the other should be taken advantage of. Combustion chambers of suitable design and having the requisite combustion area will then run satisfactorily with linings of ordinary firebricks.

If, however, there are exceptional conditions to contend with, such as high temperatures, confined combustion space, chemically active ash, etc., it is necessary to make use of the best grades of refractory materials.

In many cases carborundum (silicon carbide) can be used as a facing material for linings with good results. Carborundum, however, although generally chemically inert, will not resist the action of iron oxide or ash containing much potassium or sodium compounds.

In some few cases pure silica bricks can be used when the fuel ash composition is suitable and high temperatures have to be withstood, but special provision must be made for expansion of the bricks.

Pure alumina, magnesite, or bauxite are all high-grade refractories that may be used to resist high temperatures when ash or slag is of a basic nature.

Advantages of Pulverised Coal.

The chief advantages of using coal in pulverised form are:—

Utilisation of low grade coals, peats (coals with 30 per cent. and 40 per cent. ash); lignites, anthracite slush and pit washings can be used.

Control of flame temperatures with uniform heat regulation and greatly reduced requirement of attendant labour—in fact, labour required is equivalent to oil-firing practice.

Increased efficiencies of furnaces due to direct firing of the fuel in minute particles, causing instantaneous and complete combustion, without smoke production.

Some approximate savings in fuel consumptions that have been realised in practice are as follows:—

Boilers—80 per cent. efficiency, and savings of 15 to 50 per cent. over hand firing.

Open-Hearth Steel Furnaces—a saving of 300 lbs. per short ton of steel as against producer gas for small plants.

Puddling Furnaces—a saving of 1,500 lbs. per short ton of iron over hand firing, and from 300 to 500 lbs. over mechanical stokers.

Reheating Furnaces—20 to 40 per cent. saving over hand firing.

Heavy Forge Furnaces—25 per cent. saving over hand firing.

Light Forge Furnaces—20 to 40 per cent. saving over hand firing.

Annealing Furnaces—30 per cent. saving over hand firing.
Tinning and Galvanising—20 to 30 per cent. saving over hand firing.
Sheet and Pair Furnaces—30 to 40 per cent. saving over hand firing.
Copper Smelting Furnaces—40 per cent. saving over hand firing
Locomotives—30 to 50 per cent. saving over hand firing.
Cupolas—30 to 50 per cent. saving in coke and hotter iron.
Crucible (Brass Melting) Furnaces—The use of coal in place of metallurgical coke or oil.

The output from many of these furnaces has been greatly increased by reason of coal-dust firing, what are known as 'stickers' in the tin-plate trade having been reduced 60 per cent., whilst the quantity of tin and zinc used has been reduced considerably owing, in a great measure, to the improved surface of the metal, and also to the more even heating of the kettles.

Reduced oxidisation of steel and iron heated in powdered coal-fired furnaces and increased life of annealing boxes have accounted for an annual saving of many thousand pounds in some works.

Very important economies have been made in firing malleable iron melting and annealing furnaces with pulverised coal, so much so that The Grindle Fuel Equipment Co. of America have specialised exclusively on this work.

In a properly designed plant, and with due attention to ordinary common-sense regulations, there is *no fear of explosion* from the coal-dust, and, as has been already stated, the old troubles with the ash slag have been overcome.

There are certainly many instances where the use of fuels in powdered form would show a handsome return for capital invested, and the following table will enable an estimate to be made as to economy that can be expected.

Approximate Cost of Complete Mill House, Plants and Operation Expenses.

If static dryers are installed the cost of plant can be reduced by 5 per cent. up to 350 tons, and by 7½ per cent. thereafter, and the cost for coal for rotary dryers is then omitted.

Daily Output in Tons.	Labour. Cost per Ton.	Power. Cost per Ton. *	Dryer Fuel, Cost per Ton. 2 per cent. of coal dried.	Repairs, Cost per Ton.	Without Stand-by Plant.			With Stand-by Plant.		
					Cost of Mill House Plant, including Building.	Interest per Ton at 6 per Cent.	Depreciation per Ton at 10 per Cent.	Total Preparation. Cost per Ton.	Cost of Mill House Plant, including Building. Cost of plant exclusive of foundations and erection.

* Can be reduced to ⅓rd for power-station plants.

Table of costs is based on the following assumptions :—

Labour at £4 per man per 44-hour week.

Power at 1½*d.* per kilowatt-hour (a high cost even for local supply), and an average allowance of 20 kw.-hours per ton of coal pulverised and delivered to the exit of mill house, including power for all operations. Dryers to be fired with pulverised coal, which is taken as 40*s.* per ton at the dryer burners ; an average allowance of 2 per cent. of the coal dried is made for dryer fuel, assuming the moisture content of coal to be reduced from 15 per cent. to 1 per cent.

Yearly output is based on 300 working days.

Vertical or Horizontal Flame Projection.

When the straight flow types of burners are used, the burning of bituminous coal and lignite is best effected by means of horizontal burners, and when fuel of less than 20 per cent. volatile matter is to be burned, straight flow burners are placed vertically. The short flame turbulent types of burners are placed horizontally for all classes of fuel.

Illustrations of boilers so equipped with horizontal and vertical burners, and marine, etc., applications, are shown in figs. 34, 35, and 36.

REFUSE DESTRUCTORS.

Calorific Value of Refuse.

The calorific value of refuse is about $\frac{1}{5}$ to $\frac{1}{7}$ that of an equal weight of good dry coal.

Average composition and calorific value of London ashbin refuse, containing the average percentage of water :—

Component parts of Refuse.	Amount in 100 lbs. of Refuse.	Calorific Value.
	Lbs.	B.Th.U.
Coal	·35	3,260
Coke	·15	1,200
Bones and offal	·37	1,970
Breeze and cinder	25·55	102,000
Rags	·40	1,330
Paper, straw, fibrous material, and vegetable refuse	13·15	33,100
Ash	47·00	Nil
Dust and dirt	9·75	,,
Bottles	·48	,,
Metals, including tins	·68	,,
Crockery	1·72	,,
Glass	·37	,,
	99·97	142,860

The above is the average of 1,000 cart-loads.

About 60 per cent. of the refuse is combustible.

The character of the refuse varies a great deal. In factory districts the percentage of unburnt cinder is high, whereas in residential districts with gardens it is much lower.

When it is considered that ordinary green garden refuse when piled in a heap over a nucleus of fire will consume itself, it is obvious that refuse containing cinders will contain enough heat, if properly applied, for its perfect destruction. It is essential that combustion should take place in brick cells, and that no heat should be abstracted until combustion is complete, after which the gases may be used for steam raising. If 40 per cent. only of the refuse is combustible, its calorific value per pound will be about 5,800 B.Th.U. if it were dry. Taking it only as 1,500, this is more than would raise the temperature of the whole gaseous and solid matter to a red heat. If half the weight were water, this would absorb about 600 B.Th.U. to evaporate and about 300 to become red hot, or 900 in all. The remainder of 600 B.Th.U. would raise the gases and solids to nearly 5,000° F. Thus destruction may be perfect with only the equivalent of one-tenth its weight of dry carbon. Inodorous combustion demands high temperature, and hence must occur in brick cells, with suitable movement of the fuel, so that the gases and steam cannot escape until fully incandescent.

The largest and most completely equipped refuse disposal plant in the world has recently been put into service by Heenan & Froude, Ltd., of Worcester, for the city of Glasgow.

The nominal capacity of the plant is 670 tons of crude city refuse per day, but records show that 750 tons can be dealt with if required.

The refuse is mechanically handled throughout and, with the exception of the removal of metals, the whole is cremated. The steam generated is used for driving two 5,000 kw. 3-phase 50-cycle turbo-alternators running condensing.

Over 90 per cent. of the current is transformed from 6,500 V. to 20,000 V. and delivered to the Dalmarnock Power Station for distribution.

The remainder (usually about 7 per cent.) runs the station auxiliaries and charges the batteries of the fleet of refuse collection vehicles after being transformed and converted as required.

Forty cells are provided for the burning of the refuse arranged in 8 groups of 5 cells each, complete with water-tube boiler and superheater. The grates are withdrawn by hydraulic power, the clinker dropping on to a lower platform, where it remains for the time being and gives up its heat to the air for the combustion of the fresh refuse on the grate above. This ensures rapid ignition and an increased thermal efficiency of the plant. When next clinkered, the old clinker is scraped off the lower platform by knuckled scrapers on the underside of the grate and the new clinker drops into its place, in turn igniting the fresh refuse and heating the air for combustion. The old clinker is removed in wagons running on a light railway in the basement.

The actual power delivered to Dalmarnock is shown by the dotted line, and the difference is the power required for driving the station auxiliaries and for charging the refuse collection vehicles which are of 5-ton capacity (15 cub. yds.).

The plant was under steam for 4,060 cell-hours out of a possible total of 5,280, and the high value of 215·6 kw. hours was obtained per cell-hour.

LIQUID FUELS.

Whereas solid fuels are solely used for external combustion it is possible to employ almost all liquid fuels for either external or internal combustion. On comparing the most important liquid fuel petroleum with the most important solid fuel, coal, many remarkable advantages of the former over the latter are found to exist. The heat value of petroleum is some 50 per cent. greater than that of average coal, the stowage space being slightly less. Liquid fuels are more convenient to store (places inaccessible to coal may be employed) and are more easily transported than solid fuels. Liquid fuel is almost entirely free from ash. When used for internal combustion the thermal efficiency of liquid fuels is double that of the solid fuels used for power production. Certain liquid fuels can be employed in high speed engines, whereby a higher power per unit weight of engine is obtainable than by any other type of prime mover.

The most important liquid fuels are petroleum, shale oils, coal tars and their products, and lignite tars and products.

Petroleum.

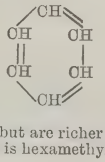
Petroleum occurs in the earth, and is generally found in strata of conglomerate or of oil sands. It is generally accompanied by gaseous and also by solid hydrocarbons. The crude oil is usually brown or black, and the products of different fields vary greatly both in physical and chemical properties.

Petroleum consists almost entirely of carbon and hydrogen. These are present in the form of compounds known as hydrocarbons. Hydrocarbons may be divided into three main groups, known as aliphatic, aromatic and hydroaromatic hydrocarbons. These groups may be subdivided into numerous series, the members of which possess certain definite relationships between the number of carbon and hydrogen atoms present in the molecules. The physical properties of the members of these series generally progress by fairly regular steps. The carbon atoms in the aliphatic hydrocarbons are connected together in the form of chains, and the more important series of this type of hydrocarbons are :—

Paraffin Series. General formula—C_nH_{2n+2}		Olefine Series. General formula—C_nH_{2n}	
Methane	CH_4	Ethylene	C_2H_4
Ethane	C_2H_6	Propylene	C_3H_6
Propane	C_3H_8	Butylene	C_4H_8
Butane	C_4H_{10}	Pentylene	C_5H_{10}
Pentane	C_5H_{12}		

The carbon atoms of the aromatic compounds are connected together in the form of rings, a typical compound being :—

Benzine, formula C_6H_6 . . .



The hydroaromatic compounds also contain carbon rings, but are richer in hydrogen than the aromatic hydrocarbons. A typical hydroaromatic compound is hexamethylene, C_6H_{12}.

Petroleum oils contain members of all these series, but the proportion varies according to the locality from which the oil has been obtained. Pennsylvanian oils consist mainly of aliphatic hydrocarbons, Russian oil mainly of hydroaromatic compounds. The products of the destructive distillation of coal consist mainly of aromatic compounds. Crude petroleum from Mexico and South America generally contains quantities of a viscous sulphur-containing body known as asphaltum, which has great influence on their properties as fuels. Little petroleum is consumed in the crude state, it being usual to separate it into fractions boiling over various ranges by means of repeated distillations. Many petroleum fractions are also treated with sulphuric acid and with caustic soda in order to remove certain undesirable constituents.

The principal fuels obtained from petroleum are :—

Benzine	boiling from 70°–150° C., 158°–302° F.	Specific gravity ·700–·760
Kerosene, illuminating, or paraffin oil . . .	boiling from 150°–300° C., 302°–572° F.	„ „ about ·800
Gas oils, solar oils, etc. .	boiling from 250° C., 482° F. upwards.	„ „ „ ·850
Petroleum residuum, 'fuel oil,' boiling point varies greatly		„ „ ·880–·950

The world's production of petroleum in 1929 was 1,488,604,000 barrels, and the United States production was 1,005,598,000 barrels, or 67·55 per cent. of the total.

The import of motor spirit or petrol into the United Kingdom in 1929 was 826,279,000 galls.

Benzine.

Benzine is the petroleum fraction from which motor spirits are prepared. Motor spirits are generally called petrol in this country. Petrol contains about 14 per cent. hydrogen and 86 per cent. carbon. Heavy fuel oils contain about 12 per cent. hydrogen and 88 per cent. carbon.

Kerosene.

Illuminating oil or kerosene, generally known in this country as 'Paraffin Oil,' possesses a specific gravity in the neighbourhood of ·800. It is slightly lower in calorific value than petrol, but on account of its higher specific gravity it yields more heat per unit volume of fuel. The ultimate composition of kerosene is approximately carbon 87 per cent. and hydrogen 13 per cent. Apart from illuminating purposes, kerosene finds frequent use as a fuel for vaporising engines. A large number of heavy distillates of petroleum are prepared for various technical purposes. Of these gas oil is probably the most important. Gas oil is prepared with a view to its use in the preparation of carburetted water gas or oil gas, and is also used as fuel for semi-Diesel and Diesel engines. It is a brown clear liquid of specific gravity about ·850, and has a net calorific value of about 18,000 B.Th.U. The distillates, whether prepared from asphaltic or non-asphaltic petroleum oils, are generally very similar in quality, though the proportion of each distillate yielded by the different crude oils may vary considerably. The residuum which is run off the still at the end of distillation, and is frequently marketed as 'fuel oils,' varies very greatly in properties according to the nature of the crude oil from which it originates. The non-asphaltic petroleum residuum which is sold as fuel oil is generally dark brown or black, almost opaque, quite mobile, and has a specific gravity of ·870 to ·920. It is largely used as a fuel for semi-Diesel and Diesel engines, also for boiler firing in the Navy. The residua prepared from asphaltic oils are usually black opaque liquids possessing high viscosities and specific gravities from ·920 to ·980, the viscosities and specific gravities being dependent on the asphaltum content.

Shale Oil.

Shale exists in many parts of the British Empire, the shale oil industry being most fully developed in Scotland. The shale is mined in a similar manner to coal, and is then subjected to destructive distillation, the principal products of value being ammonia and crude shale oil. The crude oil is subjected to distillation, whereby a series of products similar to the petroleum distillates is obtained. The shale oils are richer in unsaturated bodies than petroleum. In fuel properties they very closely resemble the petroleum products.

Petrol.

Petrol, known in France as 'Essence' and in America as 'Gasoline,' is a mixture of liquid hydrocarbons principally composed of the chemical 'paraffins,' Hexane C_6H_{14}, Heptane C_7H_{16}, Octane C_8H_{18}, and Nonane C_9H_{20}: these have boiling points 155°F., 208° F., 248° F., and 302° F. respectively. It is obtained by distillation from crude petroleum and, as now used, varies in sp. gr. at 60° F. from about 0·70 to 0·76, the average being about 0·725. The consumption in Great Britain rose from about nineteen million gallons in 1905 to upwards of two hundred million gallons in 1919. Petrol, being a mixture of hydrocarbons, has no fixed boiling point, and its density increases during evaporation; it was largely from this cause that surface carburettors proved unsatisfactory, selective evaporation occurring and a heavy non-volatile residuum being finally left; with the jet-carburettors now almost universally employed no selective action is possible.

As petrol is very expansible, tanks and closed vessels should never be quite filled with the liquid, so as to avoid risk of rupture following a rise in temperature. Coefficient of expansion, 0·00063 per ° F. (0·001138 per ° C.).

The composition of commercial petrol averages about 85¼ per cent. carbon and 14¾ per cent. hydrogen, and the net calorific value per lb. varies but little from 18,900 B.Th.U.

Heavy petrol gives quite satisfactory results with modern carburettors; motor omnibuses employ 0·760 spirit very largely on account of its lower cost.

It was formerly assumed that the suitability of a motor spirit could be determined from its specific gravity, but in recent years the use of benzol in admixture with petroleum spirits has become common, and such a mixture is a very satisfactory fuel, in spite of its having a higher specific gravity.

On the other hand, if the air supply exceed about 15 lbs. per lb. of petro., there is an air excess and no CO appears in the exhaust; instead one gets free oxygen. The practical range is from about 11 air to 1 petrol, to 17 air to 1 petrol; recently the Royal Automobile Club has adopted as the standard for carburettors such a mixture as would give an exhaust containing about 1 per cent. of free oxygen; this prevents the presence of CO, and gives nearly the highest thermal efficiency and also nearly the maximum power. Maximum thermal efficiency usually occurs with a somewhat greater excess of air, and maximum power with a slight defect of air, due in this latter case to the higher mean pressure obtained by reason of the considerable expansion in the products of combustion with 'rich' mixtures. One lb. of petrol, occupying 4 cub. ft., requires for its complete combustion roundly 15 lbs. of air occupying 196 cub. ft. at 60° F.; the 16 lbs. of mixture thus occupies a volume of 200 cub. ft. at 60° F., and contains 2 per cent. by volume of petrol vapour—that is, assuming that the petrol is gasified, and not atomised.

Theoretical Efficiency of Petrol Engines.

The theoretical efficiency, E, of an engine operating on the constant volume cycle is—

where, $$E = 1 - \left(\frac{1}{R}\right)^{n-1}$$

R = expansion ratio.

If no heat is lost, then $n = 1{\cdot}45$, but in practice heat is lost during compression, with a result that the exponential n is reduced to the value of 1·38. Ricardo states that when heat leakage, frictional losses, and losses due to friction of gases have been allowed for, then $n = 1{\cdot}25$, so that the maximum efficiency obtainable in practice may be considered to be

$$E = 1 - \left(\frac{1}{R}\right)^{0{\cdot}25}$$

Cracking Process.

A very large proportion of the world's production of motor spirit is now obtained by cracking from heavier oils. The original Burton process has been largely replaced by the modern liquid-phase cracking plants of Dubbs and Cross. In these the oil is heated while travelling rapidly through tubes arranged in a furnace, and thence passes to a reaction chamber, where the cracking mainly takes place. In the Dubbs plant a pressure of 200 lbs. per sq. in. is maintained, while the Cross plant employs a higher pressure of 800 lbs. per sq. in.

The specific gravities and distilling temperatures of petrols are liable to be varied from time to time as the market conditions warrant. The increased demand for motor spirit during recent years has been to a large extent met by including such higher and lower boiling distillates in the motor spirit fraction. By subjecting the crude oil to high temperatures in the absence of air, frequently accompanied by high pressures, a decomposition of the more complex hydrocarbons is brought about. This action, which is technically known as 'cracking,' results in large yields of motor spirit. The motor spirit prepared in this way is rich in unsaturated compounds, possesses a characteristic odour, and is higher in specific gravity than the direct distilled petrol which comes over between the same temperatures.

Some of the petrol at present being imported into this country is naturally rich in benzene and toluene, and this is particularly the case with the Borneo spirit imported by the Shell group, and it has been found, both experimentally and in practice, that owing to the higher spontaneous ignition temperatures of benzene and toluene, mixtures containing these hydrocarbons do not so readily cause preignition or detonation in petrol engines. In view of this, petrol which does not naturally contain benzene has occasionally been mixed with benzene in order to decrease the liability to preignition.

PROPERTIES OF VARIOUS MOTOR SPIRITS (1931).

Initial boiling point is the temperature at which the first drop falls from the bulb of the thermometer when the latter is placed ½ in. below the outlet tube of flask.

Drop temperature is taken when the first drop leaves the end of the condenser.

Acid Coloration.—Acid has brick-red colour, and petrol separates out slowly.

Aromatic hydrocarbon content = 10·2 per cent. by weight.

Shell No. 1 Motor Spirit: Specific gravity, 0·754 at 15° C.

ENGLER DISTILLATION TEST: Initial boiling point, 34° C.

Drop per cent. .		53·5	67·0	78·0	86·5	92·0	95·0

Acid Coloration.—Acid only slightly discoloured, light brown, and petrol separates out almost immediately.

Aromatic hydrocarbon content = 21 per cent. by weight.

DETONATION.

High efficiency in petrol engines is best attained by employing very high compression ratios, but in practice it is found that a high compression ratio is accompanied by 'pinking' or 'knocking' when running at slow speeds with heavy loads when ordinary motor spirit is used. For such spirits the limiting compression ratio is about 4·5 to 1. Benzol is very much less prone to give this phenomenon of knocking, or detonation, and it permits of the use of a considerably higher compression ratio. The use of alcohol as a fuel permits of a compression ratio of as much as 7 to 1. Certain organic compounds have been found by Midgley & Boyd to be much more efficient than benzol in preventing detonation; for example, tetraethyl lead is 625 times as powerful as benzene. Fuel containing a minute proportion of this anti-detonating agent has been extensively used in the U.S., and is known commercially as 'ethyl gas.'

* *The Motor*, September 7, 1921.

BRITISH ENGINEERING STANDARDS ASSOCIATION. SPECIFICATION FOR MOTOR SPIRIT.*
(No. 121—1923.) (*Abstract.*)

General.

The liquid shall consist of hydrocarbons and be free from visible impurities.

Distillation.

The range of distillation as determined in the prescribed manner (I.P.T.) † shall conform to the following limits of temperature :—

When the liquid is distilled according to the standard method, the first-drop temperature indicated by the thermometer shall not exceed 55° C.

When 20 per cent. by volume of the distillate has been collected, the temperature indicated by the thermometer shall not exceed 105° C.

The whole of the liquid shall have distilled when the temperature indicated by the thermometer is 225° C.

Acidity.

The motor spirit shall be free from mineral acid.

Benzol.

Benzol had come into prominence before the war as an alternative home-produced fuel for the engines of motor vehicles, partly in consequence of the high price of petrol. Since the withdrawal of the restrictions on the use of benzol its use has become more general than before, though the motoring public do not yet fully appreciate its value as a fuel. Benzol is the commercial name for a mixture of hydrocarbons prepared by the distillation of coal tar, and also obtained by stripping the gas which is produced as a by-product from coke ovens. Commercial benzol consists almost entirely of a mixture of the hydrocarbon benzene (C_6H_6 : not to be confused with the petroleum fraction 'benzine') and the hydrocarbon toluene (C_7H_8). The usual commercial grades are '90 per cent. benzol,' which on distillation yields 90 per cent. of distillate at 100° C., and consists of approximately 70 per cent. benzene and 30 per cent. toluene, together with traces of the xylenes (C_8H_{10}), and '100 per cent. benzol,' which on distillation yields 100 per cent. of distillate at 100° C., and contains a higher proportion of the hydrocarbon bezene than 90 per cent. benzol.

There is little to choose between these two bodies as motor fuels, and provided they have been satisfactorily refined they are both preferable to pure benzene, as the mixtures do not so readily solidify in cold weather. Pure benzene solidifies at a temperature of + 6° C. (43° F.), and boils at 80·4° C. It possesses a specific gravity of ·88 at 15° C., and a gross heat value of about 18,090 B.Th.U.

Both commercial benzol and pure benzene possess very high temperatures of spontaneous ignition, and they will withstand compressions of about 200 lbs. per square inch in internal combustion engines without being affected by preignition. This property, together with the high specific gravity, accounts for the increased mileage per gallon obtained when using benzol as fuel instead of petrol. Benzol gives about 16 per cent. greater mileage than petrol, and also gives greater power to the engine. When changing over from petrol to benzol it is advantageous slightly to reduce the size of jet, though it is not absolutely necessary to make any modification. The colour of benzol for motor use should be perfectly clear and white, as yellowish colour indicates unsatisfactory refining. Certain bodies (mainly phenols, unsaturated hydrocarbons and sulphur containing compounds) are present in benzol when it is first prepared by distillation. These compounds are removed by treatment with caustic soda solution and afterwards with concentrated sulphuric acid. If these bodies are not removed there is a liability for the benzol to form resinous substances after prolonged standing, and also to form gummy deposits in the engine. Petrol undergoes a similar refining process during its preparation, but it is rare to meet with badly refined petrol nowadays, as the quality necessary for the motor spirit market is well understood by the petroleum firms. Petrol and benzol are perfectly soluble in each other, and can be used with satisfaction in the form of mixtures.

† Institute of Petroleum Technologists' method.

BRITISH STANDARD SPECIFICATION FOR BENZOL FOR MOTOR FUEL.*

Report No. 135, 1921 (*Abstract*).

(1) The term 'Benzole' shall denote a liquid consisting essentially of a mixture of benzene and not more than 30 per cent. by volume of toluene and xylenes.

(2) The material shall be a clear 'water white' liquid, free from undissolved water and other visible impurities.

(3) The specific gravity at 15·5° C. (60° F.) shall be not less than 0·870, and not more than 0·885.

(4) When 100 cc. of the material are distilled in the Standard Distillation Apparatus, at a rate of 7 cc. per minute, there shall distil at 760 mm. pressure—

Not less than	60 cc.	at or below		90° C. (194° F.).
„	„	75 cc.	„	100° C. (212° F.).
„	„	90 cc.	„	120° C. (248° F.).

The flask shall be dry at a temperature not exceeding 125° C. (257° F.). The temperature recorded by the thermometer shall be corrected for emergent stem and barometric pressure.

(5) The amount of non-volatile residue remaining when 20 cc. of the material are evaporated, and subsequently heated for two hours on a water bath at 100° C. (212° F.), shall not exceed 0·01 per cent. by weight.

(6) The coloration imparted to pure sulphuric acid (90 per cent H_2SO_4), free from nitric acid, when 90 cc. of the material are shaken with 10 cc. of the acid for five minutes at ordinary temperatures, shall be not more than a light brown.

(7) The total sulphur content shall not exceed 0·4 per cent. by weight. Freedom from acid and alkali.

(8) The material shall give no reaction for free acid or alkali when tested.

(9) The material shall give no reaction for sulphuretted hydrogen when tested.

(10) The freezing point shall not be higher than — 14° C. (7° F.).

Detailed descriptions of the methods employed in testing are given in the original publication.

Alcohol.

Although the heat value of alcohol per lb. is comparatively small, yet, on account of its heaviness as a vapour, and the small volume of air required to burn it compared with benzene and petrol, it yields 89·2 B.Th.U. per cub. ft. of mixture at 60° F. and atmospheric pressure. Moreover, the products of combustion are 6½ per cent. greater in volume than that of the unburnt mixture, with corresponding increase in the pressure developed. There is thus, thermally considered, not very much to choose between alcohol and petrol; alcohol is, in fact, an excellent fuel for suitably designed internal combustion engines, and is largely used in Germany, where its production is encouraged by the Government; in 1904 the price of alcohol in Germany was only 9*d.* per gallon when purchased in large bulk.

Mr. E. Bury of the Skinningrove Iron & Steel Works, Middlesbrough, has made trials of a process for the abstraction of ethylene from coke-oven gas and its recovery as alcohol, by which an average yield of 1·6 gallons per ton of coal carbonised is obtained. The application of this process to the whole of the 14,635,000 tons of coal reduced to coke in this country in 1918 would yield 23 million gallons of alcohol. It is calculated that the recovery of alcohol from the gas-works of the country on similar lines would yield 27 million gallons per annum.

Alcohol has a great affinity for water, and ordinary commercial qualities contain water in various proportions up to about 15 per cent.; in the following table estimated calorific values per lb. are given for alcohol-water mixtures containing from 0 to 50 per cent. of the latter ingredient.

* By permission of the British Engineering Standards Association.

Alcohol engines require larger carburettors and piping and valves than are necessary when petrol is used. As the latent heat of alcohol much exceeds that of petrol, especially when water is present in any considerable proportion, it is also necessary to well jacket the carburettor with hot water or exhaust gas, and to heat the in-going air to about 350°F. in order to ensure complete vaporisation. The cylinder-jacket water should also be kept nearly at 212°F.; too cool a cylinder results in imperfect combustion of the mixture, acetic acid, aldehyde, etc., being formed instead of CO_2 and H_2O only, with loss of efficiency and corrosion of internal parts. Starting up from cold is a special difficulty with alcohol, and engines are usually started with petrol, the alcohol being turned on when everything is well warmed up. Some engines are arranged so as to start and stop on petrol; in this way any traces of water or acid from the alcohol are cleared out of the cylinders and passages during the last few revolutions of the engine, and risk of corrosion of parts is thus avoided. Tests on a 14 horse-power 'Locomobile' alcohol engine of 8·28 ins. bore and 11·8 ins. stroke made by Prof. E. Meyer in 1901 showed a brake thermal efficiency of 24 per cent., using alcohol containing about 13 per cent. of water. The volume ratio of compression was 5·9. The cylinder-jacket water temperature was maintained at 208°F. The engine ran at 280 revs. per minute and developed 13·9 b.h.p. at full load.

COMPOSITE MOTOR SPIRITS.

Various mixtures containing alcohol, etc., have been put on the market as motor spirits. 'Natalite' is said to be a mixture of 40 per cent. of ether and 60 per cent. of alcohol (prepared from molasses), with traces of ammonia and denaturants, and is extensively used in South Africa. 'Discol,' used in this country, is a mixture of alcohol, heavy petrol, and benzol, containing about 50 per cent. of alcohol.

Coal Tars and Coal Tar Distillates.

When bituminous coal is subjected to destructive distillation, gas, coke, tar and ammonia are obtained. The physical and chemical properties of the tars are dependent upon the type of coal from which they originate, and the conditions which exist in the carbonising chamber. The appliances in use for the carbonisation of coal are mainly gas manufacturing plants and coke manufacturing plants. A few special plants exist which do not belong to either of these categories.

Gas manufacturing plants may be divided into three classes—horizontal retort, inclined retort, and vertical retort plants. Retorts of the first type yield tars of high specific gravity, 1·15 to 1·25, rich in free carbon, and viscous. Vertical retorts yield thin brown tars of low gravity (about 1·05), which are comparatively low in free carbon content and rich in aliphatic hydrocarbons. The tars from inclined retorts are intermediate between the products of horizontal and vertical plants in their chemical and physical properties.

Coke-oven tars are very variable, but usually approximate to horizontal retort tars in composition.

Tars from gas producers are generally too high in water-content to be of use as fuels.

Blast furnaces yield tars containing large quantities of ash which render them useless in the raw state.

Several processes for the low temperature carbonisation of coal have been advocated, but on large quantity of the tar, which is exceptionally suitable for fuel purposes, is available.

The majority of coal tars may be employed for boiler firing purposes. Tars from vertical retorts have been found suitable for use on both two and four cycle Diesel engines, providing that certain special adjustments or fittings are employed, large quantities of such tars being used in Diesel engines on the Continent. Some coke-oven tars are suitable for use in Diesel engines. The compositions of several British coal tars are given in the accompanying table :—

The volatile products obtained by the distillation of coal tar (mainly benzol and toluol) have been extensively used in automobile engines prior to the war. Creosote and anthracene oils are high boiling distillates of coal tars and are extensively employed for fuel purposes, both for external and internal combustion. The 'tar oil' sold for fuel is usually a mixture of both these above-mentioned fractions. Analyses of some tar oils, together with a petroleum residuum, and alcohol, are shown in the table on p. 2157.

Lignite Tars and Lignite Tar Distillates.

Lignite yields valuable liquid products by destructive distillation. The tar is of a butter-like consistency and possesses a specific gravity of ·860 to ·920. Its sole use in the raw state is as fuel for Diesel engines, for which purpose its richness in aliphatic hydrocarbons makes it behave similarly to petroleum. It therefore does not require either raised cylinder compressions or the use of an ignition oil.

Fuels for petrol engines and heavy oil engines can be obtained from lignite tar by distillation. Their properties are very similar to those of the corresponding fractions obtained from petroleum.

Tar oils were used in considerable quantities on Diesel engines in this country during the war period on account of the scarcity of petroleum. The difficulties encountered in burning tar oils are mainly due to their comparatively high spontaneous ignition temperature. The ignition of the fuel charge in a Diesel engine is dependent upon the temperature of compression, no special ignition device being provided. With the fuel oils derived from petroleum or shale it has been found that a compression pressure of 450 to 500 lbs. is sufficient to ensure regular ignition under starting conditions and at all loads. Whereas the spontaneous ignition temperature (in atmosphere of oxygen) of petroleum and shale oils is in the neighbourhood of 270° C., this value for tar oils is generally over 400° C.* As a result of the high ignition point engines will not start, or run at low loads, on tar oil unless special means are taken for raising the temperature of the air in the combustion space at the time of fuel injection. The more important methods adopted for this purpose are—(1) to heat the cycle air, blast air and fuel, (2) to increase the compression ratio, (3) to employ an ignition oil, and (4) to inject a small charge of tar oil prior to the main tar oil charge.

* Moore, *Jour. Soc. Chem. Ind.*, February 15, 1917, p. 109.

Heating of cycle air, blast air and fuel is difficult to effect under starting conditions and has a deleterious action on the fuel valve when running. The increase of compression necessitates a specially heavy design of engine to withstand the higher stresses on liners, cylinder cover, and bearings. To ensure certain starting on tar oils the compression would require to exceed 600 lbs. The starting difficulty may be overcome by running the engine on a petroleum oil before closing down and when starting. If the engines can be always maintained at half load or over, a compression pressure of about 550 lbs. per square inch will give good running.

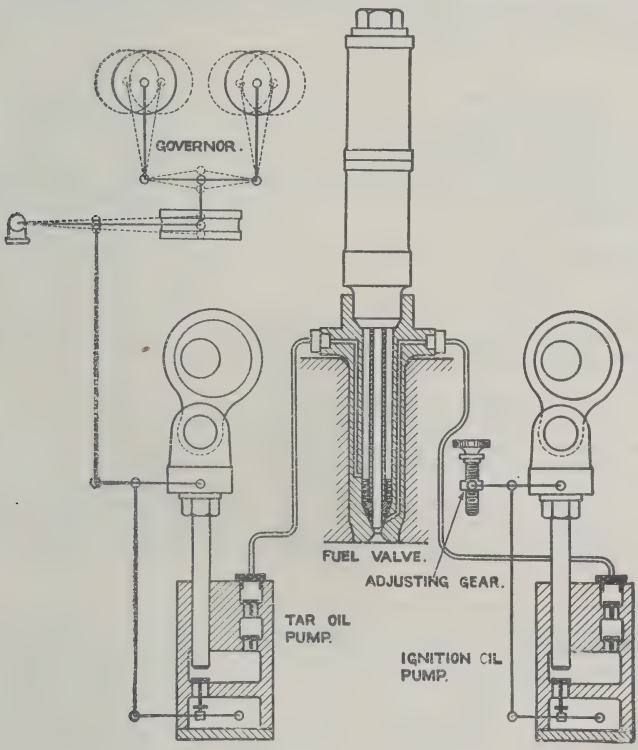

FIG. 37.—Diagrammatic Arrangement of Fuel Pumps for Tar Oil Engine.

The introduction of a small charge of a petroleum oil into the working cylinder prior to the main charge of tar oil has been found the most satisfactory method of burning tar oils. The ignition oil charge is pumped to the atomiser nearer the cylinder than the place where the main tar oil charge enters. Thus when the fuel valve opens the ignition oil is first injected into the cylinder and is immediately followed by the tar oil charge. The combustion of the ignition oil heats the air in the cylinder so that the temperature exceeds the spontaneous ignition temperature of the tar oil. The proportion of ignition oil is 6 to 8 per cent. of the total fuel at full load; at other loads the quantity of ignition oil remains practically constant, the proportion increasing to about 50 per cent. at no load. This method has been found to yield satisfactory results at all loads, and under starting conditions, with cylinder compression pressures of 480 to 500 lbs. per square inch. An arrangement of ignition oil gear as given in a paper by Mr. C. Day,* is shown in fig. 37. Devices have been designed to give a small charge of tar oil prior to the main charge

* Paper read before the Diesel Engine Users' Association, January 19, 1916.

of tar oil. The device is so arranged that the initial tar oil charge is not accompanied by any appreciable blast air, the expansion of which would reduce the temperature of the combustion space. Such devices are said to have given good results on the Continent, but are little used in this country.

In addition to the ignition question tar oils are particularly liable to form deposits in the atomisers of Diesel engines. A résumé of some experiences of burning tar oils on Diesel engines was given by Mr. G. Porter in a paper read before the Diesel Engine Users' Association, May 24, 1917. In this paper several specifications for tar oils for use in Diesel engines are given. An abstract of these specifications is appended below :—

Specifications of Tar Oil Fuel for Diesel Engines.

(1) Specification of the M.A.N. Company :—

The tar oil must be a distillate of coal tar.

The oil must flow freely at 61° F., and on being cooled down to 46·5° F. and resting in a place undisturbed by vibration no separation shall take place at this temperature within the space of half an hour.

The following constituents shall not be present in quantities greater than the stated percentages—

Ash	·05 per cent.
Sulphur	1·0 „

Proportions of water and coke residue not stated.

Per cent. insoluble in xylol ·2.

(2) Continental specification for tar oil quoted by Mr. C. Day in his paper on 'Tars and Tar Oils as Fuel for Diesel Engines' (January 19, 1916) :—

Tar oils must not contain more than a trace of constituents insoluble in xylol.

The water content should not exceed 1 per cent.

The coke residue should not exceed 3 per cent.

At least 60 per cent. of the oil should be distilled on heating up to 300° C. (572° F.).

The net calorific value should not be less than 15,840 B.Th.U. per pound.

The open flash point must not be below 65° C. (143·6° F.).

The oil must be quite fluid at 61° F.

(3) Specification of tar oil proposed by Mr. C. Day (January 19, 1916) :—

The tar oil must be a product of the distillation of coal tar. No product that has not undergone distillation must be present.

Per cent. insoluble in xylol . . .	Not more than		2·0
„ ash	„	„	0·08
„ water	„	„	2·5
„ coking residue	„	„	3·0

The oil must be liquid at 60° F. when maintained at that temperature for half an hour.

(4) Specification of tar oil by Mr. Batho (the Diesel Engine Users' Association, February 23, 1916) :—

Specific gravity—Between 1·0 and 1·1.
Viscosity—Generally 2° Engler.
Flash point—100° F. to 130° F.
Colour—One drop on white paper should show no black residue, as is the case with tar.
Lower calorific value—Between 15,800 and 16,500 B.Th.U. per 1 lb.
Ash—Should not exceed 1 per cent. (unburnt residue of tar oil is mostly harmless).
Water—Should not exceed 1 per cent.
Sulphur—·5 to 1 per cent.

The burning of raw tars on Diesel engines has been accompanied by the same difficulties as the burning of tar oils, but an additional trouble is encountered on account of the free carbon which is always present in raw coal tars.

Furnace Firing with Liquid Fuel.

Liquid fuel possesses many advantages over coal or other solid fuels for furnace firing. The advantages when using heavy petroleum oils may be briefly enumerated as follows :—

(1) Petroleum fuel oil possesses a gross heat value of approximately 19,200 B.Th.U., whilst the gross heat value of coal averages about 14,000 B.Th.U. This fact alone shows two pounds of oil to be about equivalent to three pounds of coal.

(2) In spite of its lower specific gravity, oil can be stored in less space than a corresponding weight of coal.

One ton of coal occupies about 43 cubic eet.
„ oil „ 40

For marine purposes oil is conveniently stored in ballast tanks and inaccessible places, which could not be utilised for coal bunkerage.

(3) Oil rarely contains more than 0·1 per cent. of ash, a negligible quantity, while coal may contain as much as 15 per cent. ash. This ash necessitates the removal of clinker from the fires, and besides involving expense it causes a serious loss of heat.

(4) Oil can be conveyed by pipe line, a cheaper, cleaner and more rapid method than any method of coal conveying.

This is of great importance in naval work.

(5) Oil firing does not involve so much manual labour and attendance charges which accompany furnace firing with solid fuel.

(6) A boiler fired with oil will raise about 30 per cent. more steam than the same boiler coal fired.

(7) The furnace doors can be kept closed when oil firing, thereby increasing the efficiency of the boiler and lessening the wear and tear on the boiler plates caused by frequently being chilled with cold air, as is the case when burning solid fuel.

(8) Boilers can raise steam much more quickly when oil fired, thus lessening stand-by charges.

(9) Boilers fitted for burning both solid and liquid fuel may be run on coal under normal conditions, while oil can be burned for peak loads, thus minimising the number of boilers in use.

1 lb. coal under favourable conditions raises 9 lbs. steam.
1 lb. oil under similar conditions raises 14½ lbs. steam.

It is essential that firing devices for liquid fuel should break the oil into an exceedingly fine state of division, so that the air can reach the oil readily and ensure speedy combustion.

The methods of breaking up the oil are :—

(1) By means of steam.
(2) By means of compressed air.
(3) By a high pressure on the oil, which is pulverised on passing through a fine jet.
(4) By means of mechanical breaking up in a pulverising chamber.

Steam Jets.

The majority of oil-burning installations used on land are operated by steam. Steam is always available at the face of the boiler, and at the same time steam burners, though not giving quite so high an efficiency as air burners, give a soft flame, which is less liable to injure the plates or tubes with which it comes into contact. For marine purposes there is a distinct disadvantage in the use of steam on the oil burners, as it causes the loss of a considerable quantity of water, which has to be carried in storage tanks or else has to be specially prepared by a distillation plant whilst at sea. This drawback does not apply to land installations, where plenty of water is usually available. Steam burners operate on a variety of principles, the majority of constructions being somewhat in the form of an injector.

The Kermode steam jet burners, which have met with much success on land service, are designed to impart a rotary motion to the gases by passing the oil through a helical groove. The steam is passed through an annular space surrounding the oil duct, and in addition to causing atomisation, it is used to induce an air current which assists in the combustion of the fuel.

With the Holden steam jet burner, fuel steam and air are passed through annular spaces, the centre of the burner being left open to facilitate cleaning.

Another principle used for pulverising oil by a steam jet is to allow the oil to trickle from a weir over a thin slit through which the steam is passing. This system is used in the common type of burner known as the 'Mexican trough.' A modification of this principle is also used in the Ajax burner, made by Meldrums Ltd.

Compressed Air Burners

The use of compressed air for pulverising purposes allows a higher efficiency on boiler-firing installations. At the same time the saving is not so great as might be anticipated, as the steam

or power used for driving the compressors is almost as great as the amount lost through steam burners. The flame has a higher temperature than that of the steam jet, and greater care must be taken to prevent it impinging on the plates. Some of the most recent types of compressed air burners will operate on air at low pressure (about 10 lbs. per square inch), and therefore do not necessitate costly air compressors, as they can be operated with complete satisfaction by low-pressure air from a rotary blower. Such burners are the 'White' burner, the 'J. Samuel White,' and one of the burners by Alldays & Onions.

The Oil Pressure System.

This is mainly used for marine purposes, and complete oil-burning installations on this principle are comparatively expensive, on account of the necessity for well-constructed and effective preheaters, filters, and the specially constructed fuel pumps.

In this type of burner the oil is forced through fine jets under a comparatively high pressure. Many burners are so constructed as to impart a rotary motion to the pulverised fuel (*e.g.* Korting burner). The pressure system, although expensive, is probably the most efficient of oil-burning appliances. The power consumed in driving the fuel pumps is almost negligible, and the combustion is excellent. The pressure system is meeting with much success in marine work at the present time. Good examples of this type of apparatus are made by the Wallsend Slipway Co., Kermode, Korting, and J. Samuel White & Co.

Mechanical Pulverisers.

It is possible also to pulverise oil by mechanical means, such as breaking the oil up in a squirrel cage. The rich oil-fog thus produced can then be treated as a gas and burned together with secondary air in the furnace. Installations of this type, however, have not met with much success, probably on account of their high initial cost.

Atomisers.

Holden's steam atomiser is shown by fig. 38; fig. 39 shows the Guyot atomiser used in the French Navy.*

Where boilers have the mixed coal and oil system, the oil is best atomised into the front of the furnace, parallel with the grate and about 10 ins. above it.

Where liquid fuel is used alone, the draught required is very small, because the greater part of the draught is always spent in overcoming the resistance of the fuel bed on the grate.

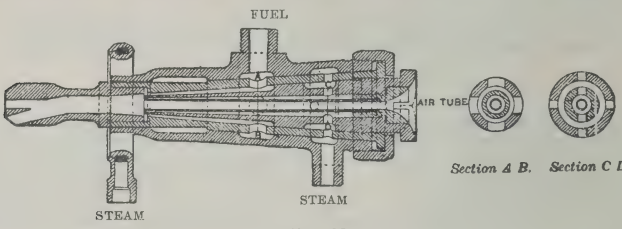

Fig. 38.

Whereas the calorific capacity of liquid fuel is roundly 20,000 B.Th.U. per pound, as compared with 15,000 for best coal, the commercial value is more nearly as 2 : 1, because liquid fuel can be burned perfectly with very little excess of air, and the temperature in the furnace is higher, the boiler efficiency is better, the boiler being also cleaner, and there are no expenses for removal of ashes and for flue cleaning. About 15½ pounds of air are required chemically to burn one pound of liquid fuel, or say 200 cubic feet of air. In the mixed system of coal and oil firing, a large excess of air may be admitted through the coal fire, and will be used by the oil, which is atomised above the fire.

In locomotives the blast-pipe may be much enlarged for liquid fuel so as to soften the draught. The Macallan variable blast-cap is used on the G. E. Section of the L. & N.E. Railway for this purpose. The flow of oil requires special regulation. Exactness is secured by such devices as a stop-cock, in which the hole through the plug is square and placed diagonally, thus admitting of fine regulation.

* From 'Liquid Fuel and its Combustion,' by W. N. Booth.

To be successful, the burning of oil fuel must follow the lines of successful bituminous coal combustion, viz., air mixture, space, and temperature; hence the need for refractory brick linings to keep off the too early chilling effect of cold plates. In steam raising, liquid fuel has a higher percentage efficiency than solid fuel, because less excess of air need be employed; furnace temperature is higher, causing higher efficiency of heating surface, which is also cleaner. There is a large saving in labour of stoking, cleaning, ash removal, etc., but perhaps greater expense in firebrick renewals.

Liquid fuels can be burned by means of mechanical burners, without steam or air spraying, if heated to not much more than 140° F., and forced through a whirling jet nozzle at a pressure of not less than 40 lbs. per sq. in. and, with benefit, up to 150 lbs.

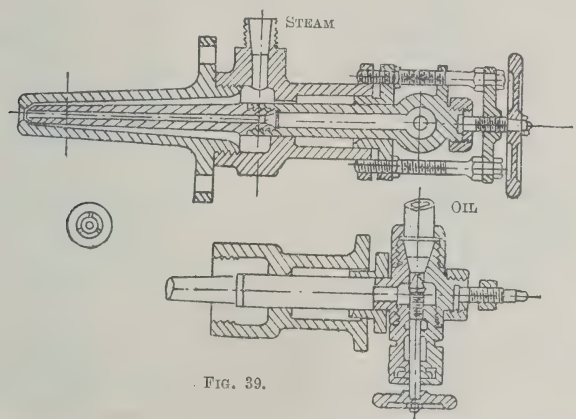

Fig. 39.

For general purposes ashore, high-pressure steam is a more satisfactory spraying agent than air. At sea, for forced draught conditions, the United States Navy Liquid Fuel Board consider air to be the best medium, especially as it avoids the otherwise inevitable loss of fresh water.

In the ss. 'Nebraskan,' oil heated to 175° F. was atomised by air of 1½ lb. pressure. The oil had a pressure itself of 15 lbs., and a very fine spray resulted; the air was heated. Retarders were necessary in the 3-in. tubes of the Scotch boilers to enable the heat of the gases to be utilised by retarding the flow, or probably by mixing up the gas.

Wallsend-Howden Patent Liquid Fuel Burning System.

In this system the liquid fuel is injected into the furnaces under pressure by means of special of fuel pumps, these pumps being fitted in duplicate so that one can act as a stand-by in cases of breakdown to the working pump. On its way to the burners the liquid fuel is passed through strainers and heaters in which it is thoroughly filtered and then heated to the correct temperature.

The oil is forced into the furnace in the shape of a conical spray of exceeding fine particles, which burst into flame at a distance of six to eight inches from the nozzle. The flame being conical, and there being no fire-bars fitted in the furnace, the whole circumference of the furnace is available for heating surface. This is a great advantage in the ordinary multitubular boiler, as the lower portion of the boiler becomes heated sooner than would be the case with coal, and consequently the circulation of the water in the boiler is improved. Moreover, as the lower portion of the boiler is heated up uniformly with the upper portions, and as there is no inrush of cold air, since there are no furnace doors to be opened, there is practically none of that straining action which results from unequal expansion and contraction, due to rapid changes consequent on the opening of the door in coal stoking.

In the improved construction of the furnace front arrangement (fig. 40), which constitutes the principal feature of the arrangement, each of the oil fuel spraying nozzles projects through a baffle plate or the front plate of the casing into an air trunk having lateral openings at its outer end. This air trunk projects concentrically with a second air trunk carried by the furnace front, and the annular space between the inner and outer air trunks is fitted with deflectors constructed in such a manner as to give the air passing through the annulus a spiral motion. One result of

this arrangement is, that the openings for the supply of air are so disposed that direct radiation of heat from the furnace is prevented. The admission of air through the second or outer air trunk keeps the outer casing cool, and hence radiation from this part is reduced to a minimum. A feature of the arrangement is the small amount of brickwork required.

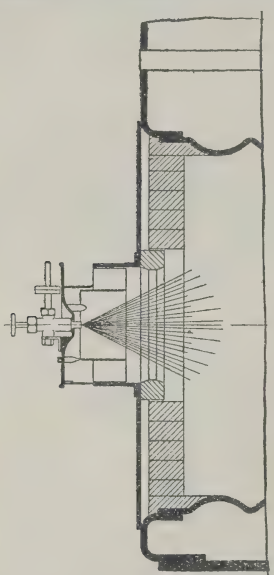

FIG. 40.—Arrangement for Working under Natural Draught or Closed Stokehold Draught.

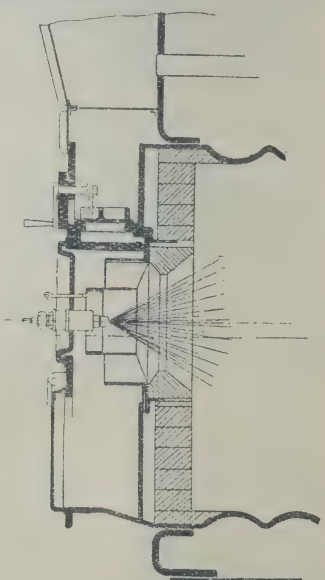

FIG. 41.—Arrangement for Working under Howden's Forced Draught.

With this system steam can be raised on any boiler from the start by means of oil fuel. This advantage is obtained by means of a special design of auxiliary heater and pump.

The Wallsend System is specially adapted for burning oil in conjunction with coal.

When burning liquid fuel on this system with Howden's Forced Draught, fig. 41, 16·22 pounds of water were evaporated (from and at 212° F.) per pound of oil burnt. The calorific value of the liquid fuel was 18,770 British Thermal Units, giving a boiler efficiency of 83·9 per cent.

THORNYCROFT OIL FUEL SYSTEM.

In this system, fig. 42, the oil is sprayed under pressure into the furnace by means of a special patent sprayer having both edges of supply grooves tangential to the whirling chamber, the spray being produced within a steel cone of special construction which introduces and mixes the air and the oil-spray in such a manner as to produce perfect combustion. The system can be applied to either water-tube or marine type boilers. Water-tube boilers can be arranged for either oil only or coal combined with oil.

The oil, which may be of any crude description such as Texas, Borneo, Mazout, or Shale, is stored in tanks in any part of the ship, and is drawn to the stokehold by a pump which forces it through the necessary strainers and the tubular steam-heater to the sprayers.

Lighting up is effected with crude oil by means of a U tube and hand-pump. Steam can be raised in from half to three-quarters of an hour.

When fitted in conjunction with Thornycroft boilers of latest design and fairly large size the makers are prepared to guarantee that the equivalent evaporation will be at least 16 lbs. of

water from and at 212° F. per lb. of oil per hour, if the rate of evaporation does not exceed 4 to 5 lbs. per sq. ft. from and at 212°, and they can guarantee a maximum output of 18½ lbs. per sq. ft. from and at with an evaporation of 14 lbs. per lb. of oil from and at. This rapid rate of evaporation has no detrimental effect on the boiler if the arrangement is properly designed,

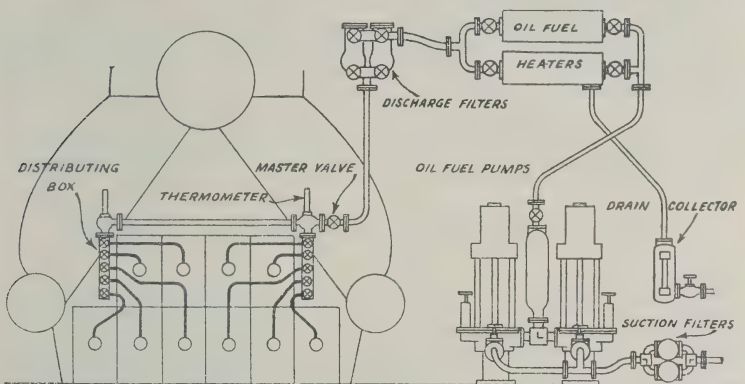

FIG. 42.—The Thornycroft Oil Fuel System.

while the combustion is smokeless up to moderate powers, and smoke is only just visible at the highest powers. These results enable very large powers to be developed on small weight, and with the highest efficiency, and at small cost. The number of men necessary for a stokehold developing 16,000 h.p. is only 3.

THE PRIOR OIL FUEL SYSTEM.

The burner in this system (which has been introduced by the Akt. Ges. Prior, of Lugano) has a trough-like form and the oil flows into it by gravity. Air for burning the fuel is supplied through rows of holes drilled in the hollow walls. By varying the positions of these air apertures and the shape of the trough the burner can be adapted, it is claimed, for widely different services.

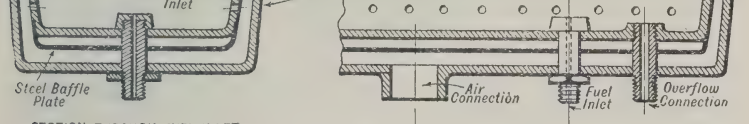

FIG. 43.

The oil to be burned is fed by gravity, and an air pressure of about 8 in. water column is provided by a fan. The burner itself (fig. 43) consists of an open cast-iron trough with hollow walls which serve as air-heating spaces. The oil is delivered at the bottom of the trough through one or more inlet connections with approximately a $\frac{3}{16}$ in. aperture, terminating about $\frac{1}{2}$ in. above the bottom of the trough. There is also an oil overflow connection, which is lower. Air to support the combustion of the oil is supplied through two rows of staggered holes which are arranged in the sides of the trough, and are given such an angle that the air jets tend to pick up the gasified fuel from the bottom of the burner. Below the bottom of the trough a steel baffle plate is welded on to the inner wall for the purpose of preventing undue heat from penetrating down to the air preheating spaces.

The burner is lighted by placing a piece of oily waste in the trough and turning on the fuel supply with a reduced quantity of air. Starting from cold the time taken may be only four to five minutes before the flame is brought up to a normal working height. If the burner has been

previously in use the lighting-up period will be still shorter, while with a thoroughly hot burner the flame can be shut off and instantaneously re-ignited. A feature of the burner is the way in which the height of the flame can be regulated from only a few inches or about the height of the trough, to its full height of about 3 ft. Under varying loads a bright and smokeless flame can be maintained. An indexed fuel cock enables a constant flame height to be maintained without any attention on the part of the attendant.

A wide variety of oil fuels has been tested with the arrangement, and it has been found possible to burn heavy Mexican oils without trouble. With such oils there is a slight asphaltic deposit on the inner surfaces of the burners, which, however, can be easily removed. When using ordinary furnace oils the deposit is of a sooty nature and is dispersed automatically by the action of the flame.

Air Required for Oil Fuel Combustion.

The amount of air required in practice at normal atmospheric temperature for the combustion of 1 lb. of oil fuel, is from 250 to 450 cub. ft.; this is 1·6 to 2·5 times the theoretical amount.

British Admiralty Specification for Oil Fuel for the Navy.

(*Abstract.*)

'The oil fuel supplied shall consist of liquid hydrocarbons, and may be either (*a*) shale oil or (*b*) petroleum, as may be required, or (*c*) a distillate or a residual product of petroleum, and shall comply with the Admiralty requirements as regards flash-point, fluidity at low temperatures, percentage of sulphur, presence of water, acidity, and freedom from impurities.

'The flash-point shall not be lower than 175° Fahr., close test (Abel or Pensky-Martens). The proportion of sulphur contained in the oil shall not exceed 3·00 per cent. The oil fuel supplied shall be as free as possible from acid, and in any case the quantity of acid must not exceed 0·05 per cent., calculated as oleic acid when tested by shaking up the oil with distilled water, and determining by titration with decinormal alkali the amount of acid extracted by the water, methyl orange being used as indicator. The quantity of water delivered with the oil shall not exceed 0·5 per cent.

'The viscosity of the oil supplied shall not exceed 2,000 secs. for an outflow of 50 cubic centimetres at a temperature of 32° Fahr., as determined by Sir Boverton Redwood's standard viscometer (Admiralty type for testing oil fuel). The oil supplied shall be free from earthy, carbonaceous, or fibrous matter, or other impurities which are likely to choke the burners.'

British Admiralty Specification for Oil Fuel for use in Diesel Engines.

'Quality:—The oil fuel supplied shall consist of liquid hydrocarbons, and may be either (*a*) shale oil, or (*b*) petroleum, as may be required, or (*c*) a distillate, or a residual product of petroleum, and shall comply with the Admiralty requirements as regards flash-point, fluidity at low temperatures, percentage of sulphur, presence of water, acidity and freedom from impurities.

'The flash-point shall not be lower than 175° Fahr., close test (Abel or Pensky-Martens). (This compares with a flash-point of 200° Fahr. in 1910.)

'The proportion of sulphur contained in the oil shall not exceed 3·00 per cent. (as against 0·75 in 1910).

'The oil fuel supplied shall be as free as possible from acid, and in any case the quantity of acid must not exceed 0·05 per cent., calculated as oleic acid when tested by shaking up the oil with distilled water, and determining by titration with decinormal alkali the amount of acid extracted by the water, methyl orange being used as indicator. (In 1910 it was required that the oil should be free from acidity.)

'The quantity of water delivered with the oil shall not exceed 0·5 per cent.

'The viscosity of the oil supplied shall not exceed 2,000 secs. for an outflow of 50 cubic centimetres at a temperature of 32° Fahr., as determined by Sir Boverton Redwood's standard viscometer (Admiralty type for testing oil fuel).

'The oil supplied shall be free from earthy, carbonaceous, or fibrous matter, or other impurities which are likely to choke the burners.

'The oil shall, if required by the inspecting officer, be strained by being pumped on discharge from the tanks, or tank steamer, through filters of wire gauze having 16 meshes to the inch.

'The quality and kind of oil supplied shall be fully described. The original source from which the oil has been obtained shall be stated in detail, as well as the treatment to which it has been subjected and the place at which it has been treated. The ratio which the oil supplied bears to the original crude oil should also be stated as a percentage.'

SPECIFICATIONS FOR BRITISH STANDARD FUEL OILS FOR HEAVY-OIL ENGINES.*
No. 209, 1924 (*Abstract*).

Item.	Specification A. B.S. Fuel Oil No. 1 for Heavy-Oil Engines.	Specification B. B.S. Fuel Oil No. 2 for Heavy-Oil Engines.	Specification C. B.S. Fuel Oil No. 3 for Heavy-Oil Engines.	Specification D. B.S. Fuel Oil No. 4 for Heavy-Oil Engines.
Flash point (closed) .	Not to be less than 150° F.	Not to be less than 150° F.	Not to be less than 150° F.	Not to be less than 150° F.
Hard asphalt content .	Not to exceed 0·5 per cent.	Not to exceed 2 per cent.	Not to exceed 4 per cent.	Not to exceed 12 per cent.
Ash content . .	Not to exceed 0·01 per cent.	Not to exceed 0·05 per cent.	Not to exceed 0·05 per cent.	Not to exceed 0·05 per cent.
Viscosity (Redwood No. 1 at 100° F.) . .	Not to exceed 75 secs.	Not to exceed 250 secs.	Not to exceed 750 secs.	Not to exceed 1,500 secs.
Water content . .	Not to exceed 0·5 per cent.	Not to exceed 1 per cent.	Not to exceed 1 per cent.	Not to exceed 1 per cent.
Cold test	Oil to remain liquid at 20°F.	Oil to remain liquid at 35°F.	Oil to remain liquid at 40°F.	Oil to remain liquid at 45°F.

NOTE 1.—It is desired to call attention to the fact that the Admiralty's Specification for Fuel Oils demands a flash point of not less than 175° F. for all fuel oils. The Admiralty's requirements as regards the other conditions specified for fuels for heavy-oil engines are met by the Specification A given above, and to a less extent by Specification B, but not by Specifications C and D.

NOTE 2.—Fuel Oils purchased to these specifications will have a gross calorific value of not less than the following :—

B.S. Fuel Oil No. 1, 19,000 B.Th.U.'s per lb. B.S. Fuel Oil No. 3, 18,750 B.Th.U.'s per lb.
" " No. 2, 19,000 " " " " No. 4, 18,500 " "

Special Oil Mixtures used for External Combustion.

PITCH-CREOSOTE MIXTURES.

Recently the use of mixtures of pitch and coal tar creosote has become common for furnace firing. The pitch creosote oils are marketed in three grades containing 25 per cent., 50 per cent., and 75 per cent. pitch respectively. As pitch is but little lower than creosote in heat value, and generally commands about half the price, there is a pronounced economic advantage in burning pitch mixtures wherever possible.

PETROLEUM-TAR MIXTURES.

The addition of tar or tar products to heavy petroleum oils causes a thick semi-solid deposit of pitch to separate, and this has till recently prevented the use of such mixtures. This difficulty has recently been overcome by the use of emulsifying agents which are capable of maintaining the constituents in a state of emulsion for prolonged periods.

COAL DUST-PETROLEUM MIXTURES.

The U.S. Navy authorities have met with success in preparing fuel mixtures from very fine coal dust mixed with petroleum fuel oil. The coal is prevented from settling by the action of emulsifying agents. Such oils are claimed to have given satisfaction for boiler firing on the U.S. warships.

Safety in Use of Oil Burners.

Serious accidents to engineers and firemen have frequently occurred from the practice of improper methods of lighting and handling oil fires.

In starting a new fire the steam should be turned on and the bypass opened in order that the oil and steam passage may be cleaned out and warmed up. The bypass should then be closed and the steam shut off. Then the damper must be opened ; on no account try to start a fire with a damper closed. Next light a torch or bunch of oily waste and place about 10 ins. to 12 ins. in front of the burner, turn on a small amount of steam (just enough to carry the oil from the burner tip to the torch) and crack the oil control valve a little. As it generally takes some little time for the oil to fill the burner passage, do not turn on more fuel but wait until the passage is filled, when the fire will light easily.

* By permission of the British Engineering Standards Association.

The moment the fire is out, either intentionally or accidentally, the oil should be shut off and the door opened. After a few minutes the gases (which are violently explosive) will have passed off and the fire may be rekindled.

Many authorities insist on the installation of valves which shut off the oil automatically if the flame goes out for any reason, and such valves should be so arranged that they cannot re-open automatically, but must be reset by hand. *The Drayton Regulator & Instrument Co., Ltd.*, supply patented valves of this description.

In regulating a fire the attendant should hold the door open just enough to enable him to watch the flame and be in a position to duck his head in case of a flare back. To increase the fire the oil valve should be operated first, then the steam turned on until the flame is clear. If not enough steam is used, the flame will appear red and smoky ; too much steam will cause the fire to look ragged and will have a tendency to extinguish it. In reducing the flame the steam is throttled down first, then the oil is reduced.

Once the fires have been set, they may be regulated over quite a range by increasing or decreasing the pressure applied to the oil supply without opening the fire-door or changing the steam supply. This can be done by manipulating the pump throttle or a bypass valve between the suction and discharge lines.

When extinguishing a fire, the flame should be cut down as low as possible ; then by opening the bypass immediately after shutting the oil valve, the oil passage will be blown out without danger, as the flame will not be extinguished until the passage is clear.—*A. C. McHugh.*

Automatic Regulation of Oil Burners.

The operation of oil burners can be made completely automatic by using in steam boilers the steam pressure, in water boilers the water temperature, and in furnaces the furnace temperature, for controlling automatic oil and steam or air valves. When air from an independently driven compressor or blower is used for atomising, it is important to provide automatic means for shutting off oil in case of failure of air supply, in order to avoid explosions.

For automatic control, oil must be kept at a constant temperature by automatically controlling the steam coil or electric heater in an oil-heating tank, otherwise control on account of viscosity changing with temperature is rendered difficult.

The Drayton Regulator and Instrument Co., Ltd., West Drayton, supply complete automatic regulating outfits.

Notes on Oil Fuel.

At a large London factory at which some Lancashire boilers were converted from coal to fuel oil firing, the water evaporation per lb. of coal, having a calorific value of 11,451 B.Th.U., was 7·22, whereas when working with the pressure system of oil burning, using an oil having a calorific value of 18,750, the evaporation per lb. of oil reached 14·44 lbs. The quantity of water evaporated per sq. ft. of heating surface with coal was 3·3 lbs., whereas, according to Mr. A. F. Baillie in a paper read before the Manchester Association of Engineers, the quantity evaporated with oil was over 7 lbs., thereby increasing the boiler rating by over 100 per cent.

In most engines of the hot-bulb type, oil fuel commonly known as gas oil or residuum is employed, this having a specific gravity of between 0·86 and 0·9. In some motors Tarakan crude oil has been used with success, whilst the other Mexican fuel oil, in spite of its relatively high percentage of sulphur, has operated very successfully. Paraffin is, of course, also suitable for these motors, but owing to its high price it is not often made use of.

Oil fuel heaters should be opened up and cleaned out periodically. In the operation of the average plant this should be done at intervals of not less than three months. Deposits of carbonised oil and other impurities quickly lower the efficiency of the heater by preventing the passage of the heat from the steam through the heater walls to the oil.

The fuel oil of oil-fired boilers is often maintained at too high a temperature. The best results are obtained where the oil is at a temperature just sufficient to insure proper and complete atomization. If too hot, the oil tends to turn into vapour and the burners puff and feed irregularly.

GASEOUS FUELS.

The more important gaseous fuels used commercially are generally mixtures. The combustible gases found in such mixtures are hydrogen, carbon monoxide together with the three hydrocarbons—methane, ethylene, and acetylene—also higher hydrocarbons of the series of which these are examples, together with benzene vapour, and occasionally other hydrocarbons.

Calorific Values, etc., of Gaseous Fuels.

In the table, p. 2169, the calorific values per lb. of the usual fuels are given, together with the weight of the products of combustion, both when burnt in pure oxygen and also when burnt in dry air. The ' higher value ' is that obtained when the water produced in the combustion is considered as having been condensed to the liquid condition, thus yielding up heat at the rate of about 970 B.Th.U. per lb. produced.

Usually in calculations relating to internal combustion engines it is found more convenient to deal with the volume rather than the mass of the gaseous mixture ; accordingly in the

Fuel. 1 lb. of :—	Sp. Gr. (H = 1).	Burnt to :—	Combustion per Lb. of Fuel.					Heat of Combustion in B.Th.U. per Lb.

† Of mixture with air. * Lower values.

Hydrogen.

From the above table it will be noted that a hydrogen-air mixture contracts after combustion to only ·853 of its initial volume, the pressure of the explosion being correspondingly reduced. Further, notwithstanding the very high calorific value of hydrogen *per pound*, its excessive bulkiness results in a heat evolution of only 82 B.Th.U. *per cubic foot* of its admixture with air at 60°F. and atmospheric pressure. Hydrogen-air mixtures are also very sharply explosive and trouble is experienced in engines from pre-ignition at the compression pressures usual in practice when hydrogen is present in large proportion in a gaseous fuel. Thus it is clear that hydrogen alone would be a comparatively poor and very troublesome fuel to employ for power purposes, though its presence is often beneficial in conferring sufficiently prompt inflammability upon dilute mixtures of other gases. For heating purposes a large hydrogen content is advantageous on account of the high temperature obtained in its combustion. Hydrogen constitutes about 45 per cent. by volume of modern coal gas, on the average.

Marsh Gas.

Marsh Gas (Methane) is an excellent fuel for power purposes ; it has a greater heat value per cubic foot of air mixture than hydrogen, and the volume of the products of combustion is equal to that of the mixture before combustion.

The 'natural gas' so largely used in the United States consists principally of marsh gas, that of Olean (N.Y.), for example, containing no less than 96½ per cent. of this constituent. In 1908 more than 100,000 horse-power was developed by engines operated by natural gas in the United States; the gas usually issues from the wells at high pressure, occasionally approaching 1,000 lbs. per sq. in. The Snow engine of the N.Y. & Penn. Traction Co. at Olean is supplied by natural gas issuing at a pressure of 200 lbs. per sq. in., which is reduced down to 1·8 lb. per sq. in. before being admitted, mixed with air, to the engine. With natural gas compression pressures of 150 lbs. per sq. in. are common, and mean effective pressures of 80 lbs. per sq. in. are often attained.

Acetylene.

Acetylene has so far been but little used as a fuel for internal combustion engines. It is very violently explosive when mixed with air, and owing to its endothermic nature the pressure developed is unusually high.

The range of explosive mixtures with air is also considerable; Grover found that at atmospheric pressure explosive mixtures were produced with one volume of acetylene to from 4 to 18 volumes of air; at a compression of three atmospheres even a 30 : 1 air-acetylene mixture was found to be explosive.

Acetylene is soluble in water to the extent of 1·1 volume; in alcohol to about 6 volumes; while acetone at 60°F. and atmospheric pressure absorbs about twenty-five times its volume of the gas, and at a pressure of about 180 lbs. per sq. in., about 300 volumes. A solution of acetylene in acetone contained in a porous matrix under a pressure of 150 lbs. per sq. in., is sold commercially as dissolved acetylene ('D. A.'); the 'D. A.' cylinders contain 100 times their own volume of acetylene at 60°F. and ten atmospheres. Commercial calcium carbide on addition of water usually yields about 4½ cubic feet of acetylene per lb.

If bubbled through petrol, acetylene gas becomes heavily 'carburetted'; 100 cubic feet of acetylene thus treated will produce about 150 cubic feet of 'carburetted' acetylene. According to Dr. Caro, as a heating agent this exceeds pure acetylene about in the ratio of 3 : 2.

Used as a fuel for internal combustion engines some remarkable results have been obtained with acetylene. Some early tests on a 2 h.p. engine showed that only 8¾ cub. ft. of the gas were required per b.h.p. hour, as against 35 cub. ft. of coal gas. In another case 6·35 cub. ft. of acetylene yielded 1 b.h.p. hour. And with a 6 h.p. engine using a 20 : 1 mixture, and a compression pressure of 115 lbs. per sq. in., Cuinat found that only 6·26 cub. ft. of acetylene were consumed per b.h.p. hour, the consumption by volume of coal gas being about three times as great. Specially designed acetylene engines of from 1 to 10 b.h.p. are built; these are mainly employed in pumping water for the generators of large village installations. The average consumption is about 7 cub. ft. of acetylene per b.h.p. hour, costing about 2¼*d.*; it is thus an expensive fuel for power purposes, as at present produced.

Several types of acetylene self-starting devices for the engines of motor vehicles have appeared during recent years, but unless caution be exercised in their use the extreme suddenness and violence of the starting explosion may result in damage to piston or cylinder.

See also Index.

Carbon Monoxide.

Carbon Monoxide yields the large return of 95·2 B.Th.U. per cubic foot of mixture with air, notwithstanding its low calorific value per lb.; this results from its weight being fourteen times that of hydrogen. The products of combustion occupy, however, only 0·835 of the volume of the original mixture; it is the principal combustible constituent of producer and blast furnace gas. Carbon monoxide is extremely poisonous, forming with the red corpuscles of the blood a stable chemical compound of a bright red colour termed carboxyhæmoglobin; care must always be taken to prevent any leakage of the gas into the atmosphere, and all engine and producer houses should be freely ventilated.

Olefiant Gas.

Olefiant Gas (Ethylene) is usually present to a small extent (up to about 4 per cent. by volume) in coal gas, and is a valuable producer of heat.

Owing to Government restrictions on the use of petrol during the war, many trials were made in the use of coal gas as a fuel for motors designed for the use of liquid fuels. Large gas-proof bags have been attached to the roofs of taxi-cabs, or placed underneath motor buses, and good running obtained by filling up with coal gas at frequent stopping stations. Needless to say, the mileage of such an arrangement is very limited; otherwise its performance is quite satisfactory, and, at present prices, considerably more economical than the use of petrol.

GASEOUS FUELS EMPLOYED IN GAS ENGINES.

1. Natural Gas.
2. Coal Gas.
3. Coke-oven Gas.
4. Acetylene Gas.
5. Producer Gas.
6. Blast Furnace Gas.

1. NATURAL GAS.

Natural Gas.—Large quantities of natural gas are evolved in most petroleum oilfields. The composition of the gas varies in different localities, but it always contains a high percentage of methane. The net calorific power is usually 750 to 950 B.Th.U. per cubic foot. It is used in gas engines and for heating and illuminating purposes.

2. COAL GAS.

Coal Gas is still almost exclusively used in the smaller sized stationary gas engines, especially in towns ; it is an admirable fuel for internal combustion engines of any size, however large, but its use for considerable powers is usually precluded by its relatively high cost. The introduction of the Welsbach mantle, and the largely increased use of gas for domestic heating and cooking, has enabled the gas companies within recent years to supply a gas of lower intrinsic calorific power than formerly at less cost to the consumer, and this reduction in cost has done much to encourage its use for pow.. purposes.

Calorific Power of Coal Gas.

Since the introduction of the Gas Regulation Act in 1920 the gas undertakings in Great Britain ceased to operate on official standards of candle power and are now subject to penalties in default of maintaining their respective standards of calorific power. The choice of calorific power of the gas which is distributed is left in the hands of individual undertakings, thus a wide range of quality is found throughout the country. When utilised in gas engines the factor of calorific power plays an important part, so that the operating data and adjustment of the engine must depend largely on the quality of the gas supply in any particular district. In general, it may be said that the calorific power of the gas supplied by undertakings in the country varies between 470 and 500 B.Th.U. per cubic foot, but there are a few outstanding exceptions, as, for example, the South Metropolitan Gas Company of London which distributes a gas of 560 B.Th.U. per cubic foot, and the Nuneaton Gas Company whose standard is 280 B.Th.U.

CALORIFIC STANDARDS.

	Calorific value of gas.
London (Gaslight & Coke Company)	500 B.Th.U. per cu. ft.
,, (South Metropolitan Gas Company)	560 ,, ,, ,,
,, (Commercial Gas Company)	500 ,, ,, ,,
,, (Wandsworth Gas Company)	470 ,, ,, ,,
,, (South Suburban Gas Company)	500 ,, ,, ,,
,, (Tottenham Gas Company)	500 ,, ,, ,,
Manchester	450 ,, ,, ,,
Liverpool	475 ,, ,, ,,
Birmingham	500 ,, ,, ,,
Bristol	480 ,, ,, ,,

So far as the composition of towns' gas is concerned, it is not possible to lay down any arbitrary figures for the reason that the ultimate analysis varies not only in different localities, but it varies to some degree even in the same locality in accordance with the proportion of water-gas which is added to the mixture of coal-gas and water-gas distributed. As a general guide, however, the analysis given below represents the composition of a normal straight coal-gas having a calorific power of 520 B.Th.U. per cubic foot.

Composition of 520 B.Th.U. Coal-Gas.

	Per cent. by Volume.
Hydrogen	47·0
Methane	27·5
Unsaturated hydrocarbons	3·5
Carbon monoxide	7·75
Carbon dioxide	3·5
Nitrogen	10·5
Oxygen	0·25
	100·00

The gas supplied to-day by nearly all the principal undertakings consists, however, of a mixture of from 75 to 80 per cent. of straight coal-gas (of above analysis) and 20 to 25 per cent. of either blue or carburetted water-gas. In this case the typical composition will be represented by the following analysis :—

Composition of Mixed Gas consisting of 80 per cent. Straight Coal-Gas and 20 per cent. Blue Water-Gas. (480 B.Th.U.)

	Per cent. by Volume.
Hydrogen	48·0
Methane	22·2
Unsaturated hydrocarbons	2·8
Carbon monoxide	13·8
Carbon dioxide	3·7
Nitrogen	9·3
Oxygen	0·2
	100·0

It is important for the gas-engine user to bear in mind that in recent years it has been established that one B.Th.U. will always give the same service irrespective of the quality or concentration of the mixture. In other words, from the point of view of efficiency a poorer mixture (say, 400 B.Th.U.) can be utilised as efficiently as a rich one (say, 550 B.Th.U.) so long, of course, that combustion is always complete. Proper adjustment depends, therefore, on the variation of the air supply in accordance with the quality of the gas in any particular locality. The volume of air theoretically just necessary for complete combustion may be estimated by aid of the second table on page 2170.

Increased economy in consumption is obtained by using mixtures of gas with such excess of air, or other gases, that only about 50 B.Th.U. are introduced per cub. ft. of piston displacement for cylinders up to about 20 ins. diameter, while for larger cylinders (30 ins. dia. and above) the figure must be reduced to 40 or even 35 B.Th.U. in order to avoid overheating troubles.

When excess of oxygen is present in the mixture, practically no carbon monoxide is found in the exhaust; with deficiency of oxygen, or irregularity in the mixture, the contrary is to be expected.

Usually in practice the volume ratio of mixture employed is from 7 to 10 of air to 1 of coal gas; the richer mixture gives a greater power output, the more dilute a greater economy in consumption of gas per horse-power hour.

3. COKE-OVEN GAS.

Coke Oven Gas is produced in large quantities at many collieries in the process of manufacture of coke for metallurgical purposes; its composition varies somewhat widely, but it is usually specially characterised by its large content of hydrogen; this renders it peculiarly liable to pre-ignite on compression, and lower compression pressures than usual are generally adopted (90 to 100 lbs. per sq. in. only) on this account when coke-oven gas is used for power purposes.

Recently, however, the pre-ignition difficulty has been entirely overcome by Sir Dugald Clerk's patented process of introducing from 10 per cent. to 20 per cent. by volume of cooled *exhaust gas* into the inlet pipe; the addition of this inert gas reduces inflammability by diminishing the quantity of oxygen present, and diluting the charge without reduction of its mass. The application is very simple and easily made, and the maximum practicable power of the engine is materially increased.

An average characteristic composition by volume of coke-oven gas may be taken as :—

H, 50 per cent.; CH_4, 25 per cent.; CO, 5 per cent.; $CO_2 + N + O$, 20 per cent.

Such a gas has a lower calorific value per cub. ft. at 60° F. (15·5° C.) and 1 atm. of about 390 B.Th.U., and requires, roundly, 3¾ cub. ft. of air for complete combustion; the heat evolved per cubic foot of this maximum mixture is accordingly $\frac{390}{4{\cdot}75} = 82$ B.Th.U. Actually, the calorific value varies from 350 to 450 B.Th.U. per cub. ft. at 60°F. and 1 atm., and requires from 3 to 4 cub. ft. of air for complete combustion.

In a test by Prof. E. Meyer of a 500 h.p. two-stroke Borsig-Oechelhauser engine of 26½ ins. dia. bore and 37½ ins. stroke (of each piston), running at about 106 revolutions per minute, and driven by coke-oven gas of 395 B.Th.U. (lower) value per cub. ft., the heat consumption per b.h.p. hour deduced from the blower driven by the engine amounted to 9,070 B.Th.U. corresponding to $\frac{9070}{395} = 23$ cub. ft. of coke-oven gas per b.h.p. hour only; the mean effective pressure averaged 70 lbs. per sq. in.

4. ACETYLENE GAS.

Experiments carried out in Germany with acetylene gas for internal combustion engines showed that the proportion of air to gas should be in the ratio of 12·02 to 1 to avoid the formation of soot. The maximum compression which may be used for a mixture of acetylene and air is about three atmospheres, compared with 4–5 atmospheres for petrol and 10 atmospheres for coal gas. One ton of carbide is sufficient to produce 10,000 cubic feet of acetylene.

5. PRODUCER GAS.

In normal combustion, when an excess of air is present in the combustion space, the carbon of the fuel is burnt to form carbon dioxide according to the reaction

$$C + O_2 \rightarrow CO_2.$$

Nitrogen from the air passes through the combustion space into the resulting gas without entering into the reaction. By this reaction one pound of carbon generates 14,647 B.Th.U.

By restricting the air supply and arranging to maintain a comparatively great depth of fuel upon the grate the carbon may be burnt into carbon monoxide according to the reaction

$$2C + O_2 \rightarrow 2CO,$$

nitrogen again passing through the grate without being affected.

By this latter reaction, 4,400 B.Th.U. are generated for each pound of carbon gasified, the residual heat value obtainable from the carbon by complete combustion, *i.e.* 14,647 − 4,400 = 10,247 B.Th.U., remaining in the resultant gas.

The greatest quantity of heat obtainable in the form of cool carbon monoxide from the air-carbon reaction is therefore only $\frac{10,247}{14,647} = 70$ per cent. of the heat originally available in the carbon.

Of the 30 per cent. of heat given out during the reaction, a large portion leaves the producer in the form of sensible heat.

The heat generated in the producer is sufficient to cause a temperature too high for satisfactory working.

In order to cool the producer and to utilise this excess of heat, steam is introduced into the combustion space, when, if conditions are favourable, the following reaction takes place:

$$C + H_2O \rightarrow CO + H_2$$

For each pound of fuel entering into the reaction 4,320 B.Th.U. *are absorbed* from the heated fuel.

By the use of air and steam in certain proportions, it is possible to absorb the excess heat generated by the air reaction and maintain a practically constant temperature in the producer.

By alternately blowing the producer with an excess of air and raising its temperature by the combustion of carbon, either to the monoxide or to the dioxide, and then cutting off the air supply and passing steam into the hot fuel until the producer temperature has again fallen, it is possible to generate water gas (the result of the steam-carbon reaction) which may be collected separately.

Water gas in conjunction with oil gas (generated by the cracking of heavy petroleum distillates) is largely used for the preparation of illuminating gas in normal times.

As the fuel used is not pure carbon, other considerations than those mentioned in the above theoretical outline affect producer design and working. As coals undergo a destructive distillation in the producers it is necessary to make use of special devices for the removal of tar from the producer gas. The recovery of ammonia generated from the nitrogen of the coal is also of the greatest importance in the economics of producer gas plants. These particulars are treated in greater detail in the following descriptions of various types of plant.

(*a*) Pressure producer gas from anthracite (Dowson).
(*b*) „ „ „ coke („)
(*c*) Suction and suction-pressure producer gas from anthracite (Dowson).
(*d*) „ „ „ „ wood, sawdust, chips (Dowson).
(*e*) „ „ „ „ charcoal (Dowson).
(*f*) „ „ „ „ coke and anthracite (Dowson).
(*g*) „ „ „ „ coke (Dowson).
(*h*) „ „ „ „ bituminous coal (Dowson).
(*i*) Pressure producer gas from bituminous coal (Mond).
(*j*) Suction and suction-pressure producer gas from anthracite (Mond).
(*k*) „ „ „ „ coke („)
(*l*) „ „ „ „ charcoal („)
(*m*) Suction-pressure producer gas from wood, semi-bituminous („)
(*n*) Suction producer gas from bituminous coal (Farnham).
(*o*) Producer gas from other substances, as colliery refuse, sawdust, wood chips, cocoanut shells, belt pickings, lignite, and peat.

In the table on page 2175 some results of analyses are given of producer gas from anthracite, coke, and bituminous coal. The number of cu. ft. of air necessary for just complete combustion is obtained by aid of table on page 2170 from the formula :—

$$\text{Cu. ft. of air} = \frac{4{\cdot}8}{100}\left\{\tfrac{1}{2}(H + CO) + 2\ CH_4 - O\right\}$$

Gas Producers and Producer Gas.

Some account of producers and producer gases from material supplied by manufacturers of gas plant is given hereunder :—

Dowson Gas.

The Dowson gas is made by passing a mixture of superheated steam and air through incandescent fuel. There is no external fire, as in ordinary gas retorts, and no skilled labour is required to work the apparatus.

The original type of Dowson plant included a small steam boiler, to give the steam required and to work an air injector. Excellent results have been obtained in this way, and for some purposes it is still the best plant to use. It is now known as the 'Dowson Steam-jet Pressure Plant,' and is used when gas is required from one apparatus to serve several gas engines or one or more engines and heating appliances.

COMPOSITION OF PRODUCER GASES WITH HEAT VALUES, ETC.

Description of Producer Gas.	Kind of Fuel used.	Per Cent. Composition by Volume.						B.Th.U. per Cub. Ft. (lower) at 60°F. (15·5° C.) and 1 Atm.	Cub. Ft. of Gas made per Ton of Fuel.	Cub. Another type of Dowson gas-making plant is the 'Dowson Suction Plant,' which has been installed in large numbers in this and many other countries. This type of apparatus requires no boiler or gas-holder, and the engine itself draws the air required through the fire in the gas generator: the engine, therefore, governs the rate of producing the gas to suit its varying consumption, and there can be no waste of gas. Moreover, the dry steam required is produced by waste heat, and the fuel which is to be converted into gas is also heated by waste heat before it reaches the combustion zone. Throughout the apparatus the loss of heat is therefore reduced to a minimum, and the efficiency is exceptionally high. Sir Dugald Clerk's 'James Forrest Lecture,' delivered in 1904 to the Institution of Civil Engineers, refers to exhaustive tests made by him with this suction plant, the heat efficiency being proved to be about 90 per cent.

In both types of the Dowson apparatus anthracite peas or nuts, charcoal, or coke can be used. The consumption depends somewhat on the type of plant and the kind of fuel used. With the suction plant the Dowson Company guarantee that the consumption of small coke of good quality will not exceed 1¼ lb. per b.h.p. per hour, at full load, with any good gas engine suitably adjusted for working with the plant.

If anthracite peas (from ⅜ in. to ¾ in. cube) are used, the consumption is guaranteed not to exceed 0·9 to 1 lb. per b.h.p. per hour.

As regards stand-by losses careful independent investigations have shown that at four different places Dowson gas generators, ranging from 100 to 375 b.h.p. each, during long stand-by hours, consumed an average of only 3 lbs. per generator per hour, while gas of good quality could be ready for use in about ten minutes. With steam power the stand-by loss is far greater.

A further important advantage of the gas is that it does not condense or lose power on its way to the engine; on the contrary, the more the gas is cooled the better it is for the engine, as each charge of gas which enters the cylinder is more dense, and has consequently greater energy. With steam the condensation in the pipes, etc., is considerable; with gas there is no such loss. It is easy to prevent leaks of gas from the piping, owing to the low pressure of the gas, whereas with steam there is often much loss and inconvenience on this account.

With the suction plant there cannot be a leak of gas when the engine is working, but piping, scrubbers, etc., must be absolutely tight to avoid air leaks.

The wages of firemen are about the same for the gas plant as for a steam boiler of equal power.

The quantity of water per b.h.p. per hour in the gas plant is about 1 gall.; with steam power it is usually two or three times as great. The cost of repairs (pre-war period) is approximately as follows:—

For 100 b.h.p.	£4 per annum.	For 400 b.h.p.	£12 per annum.
„ 200 „	6 „ „	„ 500 „	15 „ „
„ 300 „	9 „ „		

As regards labour, with the suction plant the usual allowance is one man for about an hour each day to start the fire, clean, etc., and about one hour per day to put fuel in the generator. When the plant is worked with a boiler the labour required is greater, but not more than for steam power of equal size.

Although about four volumes of Dowson gas are required to do the same work in a gas engine as one volume of town gas, yet Dowson gas is produced so cheaply that the equivalent of 1,000 cubic feet of ordinary town gas costs only seven to twelve pence, according to the scale of working and price of fuel.

With Dowson gas 1 lb. of coal will produce ·70 cubic feet of gas, and 1 cubic foot of this gas requires only 1·1 cubic foot of air for complete combustion, against 6 to 8 cubic feet for ordinary gas.

A complete Dowson apparatus does not occupy more space than that required for the boiler of a steam engine of the same power.

Dowson gas is used for heating and furnace work of all kinds, as it is a cheap and cleanly fuel, under perfect control.

Their latest plant for heating is known as the high pressure type wherein the gas can be boosted to any pressure up to 100 ins. w.g., delivering the gas clean and steady to the burners. The producer is of the open-hearth type similar to the producer used on their latest suction plant. Space will not permit giving varied examples of the performance of plant and the splendid results with the gas obtained, even for delicate work such as singeing.

The following comparative estimates (pre-war period), for 25 and 50 b.h.p., show that it is much cheaper to use gas power than electricity, even where the latter is sold at 2*d.* per unit:—

25 B.H.P.	Per week. £ *s.* *d.*	Per annum. £ *s.* *d.*
Electricity—25 B.H.P.=18¾ B.Th. units × 50 hours = 937½ units at 2*d.*	7 16 3	390 12 6
Town Gas Power.—25 B.H.P. × 20 cubic ft. × 50 hours = 22,500 cubic ft. at 2*s.* 6*d.*	2 16 3	140 12 6
Dowson Gas Power.—25 B.H.P. × 85 cubic ft. × 50 hours = 106,000 cubic ft. at 3*d.*	1 6 6	66 5 0

50 B.H.P.	Per week. £ s. d.	Per annum. £ s. d.
Electricity.—50 B.H.P.=37½ B.Th.units×50 hours =1,875 units at 2*d.*	15 12 6	781 5 0
Town Gas Power.—50 B.H.P. × 20 cubic ft. × 50 hours=45,000 cubic ft. at 2*s.* 6*d.*	5 12 6	281 5 0
Dowson Gas Power.—50 B.H.P.×85 cubic ft.×50 hours=212,000 cubic ft. at 3*d.*	2 13 0	132 10 0

More recently Mr. Dowson has introduced a new type of producer, to work with bituminous coal, which is a new departure in several respects. In producers which are worked with bituminous coal the tarry vapours from the hydrocarbons in the fuel mix with the gas, and the tar is usually afterwards extracted in separate apparatus. Mr. Dowson has always held the opinion that the tar should be got rid of in the producer itself, and he has succeeded in doing this.

The producer is double-acting—*i.e.* air is drawn in through the top and through the bottom of the fuel column. The coal is put in at the top, and the upper part of the fire burns downwards. The hydrocarbons are distilled off and various reactions occur, the coke which remains sinks downwards into the lower part of the producer. The coke is there converted into ordinary producer gas by the upward current of air (accompanied by steam), which is drawn in at the bottom. The mixture of gases leaves the producer through an outlet about halfway between the top and bottom. There is no external fire, and the gas is made as quickly as it can be consumed, as in the other types of Dowson gas plant.

When working with ordinary bituminous coal, or with lignite and several other varieties of fuel, there is no tar; it is removed altogether in the producer, and no mechanical or other tar extractor is required. After leaving the producer the hot gas passes through a vaporiser to cool the gas, and to raise the steam required for making the gas. It then passes through suitable scrubbers and is ready for use in the engine to be worked with it.

This bituminous plant is worked by suction, and consequently there is no escape of gas; it is also easy to work, and the cost of labour is about the same as with an ordinary plant working with anthracite or coke.

When the plant is to be worked by the suction of an engine as in the smaller powers, viz., 25 up to 100 h.p., there is a fan to start it, as in ordinary suction plants, and this is stopped when the engine is running. For powers 100 h.p. and upwards there is a fan or blower to draw the gas from the plant and deliver it to the various engines or heating apparatus requiring gas. Each fan or blower produces the suction on the plant and governs the make of gas. Of course with all heating work and where there is more than one engine requiring gas, even for the small powers, a fan or blower is always installed to deliver the gas under pressure.

The quality of the gas made in this plant is about the same as that of gas made with coke in ordinary suction plants. The heat efficiency of the new plant is exceptionally high, and with a good engine under full load the consumption of fuel is little over 1 lb. per b.h.p. hour. The stand-by losses are small, and after standing over-night or during meal hours, good gas can be ready for the engines in a few minutes.

Many plants of this description have been installed both at home and abroad for industrial and municipal undertakings with splendid results, and in the case of the foreign installations the coal in some cases being much inferior to our British standard. These plants can be made in any size from 25 to 500 b.h.p.

The Kerpely Revolving Grate Gas Producer.

The Kerpely Gas Producer, with its mechanical ash discharge and mechanical feed and agitators, is entirely mechanical in operation. It effectively gasifies good or bad fuels, even waste fuels containing nearly 50 per cent. ash. As an example of the latter fuel, mention is made of an installation of Kerpely gas producers at a colliery in Scotland for gas-firing colliery boilers. The fuel gasified is unsaleable from the colliery and consists of 'parrot' and 'belt pickings' of the following approximate analysis:—

Parrot and Belt Pickings Mixed.

Fixed carbon (by difference)	24·50
Volatile matter	23·22
Ash	48·10
Moisture	4·18
	100·00
Calorific value	6,580 B.Th.U. per lb.

It will be noted that the fuel contains *nearly 50 per cent. of ash.*

The following is an average analysis of the gas produced from this fuel by the Kerpely gas producers, viz.:

CO_2	5·80
O	0·58
CO	23·21
H	11·50
CH_4	2·85
N	56·06
	100·00

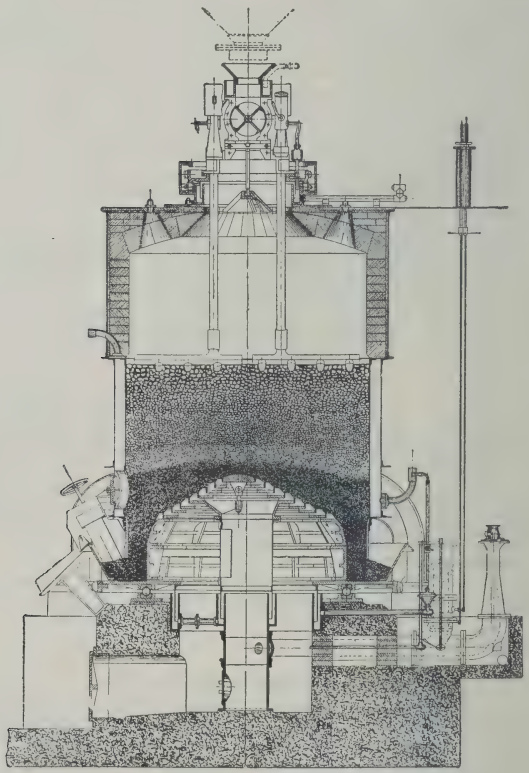

FIG. 44.—The Kerpely Revolving Grate Gas Producer.

The Kerpely grate, a sectional view of which (dimensioned for the standard 3-metre diameter producer) is shown by fig. 44, is of polygonal shape and is placed eccentrically on the water trough. It has a continuous and not an intermittent action in crushing any formation of clinker that may occur. The water-cooled jacket in the fire zone prevents the formation of clinker on the walls of the producer. The clinker, when entering the ash zone, is caught by the numerous edges of the revolving grate and pressed horizontally sideways against the seal apron, and is consequently broken or crushed into small fragments, which, dropping into the water trough, are removed by the ash scraper. The latter automatically discharges the ash and clinker accumulating in

the bottom of the producer, and, being constructed to suit the shape of the ash trough, the ash is not only pushed aside, but is piled up and continuously discharged into an ash shoot. The automatic discharge of the ash and clinker from the Kerpely producer results in considerable saving of labour in the removal of ash, and ensures continuous working of the producer and gas of uniform quality. Labour is saved in poking, a small amount only of steam is required, and a dry gas is obtained, which ensures a prolonged life of the furnace linings. The supply of air and steam to the Kerpely producer is separately conveyed to the inner and outer sections of the grate, and, being transmitted through spaces between the plates of the revolving grate, ensures uniform combustion over the whole grate area, the maximum gasification capacity per square foot of grate area, and effective control of the fuel bed.

The Kerpely producer can be fitted with the Appleby-Bentley Patent Mechanical Rotary Fuel Feed and Distributor, or this mechanical feed combined with patent balanced and adjustable fuel agitators and levellers, as the fuel conditions may determine.

These mechanical feeds and agitators are claimed to ensure greatly increased gasification (50 to 100 per cent., according to type of producer), constant high-value gas, saving of labour and fuel, and greater production from furnaces. The following table gives daily working results taken over a period of one month with a Kerpely gas producer fitted with the Appleby-Bentley mechanical feed and agitator:—

KERPELY PRODUCER WITH MECHANICAL FEED AND AGITATORS (BENTLEY'S SYSTEM).

APPLEBY-BENTLEY PATENT MECHANICAL GAS PRODUCER.

This producer is mechanical in its action, as regards fuel feeding, agitating and levelling, ash levelling and discharge. The fuel is carbonised, then gasified, producing high or low temperature gas as desired from the same producer. The apparatus has an improved blast distribution, effecting perfect combustion with high gasification. Cheap fuels can be effectively gasified by its means.

THE 'CROSSLEY' SUCTION GAS PLANTS.

Messrs. Crossley Brothers, Ltd., build several types of suction gas plants, each specially designed to suit the various classes of mineral and refuse fuels.

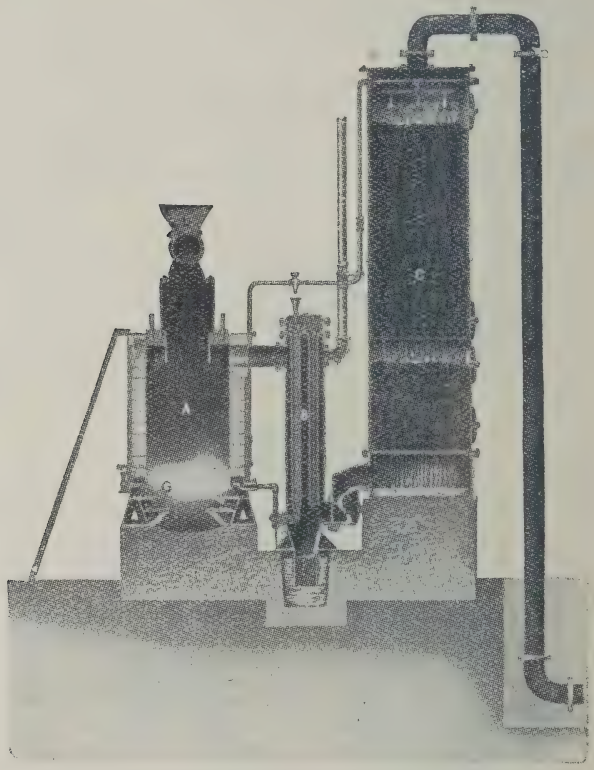

FIG. 45.—'Crossley' Suction Gas Plant.

The producer manufactured by them to work on anthracite, coke, or charcoal is of the open-hearth type shown by fig. 45.

With this type of producer the fire is always in full view of the operator, the firegrate consisting of a number of annular cast iron plates arranged in the form of steps and so disposed that the outside edge of each succeeding lower plate lies beyond the angle of repose of the fuel which falls through the opening in the plate above. These grate plates are supported on cast iron legs which also support the producer itself, comprising a simple steel shell internally lined with firebricks.

The grates are cooled by water which is supplied by small drip pipes to the top plate, from whence it overflows on to each succeeding plate in turn; a certain amount of steam is thus generated which assists in the gas production.

As will be seen from the fig. the lower part of the fuel bed can at all times be readily cleaned of ash and clinker without interfering with the process of gas making or necessitating shutting down of the plant, indeed, numbers of these plants have worked continuously for over 12 months without the fire having to be withdrawn for any purpose whatever.

The absence of a vaporiser in the top of the producer enables the operator to use a poker in a direction parallel to the firebrick lining, the clinkers being thus very easily broken away, without injury to the brickwork, and allowed to drop on to the grate plates, from whence they can be removed at will.

From the producer the hot gas passes into an external vaporiser consisting of a casing supporting a cast iron box divided into compartments, to the under side of which a number of water tubes are fixed.

With the exception of the first and the last in the series. the tubes are provided with internal circulating tubes of the ' Field ' type.

The water to be vaporised is carried to the bottom of the first tube through an internal feed pipe and then rises into the first compartment, from which it passes in through each succeeding compartment and tube in turn, until finally it is flashed into steam in the last tube, which also forms the steam connections between the vaporiser and the producer. The steam is taken from the vaporiser into an annular box-shaped casting situated at the base of the producer, from which it is distributed to the fuel bed through a number of small holes drilled around the inside edge.

In this design of plant the gas is external to the water to be heated, so that both the cooling of the gas and heating of the water are effectually provided for.

Leaving the producer, the partially cooled gas passes through two cascades of water produced by the overflow from the cooler and scrubber ; these remove the heavier impurities from the gas. It is next passed through a cooler and scrubber consisting of two coke charged compartments, each fitted with separate cleaning and charging doors, so arranged that the coke in the lower compartment (which is the first to become fouled) can be removed without interfering with that in the upper compartment. During its passage through the coke the gas is thoroughly cooled by streams of water supplied by the spray situated above the top layer.

Leaving the scrubber the gas passes into a combined drier and expansion box, and from thence to the engine.

' Crossley ' Refuse Fuel Plants.

' Crossley ' refuse fuel plants are designed to work on a variety of fuels, including waste wood of all kinds, spent tan, rice husks, olive refuse, sugar cane refuse, cocoanut shells, coir dust, cocoa and coffee refuse, etc. Particular attention has been given by the designers to the removal of impurities from the gas and to allow of continuous working of the plant by unskilled labour. A sectional view of a ' Crossley ' Refuse Plant is shown by fig. 46.

The lower part of the producer is similar in design to that of the anthracite plant previously described, with the exception that the grate is shielded by carrying the external shell to the foundation block.

Access to each section of the grate for removal of ash is provided for by large cleaning doors bolted to the producer shell ; these doors can be opened at any time whilst the plant is at work without disturbing the process of gas production.

Owing to the comparatively high moisture content of nearly all classes of waste fuels, little or no steam is required for gasification purposes, but when necessary, provision is made for generating a supply of steam by feeding water on to the stepped grate plates.

One of the features of this plant is the provision of an Airlock fuel feeding hopper of large capacity and special design to allow of the plant being used for all classes of fuel without the slightest fear of explosion or interruption of gas supply when charging.

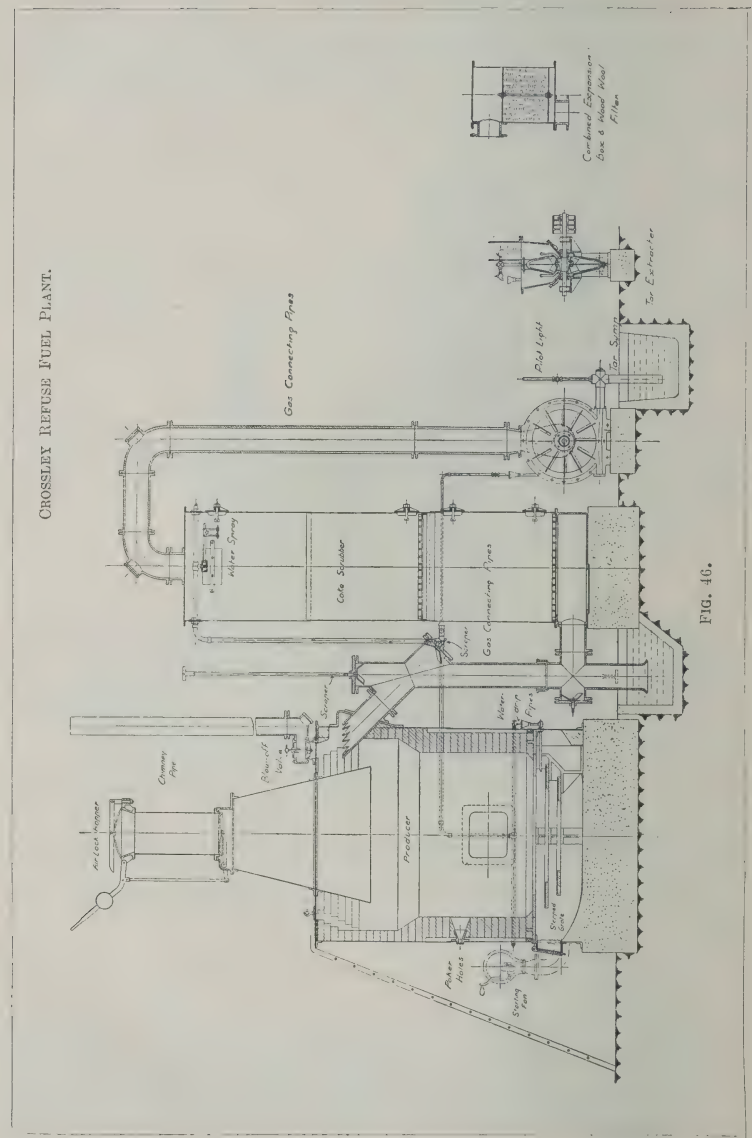
Other features of this producer are as follows :

(1) Provision for storing a large quantity of fuel in the producer itself, thus obviating the necessity of frequent charging.

(2) Exceptional facilities for spreading the fuel, thus ensuring a constant fuel depth and gas of constant calorific value.

(3) An effective design of mouthpiece for the gas outlet pipe, to reduce to a minimum any tendency for fine fuels, such as sawdust, to be drawn over with the gas.

(4) Gas outlet pipes from producer to scrubber are provided with scrapers for removing tarry deposit and dust whilst the plant is in operation. This device prevents the pipes from becoming choked and thus enables the installation to work continuously for long periods.



CROSSLEY REFUSE FUEL PLANT.

FIG. 46.

For cooling and washing the gas (preparatory to the removal of tar) a coke scrubber (of similar design and construction to that previously described) is provided.

Leaving the top of the scrubber and cooler, the gas is passed through a mechanically driven centrifugal tar extractor, where it is subjected to a combined heating and centrifugal action which throws out the tar on to the inside of the casing, from whence it is washed into the tar collecting sump by a continuous spray of water.

Before the gas reaches the engine it is passed through a combined expansion box and wood wool filter which acts as a final drier.

Messrs. Crossley Brothers also manufacture suction plants for bituminous coal, lignite or peat; these being of different design to suit the characteristics of the fuel to be gasified. The bituminous fuel plant is provided with a central cone plate grate which allows of a continuous water lute around the base of the producer for the removal of ash and clinker.

All steam required for gasification purposes is generated in an annular steel boiler, situated near the base of the producer, the smooth surface of which prevents clinker from adhering. The steam and air supply to the producer is controlled by a single valve, and the saturation temperature of the air can be regulated to a degree.

This design admits of free use of pokers through both the top and side poking holes.

For feeding the fuel a rotary barrel hopper is provided. The gas cleaning apparatus is very similar to that supplied with the 'Crossley' Refuse Plant.

Mond Gas.

The Mond Gas-Producer Plant was originally developed by the late Dr. Ludwig Mond for the conversion of bituminous fuels into power and heating gas, along with the simultaneous recovery of the nitrogen in the form of sulphate of ammonia.

Plants of both the recovery and non-recovery type are constructed for power and for heating purposes, but considerations of economy rarely justify the installation of the recovery type in units of less than 2,000 h.p. or equivalent capacity. The non-recovery type, however, is installed in much smaller units.

Both types of plant can be adapted for utilising inferior fuel, such as the waste products from collieries and coke ovens, and the gas used for gas-engine driving, industrial furnace heating or boiler firing, and in such cases with the recovery plant the return from the sulphate of ammonia will go a good way towards meeting the running expense of the plant.

The Mond Non-recovery Water-cooled Gas-Producer Plant.

(*Mond and Lymn System.*)

The modern type of Non-recovery Water-cooled Gas-Producer Plant, as installed for generating gas from bituminous producer coal of suitable grading, quality, and condition for use in gas engines or for other purposes where cleanliness equal to gas-engine practice is required, may be considered as composed of two sections: the 'Gas Generating Section'—comprising the producer and its accessories—and the 'Gas Cooling and Cleaning Section'—comprising vertical static cooler and washer, centrifugal cleaners, and sawdust scrubber.

The producer is of the central blast type, with steel casing designed to sit on concrete foundations (provided by purchasers) and dip into a water-lute, formed in the foundations, and from which the ashes can be removed evenly all round without interrupting the working of the producer. The grate is conical in form, built up of two or more C.I. sections, and provided with air slots. It is located concentrically with the producer shell, and is connected up to the blast pipe which passes through the foundations to the outside of the producer. The lining of the producer is built of special quality firebricks and fireclay. The producer is fitted with a series of horizontal poke holes about the level of the air slots in the grate, and also with poke holes on the top giving access to the whole of the fuel bed, these top poke holes being fitted with spherical closers.

A fuel hopper is fitted on the top of the producer, with sliding cover and inner cone valve operated by lever and balance weight. The fuel in the hopper is discharged into a fuel container or inner bell, the top of which is provided with suitable poke holes, and from this container, automatically on to the fuel bed; this method of charging ensuring a more constant quality of gas. The gas outlet branch is fitted on the side of the producer casing close to the top.

A steel chequer plate operating platform is arranged at the level of the top of the producer shell with suitable protecting handrailing and ladder giving access from ground level.

Fuel handling plant is frequently included, and the type usually recommended comprises a power-driven enclosed bucket type elevator, lifting the fuel from a boot at ground level into a bunker, which is mounted on substantial supports over the producer and fitted with a shute furnished with lever-operated discharge valve leading down to the producer hopper.

The air-blast for the producer is provided by a blower of the steam-jet type, arranged so as to ensure a thorough intermixture of air and steam before the blast reaches the grate, but in some installations a steam-driven Roots or turbo-type blower is included, the exhaust steam from the blower engine or turbine being led into the blast pipe.

Leaving the producer, the gas enters the cooler and washer, which is of patented design, and provides an effective means of gas washing by the employment of a novel and efficient method of utilising the momentum of upward flowing gases to atomise liquid falling in thin sheets, with a resultant intimate contact between gases and liquid without the use of any mechanical spraying device.

The apparatus consists of a cylindrical casing of mild steel, fitted with top and bottom plates, gas inlet and liquid outlet at the bottom, and with gas outlet and liquid inlet at the top. When desirable, the bottom of the casing can be arranged for water-luting.

A vertical stationary shaft is located in the centre of the apparatus, extending the height of the casing. At suitable distances from each other, a series of discs or distributing devices for the liquid are fixed on this shaft, and attached to the casing are a corresponding series of inverted truncated cones which serve as collecting devices, the design of these internal parts being varied to suit particular requirements.

Falling by gravity alternately from the distributors to the collectors and *vice versa*, the thin sheets of liquid are atomised, and in the form of fine spray actually driven by the gas—itself flowing in zigzag path in the opposite direction—on to the collectors and distributors, where the spray again forms into thin sheets of descending liquid. Each particle of gas is thus brought into contact with the liquid many times before it leaves the apparatus.

The distributors are constructed with diameters considerably smaller than the lower diameters of the collectors, and thus the gas passage is not restricted, and the loss of pressure occasioned is very small.

Packing or filling materials, such as coke, earthenware tiles, or wooden boards, which baffle the passage of the gas, are dispensed with, and the troubles of stoppage and renewals attendant upon such materials getting choked with tar and dust are thus eliminated.

This type of washer is of established efficiency, and the absence of moving parts, together with the freedom from possibilities of blockage, which is a feature of the design, make it a thoroughly reliable apparatus requiring a minimum of attention, with no upkeep charges for labour and material for packing or filling renewals such as have to be met with in other types of washer.

From the washer the gas passes to the first of two centrifugal cleaners. These two cleaners are normally arranged to work in series, but where desired, the requisite cross connections and valves can be added to enable either cleaner to be cut out of operation and by-passed for purposes of overhauling should such be necessary. Each cleaner has a tar drain water-sealed in a lute in the foundations, and the gas delivery branch of the second cleaner is joined up to a sawdust scrubber, to the outlet of which the gas main leading to the gas engines, etc., is connected.

The scrubber is a rectangular cast-iron box fitted with wooden grids, on which are spread layers of wood chips, shavings, and sawdust. The gas enters at the bottom, and passing up through these layers receives its final drying and purification.

The scrubber requires very little attention, only needing to be cleaned out and refilled a few times per year, according to the load on the plant. A special lifting arrangement is provided to facilitate the removal of the cover, and all the spent material taken out can be burnt under the boiler which provides the steam for the plant.

The drains from the various parts of the plant are run to the settling tank, which takes the form of a concrete pit with iron or reinforced concrete partition plates, so arranged as to keep back the tar and allow only the water to run to the drains. The tar is then scooped or run off and disposed of in the most convenient manner, either being sold, used for boiler-firing purposes, dehydrated, or distilled, according to the quality and quantity available and local conditions.

The auxiliaries of the plant—elevator and centrifugal cleaners—can generally be most advantageously and economically driven by electric motors if electric supply is available, a direct or continuous current being preferable to an alternating current supply.

Where requirements call for a minimum fluctuation in the gas supply pressure, an automatic governor can be added to plants in which a power-driven blower is installed. Such a governor would be of the gas-holder type, but of small capacity, and hence of negligible storage value. The bell of the holder would be so arranged that as it approaches its top position it actuates a relief valve connected to the air-blast main, reducing the blast supply to the producer when the gas make is in excess of the requirements, and thus automatically controlling the gas production.

In installations where the gas generated is used to supply gas engines and also to fire furnaces, it is advisable that a non-return valve should be provided in the gas main to the furnaces.

A suitable and sufficient supply of steam is required for blast saturation purposes, also a suitable and sufficient supply of cold water to the washer, cleaners, and producer lute. Where cold water is scarce, water-cooling and circulating plant may be installed, and a considerable portion of the water required can be used over and over again. Suitable motive power for the auxiliaries is also required, in the form of electricity or steam.

This description is typical of units up to about 1,100 b.h.p. capacity, larger units being generally similar but having two or more producers, gas main connections between producers and washer, to suit, and additional scrubber units.

Low Temperature By-product Recovery Gas-Producer Plant.

(*Mond and Lymn System.*)

Under normal circumstances, the installation of this type of plant is not, generally speaking, justified in units smaller than 2,000 b.h.p. in capacity, and local conditions and values may even require a larger unit, to afford an economical proposition. Thus, the usual plant of this type comprises more than one producer unit with corresponding superheaters, etc., but, except for plants of unusually large capacity, the washing, etc., vessels are installed in single units, with the scrubbers in multiple units, according to requirements.

This plant is made up to a certain extent of similar parts to the non-recovery type, but the design of several of these parts is modified to suit the different working conditions, and additional apparatus is included.

The plant may be considered as composed of four sections :—

(1) The Gas Generating Section, comprising producers.
(2) The Gas Washing and Cooling Section, comprising dust washer, ammonia absorber, gas cooler, and in particular cases air saturator.
(3) The Gas Cleaning Section, comprising gas cleaners and scrubbers.
(4) The By-Product Recovery Section, comprising :—
  (*a*) Sulphate of ammonia, evaporating and drying plant.
  (*b*) Tar dehydration and/or distillation plant.

If the gas from the plant is required only for heating purposes, then Section (3), or, in some cases, the scrubber portion of this section, is not required.

The producers are generally similar to the non-recovery type, but with increased depth and other constructional modifications.

A steel chequer-plate operating platform common to the battery of producers is arranged at the level of the top of the producer shells, with suitable protecting handrailing and ladder giving access from ground level.

Fuel-handling plant is generally included, and the type usually recommended comprises a power-driven enclosed bucket type elevator, lifting the fuel from a boot at ground level into an overhead bunker, together with push-plate conveyor. The bunker, constructed of steel, is generally of parabolic section, extending over the whole of the battery and suspended from substantial supports, which also carry the producer platform. The bunker is provided with discharge shutes leading down to the fuel hoppers of the producers, each shute being provided with a lever-operated discharge valve. When required, a light iron framing and corrugated sheet-iron covering is supplied to cover in the coal conveyor and bunker top. For large installations, fuel-handling plant of the travelling overhead crane and grab type offers advantages which merit its adoption.

The air blast for the producers is provided by blower or blowers of either the turbo or Roots type, and after the necessary exhaust steam has been added to it to supply the vapour for blast saturation, it is passed into the producers. In certain cases some of the vapour required for blast saturation purposes is provided by means of an air saturator working in conjunction with the gas-washing plant.

The gas from each producer passes into a gas collecting main which joins up the various producer units and from which it enters the dust washer, where intimate contact with falling sprays of water wash out a large proportion of the dust. From this vessel the gas passes on to the ammonia absorber, which is the same type of patented vessel as used for the washer in the non-recovery gas producer plant.

From the absorber the gas passes to the final cooler, which again is a vessel of the patented washer type.

For certain heating purposes the gas may be taken off for use from the exit of this cooler, but if further cleaning is required, it next passes forward to the first of two centrifugal cleaners, which in detail and arrangement are exactly similar to those described as part of the non-recovery plant.

Where the gas is required to be of gas-engine cleanliness, the delivery branch of the second cleaner is connected to a bus-pipe joining up to the inlets of the scrubbers, the outlets of these vessels being connected with a bus-pipe, from which the main for the gas engines may be taken.

Where for special purposes the final cleaning in scrubbers is not required, then the gas may be taken off from the exit of the second centrifugal cleaner.

The scrubbers are formed in separate sections in a rectangular cast-iron box, each section being provided with wooden grids on which are spread layers of wood chips, shavings, and saw-dust. The gas enters at the bottom, the various sections working in parallel, and the operation, etc., being generally similar to this portion of the non-recovery plant.

The fourth section of the plant, in which the sulphate of ammonia is made in crystal form from the liquor obtained from the absorber, is generally housed in a building to itself.

The plant comprises stock liquor tanks, into which the liquor at suitable saturation is withdrawn from the circulating system of the absorber and stored. From these tanks the liquor is pumped up to overhead feed tanks, from which it is fed into the vacuum evaporator, which operates in conjunction with a condenser of the ejector-jet type. Here the liquor is evaporated and the crystals discharged from the base into a specially designed aspirator, and from thence passed on for final drying in power-driven hydro-extractor. The dry salt is then delivered into the store, usually arranged in the basement of the building, where it is packed in bags ready for distribution or shipment.

A steel circulating tank is provided for use in connection with the absorber, and located closely adjacent thereto, to contain the weak sulphuric acid solution which is used as the circulating liquor in this vessel, and a pump, constructed of acid-resisting metal, is provided for circulating this liquor, with the requisite connections between the tank, pump, and absorber, and from the tank to the stock liquor tanks.

It is necessary for purchasers to provide acid and water supply pipes to this tank, to supply the make-up for the liquor withdrawn from circulation.

Suitable pumps are also provided for supplying the circulating water to the dust washer, but it is usually left for purchasers to supply the cold water supply and pipe-line to the top of the final cooler, to the centrifugal gas cleaners, and to the jet condenser, as also the requisite drain connections for the disposal of the waste water from condenser and settling tanks.

The tar produced is collected from the various circulating tanks into a common settling tank. From this tank it is pumped to an overhead storage tank and dehydrated either by steam or by mechanical means. The dehydrated tar can either be sold as such or pumped forward to a distillation plant to yield oils suitable for fuel, disinfectants, wood preservatives, etc., and pitch.

The auxiliaries of the plant—elevator and conveyor, centrifugal cleaners, pumps, and hydro-extractor—can generally be most advantageously and economically driven by electric motors, if electric supply is available, a direct or continuous current being preferable to an alternating current supply, but it is the usual practice to couple up the blowers to steam prime movers, the exhaust from which, as before mentioned, is utilised for blast saturation.

Automatic governor and non-return valve are provided when required to meet the same conditions as in the non-recovery type of plant, while steam, water, and motive power supplies will similarly be required.

Bituminous Suction Producers.

The production of a satisfactory suction plant using bituminous fuel has proved a problem of very great difficulty, but several types of such plant have recently appeared, and they are now built commercially by Messrs. Dowson, Messrs. Crossley, and others. In these the leading idea is to destroy any tar produced by distillation of the fuel *in the producer* before the crude gas enters the coolers and scrubbers. This is usually accomplished by taking the gas from the

hot zone of the producer, and arranging the supply of air and steam from both above and below; the fuel enters from a hopper on top, and the gases coming off from the fresh coal pass down together with some air and steam to the hot zone where reactions take place which destroy the tar by converting it into useful gases. The fuel, now largely carbonised, passes slowly downwards towards the grate supporting the whole mass, and being traversed by a current of mixed air and steam passing upwards yields carbonic oxide and hydrogen as usual.

Engines driven by these plants frequently require only about 1·2 lb. of slack to the producer per b.h.p. hour.

The 'Hornsby-Stockport' Suction Gas Plant for Anthracite, Coke, Charcoal, etc.

The outstanding features of this producer, fig. 47, are simplicity of design, ease in handling, and reliability under working conditions. Shaker grates to prevent the formation of clinker are fitted on all producers of 37 b.h.p. and upwards. The blow-off pipe of the larger sized producers

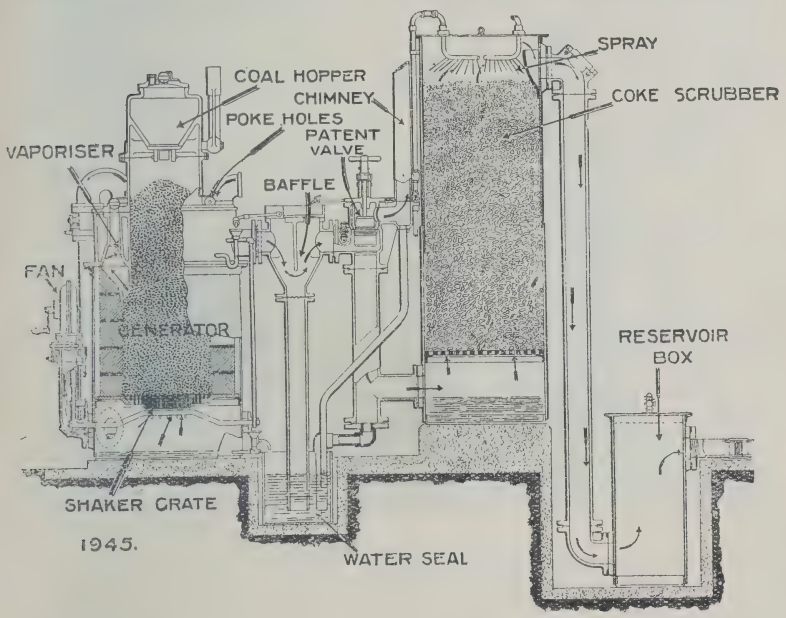


Fig. 47.—Hornsby-Stockport Improved Suction Gas Plant.

is fitted with a patented valve, closing the coke scrubber to the atmosphere when the generator is open to the blow-off pipe, thus keeping air from entering the coke scrubber.

Gas can be raised from cold in about 20 minutes.

The 'Ruston' Wood-Refuse Suction Gas Producer.

This gas producer (*Ruston and Hornsby, Ltd.*), fig. 48, is for the purpose of dealing with wood refuse, non-caking bituminous coal, lignite, brown coal, anthracite, etc.

The chief endeavour has been to obviate the stoppages for cleaning usually necessary when working on such fuels. The little cleaning that is required is at the gas outlets from the generator, and this can be easily performed in a few minutes while the plant is in operation by means of special scrapers, so that the usual week-end cleaning is done away with, and the plant can be worked continuously if required.

A special feature of the producer is the multiple gas outlet pipes from the top of the generator, which ensure an evenly burning fire.

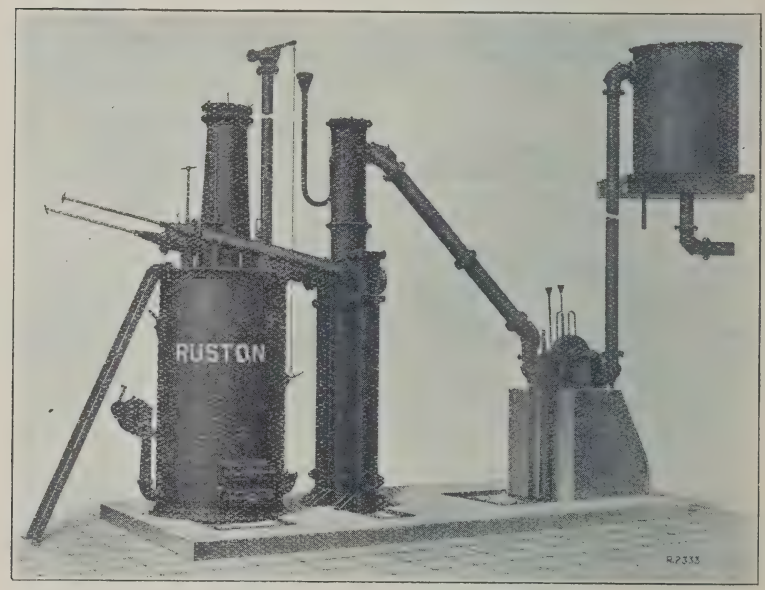

FIG. 48.—'Ruston' Wood-Refuse Gas Producer.

Other advantages claimed are as follows:—small space occupied, very little attention required, no coke scrubber to become clogged with tar, simple in design and construction, and gas free from grit, dust, or tar. The consumption of wood refuse is from $2\frac{1}{2}$ to $3\frac{1}{2}$ lbs. per b.h.p., according to the amount of moisture in the fuel, and the plant will produce four or five times the power as when the fuel is burned for direct steam raising.

When bituminous coal, lignite, anthracite, or coke is required to be used, solely or alternatively with refuse fuel, the details of the producer are somewhat modified. An annular steel vaporiser is arranged around the upper part of the generator, and an air lock feeding hopper is fitted. Poking holes are provided to give access to all parts of the fuel bed, and special facilities are given for the quick removal of ash and clinker.

A large number of these producers have been supplied at home and abroad, for a variety of refuse fuels, and for bituminous coals.

Water Gas.*

In ' Water Gas ' producers the action is intermittent, the fuel being alternately raised to incandescence by an air blast which is then shut off and steam alone passed through the glowing mass; the steam is dissociated into free hydrogen and oxygen, and the oxygen combines with the carbon present in excess and forms CO; thus :—

$$H_2O + C = H_2 + CO$$
$$2 \text{ vols.} + 1 \text{ vol.} = 2 \text{ vols.} + 2 \text{ vols.}$$

In theory, therefore, water gas should contain 50 per cent. by volume each of hydrogen and carbon monoxide; practically a small quantity of CO_2, N and O generally appears, as shown in the analysis given below. The passage of the steam through the mass of incandescent coke soon cools it down, when the steam is cut off and the air blast again turned on; the cycle of operations is then repeated.

Water gas plants are frequently installed in gas works, and the water gas is often enriched or ' carburetted ' by admixture of heavy hydrocarbon vapours and in this condition used either alone or mixed with coal gas for lighting, heating, and power purposes.

The following results of analyses suffice to give a general idea of the characteristic constitution of water gas, carburetted water gas, mixed gas (i.e. mixed water gas and coal gas), and normal coal gas :—

	H.	CH_4.	CO.	Heavy Hydrocarbons.	CO_2.	O.	N.
Water gas	48·6	0·4	44·0	—	3·3	—	3·7
Carburetted water gas	29·35	20·48	33·19	11·32	—	—	5·66

6. BLAST FURNACE GAS.

In 1895 the late Mr. B. H. Thwaite showed that the hitherto waste gases from blast furnaces could be used in gas engines, and his discovery has stimulated the construction of the very large gas engines now becoming common.

The gas is taken from the gas main and forced by a blower through a scrubber into a holder regulator, and then to the engine. About 180,000 cubic feet of gas are produced per ton of fuel consumed in the furnace, and about 124 cubic feet of gas are used in the engine for each horse-power hour.

From tests made on Mr. Thwaite's first plant at Wishaw by the late Mr. W. H. Booth, it is estimated that for each ton of fuel used per week in a blast furnace, 10 horse-power may be continuously obtained by gas engines.

It is proposed to thus utilise the gases of all blast furnaces and so produce several millions of horse-power for distribution for railway, lighting, canal, traction, and general power purposes.

Table I. gives the analyses of blast furnace gas in two cases where the Thwaite system is in use, and a comparison with producer gas, while Table II. gives results of a volumetric analysis of the Wishaw gas.

* See also Section XXXVII.

From 80 to 100 cubic feet of gas are obtained from each pound of fuel used. The foregoing table shows about 98 cubic feet of gas per pound of carbon, but some of the carbon comes from the limestone flux and from the ore, and even from the blast itself. In the gas engine, with the necessary enlargement of the gas inlet as compared with that necessary for town gas, and with a fair amount of initial compression, the action of blast-furnace gas is perfect, and no misfires are found to occur. The poverty of the gas is, in fact, no bar to its employment for power purposes. In fact the blast furnace is described in Mr. W. N. Booth's report as an ideal gas-producer. The employment of blast-furnace gas for power purposes enables cold-blast iron to be made, for with a sale for gas the economy of fuel per ton of iron ceases to be of importance.

Approximately each pound of carbon in the fuel used will produce about 98 cubic feet of gas, and each 100 cubic feet of gas produced weighs nearly 8 lbs. The tests on the small engine at Wishaw showed only about 1½ lb. of coal per electrical horse-power, or 1·12 per i.h.p., assuming an efficiency of 75 per cent. between the cylinder and the terminals of the dynamo and allowing for temperature. Approximately each ton of fuel used per week in a furnace would give continuously 10 horse-power.

There has been a very considerable extension of the use of blast-furnace gas in Germany, where full advantage was promptly taken of Thwaite's teachings, and after a period of attempting to work with uncleaned gas Thwaite's method of cleaning was practically adopted. It is very important that the gas should be cleaned of its dust. Failure has occurred at an American iron-works where the engine valves became heavily loaded with dust. Fans may be employed through which the gas is circulated, jets of water being entered at the side of the fan casing. Rotating gas washers also are employed, and washer boxes in which the gas is passed under diaphragms which project an inch or two below water and compel the gas to bubble up through the water.

Large scrubbers with cellular work of light lathwork with water trickling over them will arrest much dust. Thwaite employed a sawdust filter as a final catcher, arranged so that the sawdust could be rapidly changed. Thwaite relied much on sawdust for removal of the tar, of which it is difficult to get rid. Though blast-furnace gas may contain as little as 27 per cent. of combustible gas it presents no ignition difficulties when electrically fired in a state of compression in the cylinder. A. Witz has shown that the average calorific value of the gas from twenty-seven Belgian furnaces was 111 B.Th.U. per cubic foot, while nineteen Luxembourg samples showed 114 B.Th.U., twenty-three German furnaces showed 108 B.Th.U., and nine French and Spanish furnaces 107 B.Th.U. He takes a general average of 110, but the value may fall to 97 with an acid flux. Such poor gas will bear high compression, and will safely bear 7 to 9 atmospheres. No matter how poor a gas it will ignite if sufficiently compressed, and at Seraing as high as 11 atmospheres were employed in 1901. Hence the excellent efficiency that is obtained with blast-furnace gas.

Blast-furnace gas contains but little hydrogen, as no steam is used in the blast furnace ; it approximates, in fact, closely to the gas that would be given by an ordinary producer supplied with air only. The small hydrogen content enables very high compression pressures to be used without danger of pre-ignition ; when well cleaned, this gas is an excellent fuel for large engines, the heat evolved per cubic foot of maximum mixture at 60° F. and 1 atm. being about 57 B.Th.U. as an average lower value ; as already pointed out in an earlier part of this section, with cylinders of 30 ins. in diameter and over, in order to avoid overheating troubles it is found desirable in practice to introduce only from 35 to 40 B.Th.U. per cubic foot of piston displacement ; thus, although low in comparison with most other gaseous fuels, the heat evolution per cubic foot of blast-furnace gas mixture is fully adequate to the needs of large gas engines.

Some average results for the principal gaseous fuels used at the present day are given in the following table :—

HEAT VALUE AND COMBUSTION OF USUAL GASEOUS FUELS.

(*From Sir Dugald Clerk.*)

60° F. = 15·5° C.

THE KIRKE PATENT GAS-FIRED BOILER.

The Kirke Patent Gas-fired Boiler, invented by Mr. P. St. G. Kirke, M.A., Assoc.M.Inst.C.E., A.M.I.M.E., etc., is manufactured by *Spencer-Bonecourt, Ltd.*, 32-33 *Farringdon Street, London, E.C.* 4.

Fig. 49 shows a Kirke Patent Gas-fired Steam Boiler. The design is based on the discovery that, if such gases as coal gas, coke-oven gas, blue water gas, producer gas, and natural gas are induced into empty tubes of great length relative to their bore, together with the air theoretically required for combustion, or some 10 per cent. in excess thereof, they can be completely burnt in the tubes without being previously mixed, and the resulting products of combustion reduced to 70° C., or less, above the temperature of the water in the boiler. Further, that this can be done either with natural draft or with high induced draft of 4 ins. of water and over, provided that the length of the tubes is greater relative to their bore the higher the draft adopted.

The Kirke Patent Gas-fired Boiler in its simplest form consists of a drum traversed by a number of long tubes with nothing in them, which function as combustion chambers, as mixing chambers, and as extractors of the sensible heat remaining in the resulting products of combustion.

KIRKE PATENT GAS-FIRED BOILER. (Patents No. 134,938, etc.)

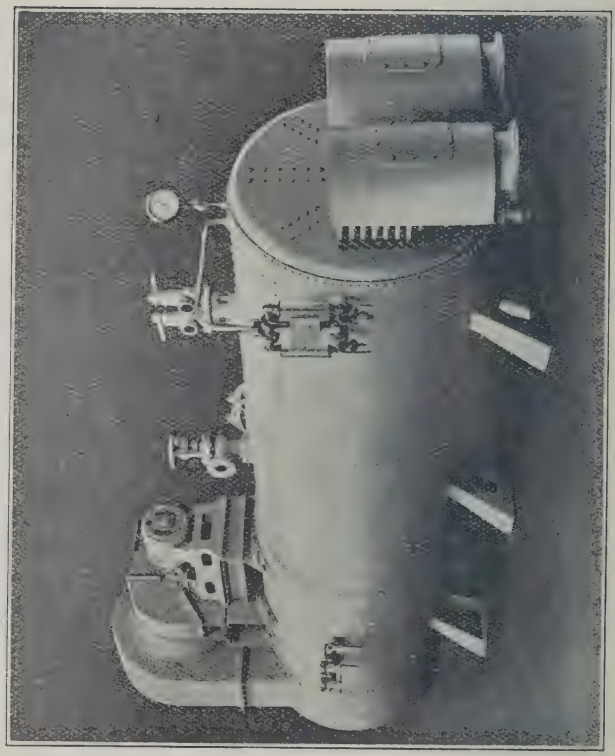

FIG. 49.

At the inlet end of the tube is a patent gas burner or distributor which discharges a jet of gas into each tube, the amount of which is determined by the size of the holes from which the gas issues and the pressure of the gas in the burner, the latter being controlled by the large gas inlet valve at the bottom of the burner. The requisite air for combustion enters each tube from the atmosphere, the quantity being controlled by the amount of draft which is varied to suit the load.

The following are figures obtained from a single tube evaporating water in an open wood tank lined with zinc :—

Gas burnt in cubic feet per hour	230
Steam raised from and at 212° F. in lbs. per hour	104
Cubic feet of gas per lb. of steam from and at 212° F.	2·21
Temperature of gases leaving the boiler	188° C.
Suction in inches of water	8
Gas pressure in inches of water	4
Evaporation per sq. ft. of heating surface in lbs. from and at 212° F. per hour	18
Net calorific value of the gas in B.Th.U.'s.	480
Thermal efficiency without economiser	91 per cent.

A single drum boiler of this type 7 ft. diameter by 21 ft. long, fired with coke-oven gas, will evaporate 21,000 lbs. of steam per hour with a suction of 4 ins. ; 16,000 lbs. with a suction of 2½ ins. ; and 10,500 lbs. with a suction of 1 in. The radiation loss from the shell when completely lagged (except for the front tube plate) is only ½ per cent. at full load and under 3 per cent. when unlagged.

The following table gives the power required by the fan, assuming 15½ lbs. of steam from and at 212° F. are required to generate 1 b.h.p.

Nature of Fuel burnt in Kirke Patent Fuel-fired Boilers.	Draft.	Percentage of Boiler Output required to create 4 in. suction.	Approximate B.H.P. required by the Exhauster for an Evaporation of 10,000 lbs. of steam from and at 212° F. per hour.
	Ins.	Per Cent.	
Water gas	4	0·93	6
Coke oven gas	4	1·00	6½
Producer gas	4	1·25	8
Crude oil	4	1·35	8¾
Coal	4	1·71	11
Blast-furnace gas	4	2·00	13

When the floor space is very restricted, it is easy to put one drum on the top of another. In this way, for a given evaporation only one-fifteenth of the floor space required by Lancashire boilers for the same evaporation is required.

The cleaning of the tubes on the water side is made easy by division of the tubes into two nests. A man can enter the boiler through the manhole and walk along the whole length of the boiler between the two nests, so that he can scrape the surface of all the tubes for their entire length, the distance between the tube centres being sufficiently great to enable him to get a suitably shaped scraper to all the tubes. This, however, is better avoided by softening the water or using a suitable boiler fluid. An internal scale-separating device is also fitted.

For superheating the steam a separate chamber containing fire tubes fired in the same way, but with natural draft, is used, the temperature being kept constant by a thermostat operating the gas valve.

The following are the approximate fuel consumptions per lb. of steam raised from and at 212° F. for various fuels burnt in Kirke patent boilers without economisers :—

Producer gas	8 cubic ft.	Poor coal-gas	2·7 cubic ft.
Coke oven gas	2½ ,,	Natural gas	1·2 ,,
Water gas	3⅝ ,,	Crude oil	$\frac{1}{17}$th lb.
Rich coal gas	2·2 ,,		

Kirke Patent Waste Heat Boiler.

This boiler, fig. 50 (Patents numbered 140,851, 209,878, etc.), consists of one or more drums, having inlet products chambers at one end and outlet products chambers at the other, connected together by a number of empty and straight fire tubes of great length relative to their bore through which the hot gases are drawn at a high vocity by means of an induced draught fan.

The high velocity enables large volumes to be handled in a boiler of comparatively small dimensions, and prevents most of the dust from lodging on, and insulating, the heating surfaces. It also reduces the cost of the boiler, and increases the return on the capital expenditure.

Notwithstanding the high velocity at which the gases flow over the heating surfaces, the great length of the tubes relative to their bore enables the temperature of the hot products to be reduced to about 30° C. above the temperature of the water in the boiler, before they enter the fan impeller. Consequently an economiser is not required, and higher thermal efficiencies can be obtained than have ever been obtained before.

Cleaning.—The fire tubes are arranged in two or more nests, between which it is possible for a man to enter, so that the tubes are exposed for cleaning on the water side over the whole of their length.

As the interior of the fire tubes is smooth, round, and straight, and the induced draught causes the hot products to travel through them at a high velocity, without changing their direction, there is nothing to catch the dust, which consequently is carried straight through to the outlet products chamber, from which it can be easily removed from time to time. To deal with dirty gases containing very large quantities of dust—such as are obtained from cement kilns—an arrangement (Patent No. 186,801) for enabling these boilers to be cleaned while they are running is now being fitted to all these boilers. The fan is arranged at the top or at the side of the boiler so as to leave the cover plate of the outlet products chamber unobstructed. In this cover plate small holes are drilled large enough to pass a tube brush or steam lance through for pushing through the whole length of tubes. One of these little holes will allow some nine tubes to be cleaned, and, while leakage of air into several of the holes is not sufficient to reduce the draught, it is not necessary to open more than one at a time for cleaning purposes.

Circulation.—The circulation in the Kirke boilers is particularly good. About 70 per cent. of the evaporation occurs in the first third of the tubes, and only about 10 per cent. in the last third. Consequently there are strong convection currents upwards at the front end and downward at the rear end.

Dry Steam.—By taking the steam off at the back end of the boiler, where the circulation is downward, and by the use of an efficient anti-primer, the steam is rendered remarkably dry. In an independent test on a boiler of this type unlagged, the steam was found to be 99·3 per cent. dry. In a second independent test carried out on a lagged boiler of this type, the moisture in the steam was so small that it could not be measured and was reported to be 'practically quite dry.' In a third case, where water-tube boilers were giving trouble with priming, it was found impossible to make a boiler of this type prime even under conditions which no boilers would be put to in practice—namely, when supplying steam to a number of colliery winding engines, all of which were purposely started up at once.

Loss due to Radiation.—In Kirke boilers the radiation loss is extremely small, owing to the fact that, except for the front tube plate, the whole of the shell may be lagged. With air at 72° F., the heat loss from uncovered steam pipes carrying steam at 100 pounds per sq. in. is 1,170 B.Th.U.'s per sq. ft., and this is reduced to 100·2 B.Th.U.'s when 2 ins. of magnesia lagging is used to cover them (see 'Mechanical Engineers' Handbook,' by S. Marks). In the case of a large standard pattern Kirke gas-fired boiler, 6½ ft. diameter, evaporating 18,000 lbs. of steam from and at 212° F. per hour with 4 ins. induced draught, the loss of steam due to radiation is, however, only 2¾ per cent. before the boiler is lagged and about ½ per cent. after the boiler is lagged.

KIRKE PATENT WASTE HEAT BOILER FOR WASTE HEAT, COAL, BLAST-FURNACE GAS, OR PULVERISED FUEL. (Patents No. 140,851, etc.)

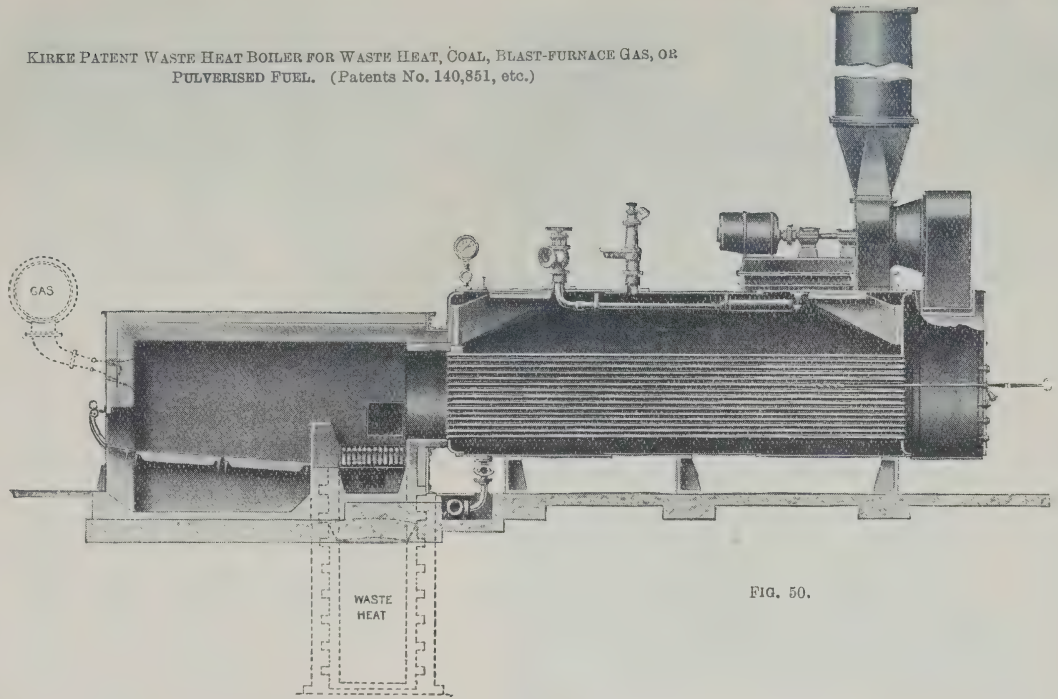

FIG. 50.

Efficiency.—Two Spencer-Bonecourt Kirke patent waste heat boilers which are generating steam from the waste heat discharged from 10 settings of Glover-West retorts at the Stratford works of the Gas Light and Coke Co., gave the following figures when tested by the staff of the Gas Light and Coke Co. :—

Date of test, November 19, 1923.

Duration of test, 24 hours.

Temperature of the products entering the boilers	689° C.
Temperature of the products leaving the boilers	225° C.
Steam pressure in lbs. per sq. in.	115
* *Mean tube efficiency of the boilers*	90·3 per cent.
Suction in the outlet products chamber of the boiler in inches of water	4·4 ins.
Suction in the inlet products chamber available for the settings and collecting flues	1·4 ins.
B.H.P. consumed by the motor for the retorts	11½
B.H.P. consumed by the motor for the boilers	24¼
Water evaporated per hour in lbs. actual	16,783
Water evaporated from and at 212° F. per hour in lbs.	18,500
Percentage of power absorbed by the draught for boiler (assuming 15 lbs. of steam from and at 212° F.) per b.h.p. hour	2 per cent.
Percentage of power developed absorbed by the draught for collecting flues and settings (assuming 15 lbs. of steam from and at 212° F. per b.h.p. hour)	0·93 per cent.
Estimated saving in small coke and breeze per annum of 300 days freed for market in tons (assuming 6 lbs. of steam from and at 212° F. per lb. of this fuel)	10,000 tons
Steam produced from and at 212° F. per lb. of coke used in the producers	5·8
Steam produced from and at 212° F. per lb. of coal carbonised	0·9 lb.
Heat loss between the outlet of the settings and the inlet of the boiler due to radiation from the steel flues	4·9 per cent.

One of these boilers fitted to a Talbot steel furnace at another works brought down the consumption of coal per ton of steel to 3½ cwts. Before the Kirke boiler was installed the coal consumption was 5 cwts. per ton of steel.

These waste heat boilers have been successfully installed on horizontal retort benches, inclined retort benches, vertical retort benches, open hearth steel furnaces, soaking pits, cement kilns, water gas plants, puddling furnaces, etc.

The boilers have also been installed in Europe, Asia, Africa, America, and Australia.

The Clarkson Boiler.

(*The Clarkson Thimble Tube Boiler Co., Ltd.*, 613 *Australia House, Strand, London, W.C.* 2.)

The 'Clarkson Thimble Tube Boiler' has for years met the needs of hundreds of steam users who require all the advantages that an ordinary quick steaming water-tube boiler provides, and for whom other considerations render inadvisable the use of such a boiler.

The boiler can be used for many duties and with various fuels, although the most suitable use for it is the extraction of the waste heat from engine exhaust gases. The makers claim that for this duty the boiler is the most serviceable on the market from almost every point of view. Installations on engines of all sizes from 7 b.h.p. to 10,000 b.h.p. have been successfully carried out.

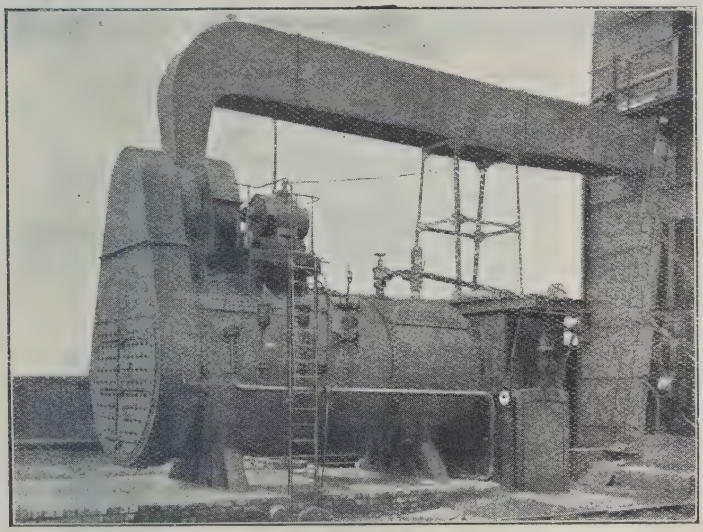
The Clarkson Thimble Tube Boiler is of the vertical water-tube type, the general construction of which is shown in fig. 51, page 2197. The tubes, being thimble shaped, are expanded into a cylindrical shell plate at one end only, so that the troubles caused by the expansion and contraction of water-tubes in ordinary boilers do not exist for the Clarkson Boiler, whilst at the same time quick steaming properties and other advantages of water-tube boilers are retained.

The boiler unit consists of two cylindrical shell plates, through the centre of which the flue gases pass. Several hundred thimble tubes are expanded into holes in the inner plate, each successive ring being staggered. A centre core fills up the cylindrical space between the tube ends and compels the exhaust gases to travel tortuously through the nest of tubes which comprise the heating surface. The water space is thus annular in shape with projections inside each thimble.

The usual boiler or heater fittings are mounted on the shell. A combustion chamber and oil burners are added to the boiler unit, and make a highly efficient steam generator.

* To obtain tube efficiency, divide difference between the temperature of the gases entering and leaving the tubes by the difference between the temperature of gases entering the tubes and that of the water in the boiler.

WASTE-HEAT RECOVERY



WITH A PROPERLY LAID OUT WASTE-HEAT RECOVERY SYSTEM, THE USE OF FUEL-FIRED BOILERS FOR POWER REQUIREMENTS IS GREATLY REDUCED AND IN CERTAIN INDUSTRIES ENTIRELY ELIMINATED . . . . FURTHER INFORMATION WILL BE SENT ON APPLICATION

Non-Scaling.—It will be realised that steam is generated inside the thimbles, and therefore when a certain amount of steam is generated it blows the water back out of the mouth of the tube. The water then returns into the tube when the steam has escaped. The pulsating action thus set up has a frequency of the order of 90 to 160 per minute, and effectively scours the tube of scale. The scale-forming matter is then directed to the foot of the boiler by the cylindrical baffle plate, which also prevents the cold feed water from impinging direct on to the tube ends, and helps an effective circulation.

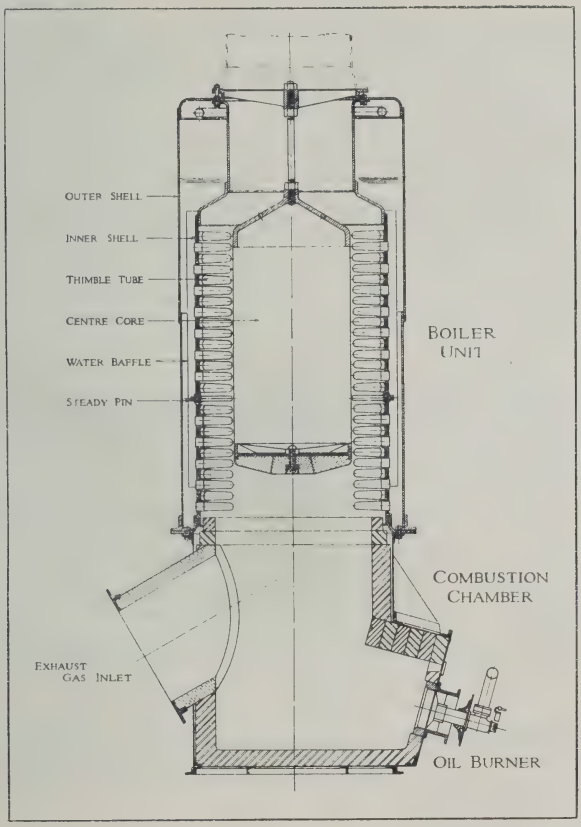

FIG. 51.

Soot Cleaning.—Should the outside of the thimble tubes foul, as may happen when running off a dirty engine exhaust, the boiler can be emptied, a wad of oil-soaked waste ignited and put at the foot of the tube nest, and the impurities burnt off with no danger of damage occurring.

Accessibility.—The tubes are easily accessible on the steam side of jointed designs, similar to that shown in fig. 51, by raising the outer shell. Larger sized boilers are now being designed with a large annular space around the inner shell, so that complete accessibility is obtainable without raising the outer shell. The whole boiler is then of riveted up construction, and sufficient space is allowed for a man to get inside the boiler and inspect all parts of the water space, and for the renewal of tubes, if necessary. The gas side of the tubes is accessible in the jointed

types by removing the centre core, whilst in some Clarkson designs the same accessibility is obtained by making the centre core sectional or telescopic, so that no head room is required.

Centre Core.—The centre core or gas baffle, of the best fire-resisting material, forces the exhaust gases to travel tortuously through the nest of tubes, and is suspended from the uptake, being steadied by three to six steady pins, screwed into the inner shell.

Exhaust Heat Extraction.

Silencing.—The Clarkson Boiler is an efficient exhaust silencer, and can be designed so that it may be run dry off exhaust gas with no ill effects, and put on to steaming load at short notice.

Back Pressure.—In estimating the size of boiler required for extracting heat from exhaust gases, the main consideration is the avoidance of any extra back pressure on the engine. The contraction of the gases as they cool in the boiler assists the exhaust from the engine cylinders, tending to reduce back pressure.

Supercharged Engines.—Where an exhaust gas boiler is required to operate on the outlet side of an exhaust gas turbine, then very little back pressure is allowable, and for this reason the Clarkson Boiler has been used on a considerable number of large marine supercharged installations. It is the only waste heat boiler which has been used on installations of this nature.

Installations.—Clarkson Boilers have now been supplied for a multitude of uses as coal and oil-fired donkey boilers for Admiralty work, for dredgers, steam cranes, steam wagons, etc., and for waste heat recovery from the exhaust gases of hundreds of internal combustion engines of all types, particularly for marine purposes. Amongst these can be numbered boilers supplied to the British Admiralty for submarines; boilers supplied for four-cycle engines on the White Star liner *Britannic* (which is incidentally the largest waste heat installation afloat); boilers supplied for most of the largest motor vessels constructed during 1930, including the *Reina del Pacifico*, *Otaio*, *Orari*, *Opawa*, *Winchester Castle*, and *Warwick Castle*, which list is by no means exhaustive.

Recent developments include simultaneous oil and exhaust gas-fired boilers, also a combined electric and exhaust gas boiler.

Fuel Firing.

Owing to the quick steaming properties and strong design of the Clarkson Boiler, it was found necessary to adapt the unit for coal or oil firing, and a range of thimble tube boilers with water legs has been built and have given satisfactory service as donkey boilers, galley boilers, and dredging duties. Types of these boilers, used on steam wagons, have withstood successfully for many years the rough treatment that is often met with in road work.

The makers claim the following advantages for this boiler:

1. A smaller size of thimble tube boiler will do the work of steam generation more efficiently and at less cost than is possible with any other type of boiler, especially other vertical boilers.
2. In consequence of low size and weight, it can be fitted in the place of silencers, in the exhaust pipe run above the engine room.
3. Silencer boilers may be fitted with alternative oil firing for use in port, and may also be designed for simultaneous oil firing, or for additional steam raising by means of electrical heaters.
4. Ample accessibility for cleaning and inspection of all internal parts, particularly in jointless designs, where the whole boiler can be made accessible in a few minutes.

Summary of Test Results on Oil Firing.

Clarkson Silencer Boiler: Type Begatoo-600. Date of Test: May 30, 1928.

Boiler.—Clarkson Patent Vertical Thimble Tube, 6 ft. diam. by 18 ft. 10 in. overall.

Working Pressure.—100 lbs. per sq. in.

Heating Surface.—600 sq. ft.

Weight complete.—12 tons.

Oil Burners.—Clyde Oil Fuel System, Low-Pressure Air.

Utility.—Silencer—Boiler passing 70% of exhaust gases of 10,000 B.H.P. twin engines, or Oil-Fired Donkey Boiler.

Guaranteed Evaporation.—4,800 lbs. of water from and at 212° F.

Evaporation per hour, actual	5,071 lbs.
Evaporation per hour, f. & a., 212° F.	6,085 ,,
Oil consumed per hour	491·7 ,,
Water evaporated, f. & a., 212° F. per lb. of oil	12·38 ,,
Steam per sq. ft. of heating surface per hour, f. & a., 212° F.	10·2 ,,
Thermal efficiency of boiler—unlagged	64·5%

WASTE HEAT RECOVERY.

(Contributed by Chas. F. Wade, A.M.I.Mech.E., A.M.I.E.E.)

The directions in which profitable recovery of waste heat must be looked for are

(i) Waste heat from various metallurgical and other furnaces ;

(ii) Waste gases from internal combustion engines ;

(iii) Exhaust steam from non-condensing engines, steam hammers, steam-hydraulic intensifiers, etc.

Waste heat from high temperature metallurgical operations, such as open-hearth melting furnaces, consists of the sensible heat of the waste gases and the heat carried away by radiation and convection from the furnace walls. The latter is permitted deliberately in order to prevent unnecessarily rapid burning of the walls. The heat of the waste gases is generally utilised for the purpose of preheating the incoming air and gas by means of regenerators and reversing valves. By jacketing the furnace walls and utilising the heat formerly wasted in radiation for air preheating, thus releasing approximately 50 per cent. of the heat of the waste gases for steam-raising in a waste heat boiler, a very substantial saving of fuel will result. The loss of heat by radiation and convection from unjacketed furnaces is certainly not less than 25 per cent. of the total heat of the fuel used. Even in a reheating furnace working at 1000° C., jacketing of the furnaces instead of regeneration in chequer chambers will often give an air temperature of over 300° C.

Small reheating furnaces for light forgings and similar work air-jacketed at the sides only will often give a temperature of over 150° C. in the air supplied for combustion. In all cases the result will be that the final temperature of the gases will be sufficient to make a waste heat boiler a profitable investment.

In metallurgical furnaces wherein the process requires a densely smoky atmosphere and the air supply is deliberately restricted, the use of a waste heat boiler for the products of combustion together with a supplementary coal fire, through which an excess of air is passed, will not only lead to large recovery of heat in the form of steam, but will also furnish a solution to the smoke-abatement problem. Without the supplementary fire-grate a supply of highly preheated air brought through ducts on the furnace settings will usually ensure reignition of the combustible matter in the smoky gases. Cold air will not do this owing to the low temperature of the gases to begin with, thus keeping the products below ignition point.

For ordinary waste heat boiler work without supplementary firing a temperature of at least 800° C. is needed to make the proposition profitable. With tubular boilers of the Cochran type the usual evaporation per pound of coal consumed in the furnace is :—

Temperature of Waste Gases.	1500° F.	1800° F.	2000° F.
Lbs. water per lb. of coal from water at 62° F.	3·08	4·25	5·00

Using boilers of the ' Bonecourt ' type, in its more modern developments, wherein gas at a high velocity, aided by mechanical draught, is in use, gases with an initial temperature of 350° C. may be used profitably.

Gases from internal combustion engines usually allowed to expand in a silencer, with corresponding fall of temperature, are maintained at smaller volume and part with their heat to the water in the boiler with a final temperature of about 75° C.

This system is of considerable value also in dealing with the waste heat from gas retort furnaces.

Where low-temperature furnaces are in use only the waste gases may be used for heating of water for shop and office heating by means of economisers, and where both high- and low-temperature furnaces are worked, the hot water from the latter should be used for feed to the high-temperature waste heat boilers. An interchange of heat and power from waste sources between adjoining establishments is often a practicable proposition where the means of power and heat generation and utilisation are collectively equal.

The heat wasted in exhaust steam can be applied to the drive of low or mixed pressure turbines, which latter will have the additional economical effect of levelling out the load on the boiler plant, in that a falling-off of the supply of exhaust steam will cause the turbine to draw on the boilers directly for a high pressure supply. Other important advantages are the returning of soft water to the boilers for feeding purposes, either with or without preliminary electrolytic treatment for oil elimination,

Other applications of the heat of exhaust steam are for heating processes in manufacture, heating of buildings, etc., all of which permit of the return of the condensate for boiler feed purposes.

All proposals for the utilisation of waste heat of any kind require to be dealt with individually on their merits, the conditions being so variable that no hard and fast rules can be laid down which will be universally applicable.

Generation of Electricity in Great Britain by Waste Heat.

In the Annual Report of the Electricity Commission * it is stated that the total units generated by waste heat during the year ending March 31, 1928, was 217,987,219 (from 21 stations), as against 78,332,571 (from 17 stations) in 1927.

* Generation of Electricity in Great Britain, year ending March 31, 1928. H.M. Stationery Office, Adastral House, Kingsway, London, W.C. 2. Price 1*s.* 6*d.* net.

Electrical Units.

(For Glossary of Terms used in Electrical Engineering—see B.E.S.A. Report No. 205—1926. For Graphical Symbols for Electrical Purposes—see B.E.S.A. Report No. 108—1922.)

Unit.	Symbol.	Name.	Value in C.G.S. Units.	Dimensions in terms of	
				Length Time Mass.	Length Time Force Velocity.
Electromotive force . . .	E	Volt	10^8	$L^{\frac{3}{2}}M^{\frac{1}{2}}T^{-2}$	$V\sqrt{F}$
Current	I	Ampere	10^{-1}	$L^{\frac{1}{2}}M^{\frac{1}{2}}T^{-1}$	$\sqrt{F}$
Quantity	Q	Coulomb	10^{-1}	$L^{\frac{1}{2}}M^{\frac{1}{2}}$	$T\sqrt{F}$
Resistance	R	Ohm	10^9	$L\,T^{-1}$	V
Capacitance	C	Farad	10^{-9}	$L^{-1}T^2$	TV^{-1}
Inductance	L	Henry	10^9	L	L
Power or rate of working . .	P	Watt	10^7	$L^2M\,T^{-3}$	VF
Energy	W	Joule	10^7	$L^2M\,T^{-2}$	L F

The values of these units are as follows:—

One Ampere (*international*) is the unvarying electric current which, when passed through a solution of nitrate of silver in water, deposits silver at the rate of 0·001118 gramme per Second.

One Coulomb is the quantity of electricity represented by 1 Ampere passing for 1 Second.

One Ohm (*international*) is the resistance to an unvarying electric current of a column of mercury of uniform cross-section and length equal to 106·3 cm. whose mass is 14·4521 grammes at the temperature of melting ice.

One Volt (*international*) is the electrical pressure which, when steadily applied to a conductor whose resistance is one international Ohm, will produce a current of one international Ampere.

One Farad is that capacity which is charged to a potential of 1 Volt by a current of 1 Ampere flowing for 1 Second.

One Henry is the inductance of a circuit in which an E.M.F. of 1 Volt is induced by a current variation of 1 Ampere per Second.

One Watt is the power, or the rate at which work is being done, when a current of 1 Ampere passes through a resistance of 1 Ohm.

One Joule is the amount of work done, or heat generated, by 1 Ampere flowing for 1 Second through a resistance of 1 Ohm.

The following multiples and sub-multiples of these units are in common use :—

One millivolt	= one-thousandth of a volt.	One microhm	= one-millionth of an ohm.
One milliampere	= one-thousandth of an ampere.	One microfarad	= one-millionth of a farad.
		One millihenry	= one-thousandth of a henry.
One megohm	= one million ohms.	One kilowatt	= one thousand watts.

The following relations will be found useful :—

One horse-power is equal to 746 watts.

One foot-pound is equal to 1·356 joules = 0·323 calorie.

One joule is equal to 0·238 calorie.

One (gm.) calorie is the work done in raising 1 gramme of water 1° C., = 4·2 joules.

One (kg.) calorie = 1000 (gm.) calorie.

One joule is equal to 0·7373 foot-pound.

One dyne is the force which, acting on a mass of 1 gramme for 1 second, will give it a velocity of 1 cm. per second.

One erg is the work done by 1 dyne acting through 1 centimetre.

One watt = 0·00134 horse-power = 0·7373 ft.-lb. per second = 44·24 ft. lb. per minute = 0·0573 British thermal unit per minute = 1 joule per second.

One kilowatt-hour = 1,000 watt-hours = one Board of Trade Unit = 1·34 horse-power-hours = 2,656,400 ft.-lb. = 3,415* British thermal units = 860,600 calories.

The practical standard of electromotive force is the Weston Normal cell, which has an E.M.F. of 1·0185 volts at 15° C., decreasing by 0·00004 volt per degree C. rise of temperature.

Laws of Currents in Conductors.

Ohm's law states that: Voltage = Current × Resistance, or $V = I \times R$.

Kirchhoff's first law states that : The algebraic sum of the currents meeting at any point of a network of conductors is zero.

Kirchhoff's second law states that: The algebraic sum of all the products of resistances and currents in all the wires forming a closed network equals the algebraic sum of all the electromotive forces in the network.

RESISTIVITY OF PURE ANNEALED METALS, AND ALLOYS, AT 0° C. (32° F.).

* British Engineering Standards Association, 'Glossary of Terms used in Electrical Engineering' (Publication No. 205—1926). The Electricity Commissioners have adopted the value 3412, which takes the *mean* British thermal unit to be $\frac{1}{180}$ of the quantity of heat required to raise the temperature of 1 lb. of water from 32° F. to 212° F.

Lenz's law states that : The current induced in a conductor flows in such a direction that its reaction opposes the change of position or state by which it is produced.

The power represented by a current of I amperes flowing under a difference of potential of V volts through a conductor of resistance R ohms $= I \times V = I^2R = V^2/R$ watts.

The heat energy generated by a current of I amperes flowing through a conductor of resistance R ohms for t seconds $= I^2Rt$ in joules.

Effect of Temperature on Resistance.

The resistance of metals increases with the temperature in accordance with the approximate formula

$$R_t = R_0 (1 + kt)$$

where k is the coefficient given in col. 5 or 6 on p. 2298 (according to the temperature scale employed) divided by 100.

If the resistance R_1 at temperature t_1 in ° C. be known, then for copper the resistance R_2 at temperature t_2 in ° C. will be :—

$$R_2 = R_1 \left(\frac{234{\cdot}5 + t_2}{234{\cdot}5 + t_1} \right)$$

Metallic Resistance Materials.

Metallic resistance materials are classified by the British Engineering Standards Association for maximum temperatures of 60, 200, 300, 700, and 1,000° C. respectively. According to Report No. 115—1924, the resistivity at 20° C. is not to differ more than 5 per cent. from that declared by the supplier, and the material must be uniform in resistance within 5 per cent. ; the temperature coefficents in the two low-temperature classes must not exceed 0·00002 and 0·00004 respectively for ten hours without the resistance changing more than 0·01 per cent. Lists of standard sizes of wires, sheets, and tapes are given in the Report.

Copper Conductors.

British Standards for Insulated Annealed Copper Conductors for Electric Power and Light.* No. 7—1926. (*Abstract.*)

The International Standards of Resistance for Copper are as follows :—At 20° C. (68° F.), the resistance of a wire of standard annealed copper 1 metre long and of 1 sq. millimetre cross-section is $\frac{1}{58}$ = (0·017241) ohm. The density of such copper at 20° C. is 8·89 grams per cub. centimetre, and the temperature coefficient of resistance is 0·00393 per degree C. At 60° F. (15·56° C.) the resistance of a solid conductor of standard annealed copper 1,000 yards long and of 1 sq. in. cross-section is 0·0240079 ohm ; the density is 8·892015, and the temperature coefficient of resistance is 0·0022221 per degree F.

At 15·5° C. (60° F.), the resistance of a copper conductor is accurately given by the expression :

Resistance in microhms = 8 × length in feet/cross section in square inches.

For the purposes of the specification an increase of 2 per cent. in the length of each wire in the stranded conductor has been assumed, and the area of the stranded conductor has been taken to be that of the solid wire which has the same resistance. In the case of multicore cables, an increase of 2 per cent. has been taken, to allow for the laying-up of the cores.

Tolerances allowed on solid conductors are, in weight, 3 per cent. ; in resistance, 3 per cent. plain, 4 per cent. tinned (0·036 in. diameter upwards), 5 per cent. (below 0·036 in.). On stranded wires, in weight 2 per cent. ; in resistance, 2 per cent. plain, 3 per cent. tinned (0·036 in. diameter upwards), 4 per cent. (below 0·036 in.).

The resistance of hard-drawn copper is about 3 per cent. higher than that of annealed copper conductors.

This specification also gives tables of sizes, resistances and weights of standard solid and stranded circular copper conductors, flexible cords and cables. Details of standard thickness of dielectric for paper, rubber and vulcanised bitumen insulated cables, the sizes and thickness of lead and tough rubber coverings, galvanised steel wire and tape for armouring are tabulated for cables up to 11,000 volts. Pressure tests are specified together with the method of procedure. An appendix contains diagrams showing sections of single and multicore cables and an extract from the British Standard Glossary of Electrical Terms and Definitions.

FLEXIBLE CABLES.

A flexible cable is one in which the conductor (or conductors) exceeds 0·007 sq. in. in cross-section, and comprises a number of wires, the diameter of the wires and the material of the dielectric being such as to ensure flexibility.

1·0	127/·103	595·0	—	—	200

The figures for vulcanised rubber cables apply to single cables run in pairs in iron conduits or in wood casing, and to single cables sheathed with tough rubber compound, and to concentric, twin, and three-core cables of any finish run singly.

The maximum permissible currents (subject to voltage drop) given in the table for conductors up to 1 square inch in area allow for a rise in temperature of 20° F. (11·1° C.). For sizes below 0·007 square inch the table is based on a current density of 4,000 amperes per square inch. The length of lead and return given in the last column is based on the figures in the third column.

Where the temperature of the air exceeds 80° F. (26·6° C.), the current should be reduced so that the normal maximum running temperature does not exceed 100° F. (37·7° C.). Rubber-insulated cables should not be allowed to attain a temperature higher than 120° F. (48·8° C.) for long periods.

IMPREGNATED-PAPER AND LEAD-COVERED CABLES.

1·0	127/·103	932·0	—	—	121

The figures for impregnated-paper and rubber-insulated cables apply to single cables run in pairs, and to concentric, twin, and three-core cables run singly.

The maximum permissible currents (subject to voltage drop) given in the table for conductor up to 1 square inch in area allow for a rise in temperature of 50° F. (27·7° C.). For sizes below 0·007 square inch, the table is based on a current density of 4,000 amperes per square inch. The length of lead and return given in the last column is based on the figures in the third column.

Where the temperature of the air exceeds 80° F. (26·6° C.), the current should be reduced so that the normal maximum running temperature does not exceed 130° F. (54·4° C.). Impregnated-paper lead-covered cables, for pressures not exceeding 660 volts, should not be allowed to attain a permanent temperature higher than 176° F. (80° C.).

ALUMINIUM CONDUCTORS.*

Conductivity.

The conductivity of aluminium depends upon the purity, and, to a less extent, upon the amount of work put upon the metal in its evolution from billet to the finished wire or bar. The British standard of resistance for hard copper is 2 per cent. higher than that of soft, and this difference also applies to hard and soft aluminium. The conductivity of all materials is normally compared with that of the International Standard for annealed copper, and on this basis hard-drawn aluminium will have a minimum conductivity of 60 per cent. Hard-drawn copper will have a conductivity of about 98 per cent. and hence compared with hard-drawn copper, hard-drawn aluminium will have a conductivity of 61·3 per cent.

Weight.

The specific gravity of aluminium wire is about 2·703. As the specific gravity of copper wire is about 8·89, the relative weight of a given volume of each metal is in the ratio of 8·89 to 2·71 = 3·3. In other words, a copper wire of any given size and length will weigh 3·3 times as much as an aluminium wire of the same size and length. Aluminium, therefore, having a conductivity of 61 per cent. of that of copper, will have a sectional area 1·642 times as great as a copper conductor of the same resistance and length, and the ratio of the weights will be 3·3 to 1·642 = 2·01; that is to say, a copper conductor of any given resistance and length will weigh approximately twice as much as an aluminium conductor of the same resistance and length.

The ratios are therefore as follows:—

	Copper.	Aluminium.
Conductance for equal section	1	0·61
Section for equal conductance	1	1·642
Diameter for equal conductance	1	1·28
Weight for equal bulk	3·3	1
Weight for equal conductance	2·0	1

Tensile Strength.

Although the tensile strength of aluminium in the annealed state is low, the strength of aluminium in the form of wire is greatly increased owing to the work put upon it during rolling and drawing. The strength can be increased more than 100 per cent. without making the elongation too small for engineering purposes.

Durability.

Aluminium has withstood the test of varying and severe climatic conditions. Lines have been in operation for over twenty years in exposed positions on the sea coast which show little signs of deterioration. The metal is less affected by sulphurous and sulphuric fumes than copper, and shows less deterioration in the presence of any of the commoner acids. On the other hand, aluminium is attacked by strong alkalies, and should not be used in such circumstances without efficient painting.

Increase of Resistance with Temperature.

The coefficient of increase of resistance with temperature varies somewhat with the extent and nature of the impurities present and the temperature range over which it is taken. At 20° C. the value for aluminium may be taken at 0·00407 per °C., at 15·6 °C. in accordance with *B.E.S.A. Specification*, No. 215–1930.

Coefficient of Linear Expansion.

The coefficient of linear expansion being somewhat greater with aluminium than with copper, due allowance should be made for this when installing long lines of solid feeders or bars.

Action of Acids

Aluminium is not acted upon by any of the common acids in a cold state, with the exception of hydrochloric acid, and withstands the effects of sea-water better than either copper or iron; but galvanic action is set up between aluminium and any of the common metals in the presence of moisture, and for this reason, if iron and copper joints must be used, they should be thoroughly protected from moisture by taping or painting with bituminous paint. It is found that galvanised iron parts can be used with aluminium owing to their closer proximity in the electro-chemical series, and the hardware employed with aluminium overhead lines is usually of galvanised malleable iron.

* See also B.E.S.A. Report No. 215—1930, 'Hard-Drawn Aluminium and Steel-Cored Aluminium Conductors for Overhead Power Transmission Purposes.'

recommended construction for the 0·125 sq. in. conductor.

Physical Properties of Aluminium and Copper.

Atomic weight of aluminium (oxygen = 16) = 26·97 (*Int. Atomic Wt. Comm.*, 1925).

Coefficient of linear expansion per °C. = 23 × 10^{-6} (*B.E.S.A. Specification*,

,, ,, ,, ,, °F. = 12·78 × 10^{-6} *No.* 215–1930).

Specific gravity, rolled or drawn = 2·703 (*B.E.S.A. Specification*, *No.* 215-1930).

With regard to the tensile strength of H.D. wires, the minimum wire diameter given should be 0·093 ins. (not 0·0935 ins.). See *B.E.S.A. Specification*.

The modulus of elasticity of H.D. aluminium conductors = 9·9 × 10^6 lbs. per sq. in.

The modulus of elasticity of H.D. aluminium stranded conductor = 9·6 × 10^6 lbs. per sq. in.

Coefficient of increase of resistance with temperature at 15·6° C. (60° F.) = ·00407 per ° C.

Coefficient of increase of resistance with temperature at 60° F. (15·6° C.) % 0·00226 per ° F.

Weight per 1,000 yds. per sq. in. of cross section = 3515 lbs.

Standard specific resistance in microhms per in.^{3} at 20° C. of H.D. aluminium = 1·1199.

All the above specific resistance figures are standard values.

Sulphur has no effect upon aluminium at ordinary temperatures, and consequently aluminium withstands the action of smoke and fog much better than either silver or copper. A thin transparent film of insoluble oxide forms immediately on the surface of aluminium when it is exposed to the atmosphere, protecting it from further oxidisation or corrosion. This film of oxide is a good insulator and will withstand the application of considerable electrical pressure before breaking down. Advantage is being taken of this feature in the manufacture of magnet windings, etc., which are otherwise uninsulated.

Capacitance and Inductance.

Aluminium being a non-magnetic material, the inductance or capacitance of the line can only be affected by the increased diameter. This increased diameter may decrease the inductance and increase the capacitance by some 5 per cent., but as all transmission lines possess more inductance than capacitance, this difference is in favour of aluminium, tending to improve the power factor of the system and to reduce the pressure drop due to inductance.

Heating Effect.

Aluminium, having a larger surface than copper of equal conductance, is more easily able to get rid of its heat, and when transmitting a given current with a given I^2R loss, aluminium will remain the cooler. This is a considerable advantage when installing electric apparatus in a hot atmosphere, or where current-carrying capacity is of more importance than the permissible pressure drop. In any case aluminium will have a higher overload capacity, from a heating point of view, than copper of equal resistance. In consequence of this aluminium is being largely used for busbars and solid rod battery connections. Erection on site is facilitated by the ease with which bends and joints can be made.

Corona Losses.—With a high voltage overhead line a serious loss of energy may occur in the form of a luminous discharge due to the breakdown of the air surrounding the conductors. The point at which corona begins is a function of the conductor diameter, and the use of aluminium or, better still, steel-cored aluminium, both of which involve a larger diameter than that of the equivalent copper, will safely enable a higher working voltage to be employed.

Aluminium Cable, Steel-Cored.

After the introduction of aluminium for electrical conductors it became apparent that if a conductor could be obtained, combining the advantages of lightness of aluminium with the strength of high-grade steel now obtainable on the market, the highest efficiency would result. Cables of this character were made up and have now been in service in such a variety of localities and conditions that their efficiency has been thoroughly demonstrated.

The cables consist of a steel core about which the aluminium is stranded. The steel for the smaller size cables consists of a single strand, while for the larger sizes several strands are used. These are composed of patent steel, having an ultimate strength of 160,000 lbs. per square inch to 200,000 lbs. per square inch, according to the diameter, an elastic limit of 70 per cent. of the ultimate strength, and an elongation of 4 to 6 per cent. on 10 inches. The wires are heavily

galvanised, and after the aluminium strands are in place over the steel, around which they fit closely by reason of the stress resulting from the load on the cable, the steel is to a large extent protected from corrosive action. This protection is due to the almost complete exclusion of moisture from the steel core by the aluminium envelope, and further on account of the insulating oxide film on the aluminium, which tends to prevent the flow of small local electric currents. Another feature which adds to this desirable condition is the fact that zinc and aluminium are closer together in the electro-chemical series than any other two metals in common use.

The following table shows at a glance the superiority in mechanical characteristics of steel-cored conductors over all-aluminium, or copper of equivalent conductance.

Size.	—	Aluminium.	Steel-cored Aluminium.	Copper.
0·025 sq. ins. copper area	Weight . .	1·0	1·48	2·04
	Diameter . .	1·0	0·98	0·79
	Ultimate load .	1·0	2·19	1·52
0·10 sq. ins. copper area	Weight . .	1·0	1·37	2·04
	Diameter . .	1·0	1·07	0·79
	Ultimate load .	1·0	1·95	1·55
0·40 sq. ins. copper area	Weight . .	1·0	1·68	2·04
	Diameter . .	1·0	1·11	0·79
	Ultimate load .	1·0	2·58	1·58

Physical Properties of Steel-Cored Aluminium Conductors.

The strength of a steel-cored aluminium conductor is somewhat less than the sum of the strengths of the component wires, owing to the fact that the aluminium wires will break before the steel wire reaches its ultimate stress. The strength of the composite conductor may be taken as (*a*) 98 per cent. of the sum of the strengths of the aluminium wires, plus 89 per cent. of the sum of the strengths of the steel wires when taken from the stranded conductor and tested, or (*b*) 98 per cent. of the sum of the strengths of the aluminium wires, plus 85 per cent. of the sum of the strengths of the steel wires based on the strengths of the component wires before stranding, *i.e.* in the coil (*B.E.S.A. Specification*, No. 215–1930).

The stress is not distributed uniformly over the different wires, and the stress in the steel will normally be about three times the stress in the aluminium.

The coefficient of expansion and modulus of elasticity of the composite conductor are calculated upon the assumption that there will be no relative movement between the aluminium and steel wires. This is found to be the case in practice, and calculations based on 'virtual' values of the constants as so determined are found to conform with sensible accuracy to observed values. The constants depend upon the ratio of steel section to aluminium section in the construction, and the following values apply to standard forms:

No. of Wires.	Coefficient of Linear Expansion per °F.	Modulus of Elasticity. Lbs. per sq. in.
7	$10{\cdot}55 \times 10^{-6}$	$12{\cdot}49 \times 10^{6}$
37	$10{\cdot}02 \times 10^{-6}$	$13{\cdot}31 \times 10^{6}$
61	$10{\cdot}90 \times 10^{-6}$	$11{\cdot}98 \times 10^{6}$

Splicing.

Small sizes of aluminium and steel-cored aluminium conductors are joined by aluminium McIntyre Joints of the same form as commonly employed with copper. For larger sizes of steel-cored aluminium conductors different systems are employed, in all of which the aluminium and the steel are joined separately. Among the methods employed may be mentioned the com-

pression joint in which the steel wires are joined by a steel McIntyre joint, which is enclosed in an aluminium sleeve pressed on to the aluminium wires, and the 'Pairard' joint, which employs the principle of wedging cones, the steel core and the aluminium wires being gripped by separate cones. With the latter type of joint a guaranteed mechanical strength of 95 per cent. of that of the conductor is obtained, together with a conductivity equal to that of the cable.

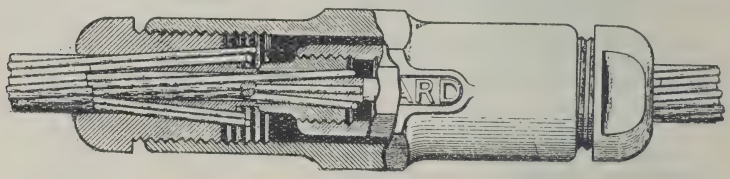

FIG. 1.

Conductivity.

The conductivity of a steel-cored aluminium conductor is taken as being that of the aluminium portion.

National Grid Transmission Lines.

The standard line conductor of the National 'Grid' Transmission System in Great Britain consists of a central core of 7 strands of galvanised steel wire, each 0·11 in. diam., surrounded by 30 strands of aluminium wire of the same diameter. The overall diameter is 0·77 in., equivalent in conductivity to a copper conductor of 0·175 sq. in. The carrying capacity of each 3-phase circuit is 50,000 kVA., and the current at 132 kV. is 219 amps. The critical corona voltage for this diameter conductor under normal atmospheric conditions is 184 kV. The earth conductor has 7 steel and 12 aluminium strands, all 0·11 in. diam. The normal span length is 900 ft. At the Firth of Forth crossing the span is 3,050 ft., and the conductors consist of 19 strands of galvanised steel each 0·125 in. diam., and 18 aluminium strands of the same diameter.

Aluminium Overhead Lines.

Span Length.

With short spans where a large cross section is required, all-aluminium conductors have a sag differing but little from that of copper, while in the case of a small cross section steel-cored aluminium may be installed with a smaller sag and lower poles. In the case of long spans steel-cored aluminium is also employed, but in this case the span length may be increased. This leads to a reduction of capital outlay and upkeep expenses owing to the reduced number of insulators.

NOTE ON FUSING CURRENTS.

The fusing currents in the tables may be taken to be correct where the fuse wire passes through an asbestos tube and does not closely touch the tube, but they do not apply where a substantial length of the wire is in contact with a porcelain holder. With the latter, more current is needed to melt the fuse.

For copper wires, the values of the current given are those necessary to fuse the wire in one minute, and are not appreciably different for other periods. For the lead-tin alloys, the fusing time is two minutes. Under normal running conditions, the actual temperature-rise at the hottest part of the fuse wire will be 100° to 150° C. for copper and 50° to 75° C. for the lead-tin alloy.

Porcelain Insulators for Overhead Lines.

British Standard Specification for Porcelain Insulators for Overhead Power Lines (3,000–150,000 Volts). No. 137—1930.*

The porcelain must be white, sound, completely vitrified, with insulation independent of the glazing, which must cover all exposed parts. The electrical design must conform to requirements in Table I., and when of more than one part the voltage drop across the assembled parts shall be proportional to their thickness. Mechanical factor of safety to be not less than 2·5. The porcelain must not engage directly with a metal screw, and must be unaffected by stresses set up by temperature changes. Every insulator shall be impressed with the manufacturer's mark before fixing, and, when conforming to this specification, bear the Association's brand. Type tests to be carried out on not less than three samples completely fitted in the following order. In tests 1 to 4, failure shall not occur below the appropriate values in Table I.

1. *Inherent Stresses.*—Insulator and glaze to withstand test voltages in columns 2, 3, or 4 of Table I. (applied as for Test 2) after being heated in water at 50° C. for one hour and immediately immersed in ice and water for one hour, the test being repeated three times.

2. *Dry Spark-over Tests.*—Testing pressure to be applied between the support and a wire of 0·4 inch diameter attached to insulator. Test to begin at one-third full voltage, and increased at 1 k.v. per second until spark-over occurs.

3. *Rain Tests.*—Insulator to be tested as in Test 2, but subjected to artificial rain at 15° C. of 1 inch in 5 minutes directed downwards at 45° from vertical. Specific resistance of the water to be not more than 20,000 ohms per cm. cube.

4. *Puncture Test.*—Insulator to be tested as in Test 2 while immersed in oil.

150	—	365	365	—	315	315	—	610	610

Note I.—The term 'Delivered Voltage' denotes the normal voltage between conductors at the delivery end.

For the purposes of this Specification the Working Voltage is assumed not to exceed the Delivered Voltage by more than 10 per cent.

Note II.—Test voltages for special insulators required for intermediate voltages may be ascertained from a curve prepared from the above figures.

Note III.—In cases where testing apparatus is not available for puncture tests at pressures exceeding 310 kV., arrangements may be made to test the insulator units separately and to estimate the equivalent puncture test voltage of the complete insulator from these individual tests.

* By permission of the British Engineering Standards Association.

† These four voltages are not included in B.S. Specification No. 77—1925, Voltages for New Systems and Installations.

5. *Mechanical Test.*—Complete insulator with metal fittings must withstand loads in accordance with Table II. For a pin insulator the tension is applied by a flexible wire rope placed round neck, and for tensioning and suspension types the load is applied between metal connecting parts on either side. Any permanent deformation constitutes failure.

6. *Porosity Test.*—The finished porcelain shall show no signs of impregnation when broken pieces free from external glaze are immersed for twenty-four hours in a 0·5 per cent. alcoholic solution of fuchsin under a pressure of 2,000 lbs. per sq. in.

7. *Routine Tests.*—Every complete pin insulator shall be inverted in water, and withstand, without puncture, for five minutes the spark-over voltage between testing terminal and wire attached to neck groove. Every unit of a tension or suspension insulator must withstand for five minutes the spark-over voltage of that unit without puncture, and the complete insulator a load 20 per cent. above maximum working load applied vertically for one minute.

Appendices to specification give experimental methods of carrying out mechanical and electrical tests.

Electricity Supply.

The standard voltages of supply laid down by the British Engineering Standards Association (Report No. 77—1925) for new systems and installations are as follows (at consumers' terminals):—

Direct current, 230 and 460 volts; alternating current, 230 volts between neutral wire and each of the principal conductors, 400 volts between any two of the principal conductors.

The standard high voltages for new systems and installations are: 3,000, 6,000, 10,000, 30,000, 60,000, 100,000, and 120,000 volts.

In each case the approximate station voltage is assumed to be 10 per cent. higher at full load.

Periods allowed by the Electricity Commissioners for Repayment of Loans.

Land—	Years.		Years.
Freehold	60*a*	Mains and services	25
Leasehold (subject to duration of lease)	30	Meters	10
Substantial buildings	30	Wiring of premises	10
Plant and machinery	20	Apparatus to be let on hire	7–10
H.P. trunk transmission mains	40*a*		

(*a*) Except in Scottish cases, for which the present maximum period is 30 years.

Generation of Electricity in Great Britain.*

The total number of units sold by undertakers in Great Britain during the year ending March 31, 1928, was 9,927,850,630, an increase of 18·7 per cent. on the figures for the previous year. The total number of stations (from which returns were received) was 570. The total coal, coke, and fuel oil consumed was 9,224,151 tons, or an increase of 4·1 per cent.

The steam stations generated 95·70 per cent. of the total; gas-producer stations, 0·19 per cent.; oil-engine stations, 0·63 per cent.; waste heat, 2·19 per cent.; refuse destructors, 0·21 per cent.; gas engines using town's gas, 0·03 per cent.; water power, 0·05 per cent. In 1927 the steam percentage was slightly more, viz. 97·16 per cent., water power less, viz. 0·59 per cent.

No figures are available for the consumption of electricity generated by privately owned stations, but figures published in 1924 show 2,564,000 kW. of such plant installed as compared with 3,943,000 kW. of plant belonging to undertakings supplying mainly to the public. Regional schemes prepared by the Electricity Commissioners to date show that 256 undertakers are affected, 2,883,870 kW. of plant installed or sanctioned (4,668,295 kW. estimated by 1940–41), 1,108 route miles of primary transmission line, and 3,725,000 kVA. of associated transformer plant are involved, with a total capital expenditure, to the end of 1934–35, by the Central Board and owners of selected stations of 27,425,121*l.*, including 4,982,000*l.* on frequency standardisation. During 1927–28, the extension of generating plant sanctioned by the Commissioners amounted to 668,357 kW.

* Eighth Annual Report of the Electricity Commissioners, 1927–28. H.M. Stationery Office, Adastral House, Kingsway, London, W.C. 2. Price 3*s.* net.

In the First Annual Report of the Central Electricity Board * an account is given of the procedure of the Board under the Electricity Act of 1926, of the schemes considered and adopted 1927–28, and a full technical description of the design, construction, and operation of the Grid System.

Ministry of Transport Regulations in reference to Overhead Electric Lines.

Every application for the consent of the Electricity Commissioners to the placing of electric lines above ground should be accompanied by the following particulars :—

1. Where the undertakers are a company, or a local authority supplying outside their own area, evidence of consent of the local authority for the district.

2. A statement showing commercial or other considerations why underground cables should not be used.

3. A brief description of the proposed system, whether by continuous or by alternating current ; the working voltage ; the kind of wire, whether copper or aluminium ; whether solid or stranded ; the total sectional area ; tensile strength and elongation ; average and maximum length of span ; minimum height of wires from the ground ; name or description of automatic protective device, if any.

4. A statement whether the supply is to form (1) an extension of an existing system of underground cables, or (2) of an existing traction system, or (3) an independent system.

5. An ordnance map on a scale of 6 ins. to the mile, showing the proposed route of the overhead lines and any existing overhead lines. The sheets of these maps must be fastened together.

6. In the case of high and extra high pressure, plans of construction of poles, etc., on a scale of about 1 in. to the ft., or a reference to previously deposited plans where these are identical with the proposed work.

Regulations of the Electricity Commissioners. (El.C. 38—1926.)

Regulations for Securing the Safety of the Public.

1. Supply pressure shall not exceed the low-pressure limit of 250 volts, except for power or arc lamps in series, when the medium pressure limit of 650 volts is permissible under the following conditions. Machine frames must be earthed, motor leads enclosed in earthed metal casing with enclosed fireproof and shockproof switches and fuses, switch when opened must completely cut off motor and all auxiliary devices. Similar conditions apply to arc lamps and incandescent lamps in series. Regulations 1 and 2 do not apply to a factory, workshop, mine, or quarry.

2. Where the voltage between the outer conductors of a 3-wire system exceeds 250 volts and is taken into premises, two pairs of terminals shall be provided and the wiring from these kept distinct.

3. The Commissioners reserve their consent to the supply of extra high pressure to consumers' premises.

4. Minimum area of conductor installed in street line to be 7/20 gauge except for lamp-post wiring.

5 Supply mains to be tested at at least 200 volts, and results of tests to be recorded before the supply is begun.

6. Insulation of every complete circuit used for supply of energy to be maintained so that leakage current never exceeds $\frac{1}{1000}$ part of maximum supply current. Measurements must be made weekly, records kept, leakage remedied without delay, and means provided for indication and localisation of leakage.

7. High-pressure circuits (650 to 3,000 volts) must not be brought into use until successfully tested for ½ hour at twice the maximum working pressure in the case of lines and 50 per cent. excess of normal for machines and apparatus. Results to be recorded.

8. Every high-pressure main, etc., to be fitted with fuse or automatic circuit breaker, except the outer earth conductor of a concentric main.

9. Automatic quick-acting device must be fitted on transformer circuits to prevent contact or leakage from high-pressure circuit to consumers' wires.

10. All metallic portions (except conductors) of high-pressure transformers to be earthed.

11. Exposed lines and their supports to be protected from injury by lightning.

12. The undertakers must inform Commissioners of all accidents.

Overhead Lines.

13. Overhead lines erected after this date (1926) to be in accordance with Commissioners' Regulations.

Electric Lines other than Overhead.

14. Conduits, street boxes, etc., to be constructed of durable material, and where laid underground to be unaffected by heavy traffic. Accumulation of gas must be prevented.

15. Precautions must be taken to prevent the charging of any metallic substance directly or indirectly from any electric line.

* Whitehead, Morris, Ltd., London. Price 2*s.* 6*d.* net.

16. All high-pressure conductors carrying conduits to be jointed, connected across street boxes, and efficiently earthed.

17. Bare conductors in conduit must not exceed 300 volts to earth, and must be secured in position. Such conduits must be moisture proof and insulators so placed that they can be inspected.

18. High-pressure lines on ground surface or public subway must either be enclosed in insulating tube embedded in brickwork, masonry or concrete, or in an earthed metal casing.

19. Means must be taken to prevent the ground surface or other conductors becoming charged by leakage from a high-pressure line.

20. A high-pressure line must be properly laid, jointed, examined, and tested and in the sole charge of the undertakers before being used for supply of energy.

Sub-stations and Street Boxes.

21. To be in sole occupation and charge of the undertakers and placed above ground wherever possible; if underground, provision must be made for ventilation and drainage.

22. In addition to regulation 14, (*a*) covers of street boxes only to be opened by special appliance; (*b*) covers of street boxes containing high-pressure apparatus other than cables must be in connection with metal strips laid immediately underneath the street, and means taken to prevent all exposed material, including the street surface, becoming charged by any means; (*c*) street boxes used as transformer chambers must not be subject to influx of water, and when of greater size than one cubic yard must be adequately ventilated; (*d*) street boxes must be regularly inspected for the presence of gas, and notice of gas influx must be immediately given to the gas authority concerned; (*e*) mains at different pressures in the same street box must be readily distinguishable.

23. Maximum power supplied to underground sub-station or street box containing one transformer must not exceed 30 kW., or 75 kW., if with two or more transformers, without consent of Commissioners.

Consumers' Premises.

24. The undertakers shall be responsible for maintenance of their property on consumers' premises.

25. The undertakers must guard against fire risks in delivering energy to premises.

26. Fuse or automatic circuit breaker in fireproof, sealed receptacle to be fitted near entry of each service main if latter is unprotected by fuse in the street box. No fuse or circuit breaker must be inserted in intermediate conductor of a 3-wire system.

27. Service lines and apparatus on consumers' premises must be highly insulated, moisture-proof and all exposed bare metal forming part of a circuit, efficiently earthed. Lines must be fixed and protected to prevent electrical discharge to nearby metal.

28. Consumers' wires must not be connected to undertaker's mains unless the resulting leakage is not in excess of one ten-thousandth of maximum current supplied to the premises. Notice of objection must be served upon the consumer.

29. Undertakers have the right, after giving notice to consumer, to test wires and fittings for leakage and to discontinue supply if excessive leakage is found (see 28), or facilities for testing and inspection are refused.

30. Consumer may appeal for an independent test to an electrical inspector on payment of prescribed fee. This regulation must be endorsed on every notice served under regulations 28 and 29.

Arc Lighting.

31 and 32 respectively fix the minimum height of any part of an arc lamp 10 feet above ground, and provide for the provision of arc lamp guards, forbidding the use of arc lamps where explosive dust or gas may be present.

Connection of Circuits with Earth.

33. Where supply pressure between adjacent conductors of a 3-wire system of mains exceeds 125 volts, the intermediate conductor for each distinct circuit shall be earthed at one point only, namely, at generating station, sub-station or transformer, the insulation being maintained elsewhere. The earth current from intermediate conductor must be continually recorded and must not exceed at any time one-thousandth of maximum supply current.

34. Penalties are provided for default of regulations 1 to 34.

Regulations for Ensuring a Proper and Sufficient Supply of Electrical Energy.

1. Supply must be constantly maintained, and in case of D.C. without change of polarity. Notice of any interruption for testing purposes or polarity change must be given to consumer.

2. Distribution mains must be sectionalised on their respective feeders and connected only through circuit breakers or fuses.

3. Variation from declared pressure of supply shall not exceed $\pm$ 4 per cent. Public notice with consent of Commissioners is required for any alteration of conditions.

4. The system and frequency of supply (in A.C. systems) must be declared. Variation of frequency from declared value must not exceed $\pm$ 2½ per cent. Notice and consent required for alteration (see 3).

5. Penalties are prescribed for default of regulations 1 to 5.

Regulations of Electricity Commissioners for Overhead Lines. (El.C. 53—1928.)

General Regulations.

1. Conductors to be of copper, aluminium, or other approved material.

2. Conductors to conform to B.E.S.A. specification for elongation, breaking load, and elasticity.

3. Minimum permissible size for copper and other line conductors (other than service lines) must have an actual breaking load of not less than 1,237 lbs. Minimum area and weight per mile for copper, No. 8 S.W.G., 0·0201 sq. ins., 409 lbs. For service lines, minimum breaking load 816 lbs.; minimum area and weight, No. 10 S.W.G., 0·0129 sq. ins., 262 lbs. per mile.

4. Conductors must be rendered inaccessible to persons not having the use of appliances. Regard must be paid to the normal use of his land or premises by the occupier. See 18.

5. Except in the case of contact between broken conductors and earth wire on the same support, precautions must be taken by the undertakers against contact between line conductor and any other overhead wire.

6. Line insulators to be carried on supports of wood, iron, steel, or reinforced concrete. Corrosion of metal work on or below ground surface to be prevented. Wooden supports must be of red fir, except oak or hardwood cross arms, unless otherwise approved.

7. Supports, in conjunction with any struts or stays, shall take all loads without damage or movement in the ground. Strength in direction of line must not be less than one quarter of transverse strength. Factor of safety for iron and steel 2·5, for wood and reinforced concrete 3·5. These factors to be calculated for 22° F. with ice covering specified in 12 or 15, and with a wind pressure of 8 lbs. per sq. ft. on whole of the projected surface, corresponding to a velocity of 50 m.p.h. at right angles to the line. Wind pressure on lee side members of lattice or other compound structures, A and H poles, to be taken as one-half that on windward side, and factor of safety calculated on crippling load of struts and upon elastic limit of tension members.

8. Service lines to be connected only at a point of support, and fixed to insulators on consumer's premises. Service lines (other than an earthed neutral conductor) which are accessible from a building must be protected by insulating material or otherwise.

Service lines over carriage ways must not be lower than 20 ft. from the ground except with consent of Commissioners.

9. Adequate protection to be made against danger to linesmen, and from a lower voltage system becoming charged above normal from a higher voltage system when conductors of the different systems are carried on same poles or supports.

10. The whole structure with all appliances must be regularly inspected and maintained.

11. Materials must conform at time of erection to B.E.S.A. specifications and to the Post Office Technical Instructions of Aerial Lines.

Specific Regulations.

A. For pressures not exceeding 650 volts D.C. and 325 volts A.C.

12. Factor of safety of line conductors, 2, based on breaking load at 22° F., with $\frac{3}{16}$ in. radial thickness of ice and simultaneous wind pressure as in 7.

13. Minimum height of any wire (except service) at 122° F., not to be less than 19 ft. across a public road or 17 ft. in other positions. In places inaccessible to vehicular traffic, 15 ft. Minimum height of a service line across or along a carriage-way, except with permission, 19 and 17 ft. respectively.

14. Where pressure to earth exceeds 250 volts D.C. or 125 volts A.C., precautions shall be taken to prevent danger

(*a*) from a broken conductor; by a neutral or earthed conductor suitably disposed or other approved method:

(*b*) from leakage; in cases of metal poles, by provision of earthed wire connecting the poles, or by supporting the insulators on insulated metallic frame connected to neutral conductor. With wooden poles by a bonding wire connected to supporting metal of all insulators and terminating at lowest part of supporting metal work. Other means may be approved.

Where lighting or uninsulated conductors are run down wooden poles to within 10 ft. of the ground, precautions against leakage must be as for metallic poles. Unearthed stay wires must be insulated by insulator placed not less than 10 ft. above ground.

B. For pressures exceeding 650 volts D.C. and 325 volts A.C.

15. Factor of safety of conductors as in 12, except that for $\frac{3}{16}$ in. ice, read $\frac{3}{8}$ in.

16. Minimum heights of conductors above ground at temperatures below 122° F. are 20 ft. for pressures not exceeding 66,000 volts, 21 ft. exceeding 66,000 and below 110,000 volts, 22 ft. 110,000 to 165,000 volts, and 23 ft. above 165,000 volts. Height from the ground of any earth wire must not be less than the minimum prescribed in Regulation 13.

17. Means must be taken to render broken conductors dead. All other metal work to be earthed by continuous earth wire earthed at four equidistant points per mile; alternatively metal shall be effectively earthed at each support. When earth contact is made by a line conductor, leakage current must be at least twice that required to operate safety devices.

18. At road, canal, or railway crossings, in addition to 16, there shall be provided (*a*) duplicate line insulators with automatic earthing of a fallen conductor or (*b*) duplicate insulators tied at intervals not exceeding 5 ft.

Where line is erected along or within 50 ft. of road, canal, or railway, (*a*) duplicate insulators or (*b*) automatic earthing for fallen conductor shall be provided. Other means may be approved.

19. Supports must be consecutively numbered, carry permanent danger notice, and guarded from unauthorised climbing.

An explanatory memorandum El.C. 53A is issued.

Regulations Relating to Extra High Pressure. (El.C. 13—1920.)

The following *additional* regulations relating to *extra high pressure* have been issued by the Commissioners.

A. *Regulations for Securing the Safety of the Public.*

3. An extra-high-pressure main before being brought into use shall be tested in position to withstand for half an hour continuously a pressure of 10,000 volts in excess of the working voltage, when this exceeds 10,000 volts, or twice the working pressure when this is less than 10,000 volts. Results of tests must be recorded.

4. Suitable fuse or circuit breaker must be provided for every main, but not in earthed outer conductor of concentric mains.

8. Where leakage from 3-phase mains is prevented by a copper strip under the lead sheath of cable, this shall not be less that 0·016 in. thick, and where steel wires are thus employed outside a lead sheath, each shall not be less than 0·1 in. in diameter. A lead sheath must be efficiently earthed and not less than 0·1 in. thick.

9. Single-phase supply mains to consist of two concentric conductors or separate conductors. Outers of concentrics to be earthed at one point: with separate conductors, leakage to be prevented as with 3-phase mains.

Street Mains.

11. These mains must be enclosed in strong metal casing where passing through street box with other mains; boxes must not contain any other undertaker's electric mains, nor water or gas pipes. Telephone wires belonging to the undertakers are allowed.

Sub-stations.

12. Must be in sole or joint occupation of the undertakers or authorised distributor.

13. When constructed below streets, must contain no switches or apparatus other than transformers.

14. The transforming apparatus must be arranged to avoid danger of excessive voltage on connected mains.

15. Precautions must be taken against fire risks.

17. Gives right of entry and examination to the Commissioners.

Connection of Circuits with Earth.

18. Earth connection to be made at only one point on a circuit, viz. generating station, sub-station, or transformer. Insulation must be maintained elsewhere.

19. When neutral star point of each distinct 3-phase circuit is earthed through a resistance, this must be low enough to ensure the action of the cut-out in the mains.

Separate electrostatic voltmeters must be connected in the generating station between each distinct circuit and earth to act as leakage indicators. Faulty circuit insulation must be immediately restored.

20. Penalties are prescribed against default which are not to affect liability of undertakers in respect of damages caused by default.

B. *Regulations for Ensuring a Proper and Sufficient Supply of Electrical Energy.*

1. Undertakers must maintain sufficient and constant supply from the main to authorised distributors and consumers.

2. Maximum load on a main not to exceed 1,000 kW. without consent of Commissioners, unless provision is made for alternative supply in the event of breakdown.

3. Minimum pressure to be declared. Pressure at authorised distributors' terminals must not be less than this minimum, and not exceed it by more than 12½ per cent. Alteration of minimum to be allowed only by consent of Commissioners after one month's public notice of such application.

4. Frequency to be declared 50 or 25 cycles per second; 2½ per cent. variation allowed. Consent and notice of alteration as in 3.

5. Penalties are prescribed for default.

These regulations are in addition to any regulations relating to mines and factories made by any Act, and also include regulations 9, 16, 18, 20, and 27 of El.C. 38, summarised above.

The Electrical Equipment of Buildings.

REGULATIONS ISSUED BY THE INSTITUTION OF ELECTRICAL ENGINEERS.

(Ninth Edition, 1927.)

(*Abbreviated.*)

SUPPLY PRESSURE.

These regulations provide for wiring based on the following pressures of supply :—

Medium pressure, i.e. above 250 volts and below 650 volts.
Low pressure, i.e. above 30 volts A.C. or 100 volts D.C., but not exceeding 250 volts.
Extra low pressure, i.e. below 30 volts A.C. or 100 volts D.C.

GENERATING PLANT.

Generators must comply with the following :—

(*a*) They must be placed in well-ventilated rooms where inflammable dust or gases cannot accumulate.

(*b*) They must be protected from damp, dust, or mechanical injury.

(*c*) No unprotected woodwork or other combustible material shall be within a distance of 12 ins. from them measured horizontally, or within 4 ft. measured vertically above them.

(*d*) When the supply is at medium pressure, the generating plant shall have its frame and bedplate earthed.

SECONDARY BATTERIES.

(*a*) A p.d. exceeding 50 volts must not exist between adjacent cells without adequate protection. Each cell shall be readily accessible from the top and at least from one side.

(*b*) In a lead-sulphuric acid battery with more than 33 cells, and in a nickel-iron alkaline battery with more than 53 cells, the cells shall be supported on glass or vitreous porcelain insulators. The stands shall also be insulated if there are more than 56 and 88 cells respectively.

(*c*) When acid is used as an electrolyte for the cells, the battery-connecting bolts, unless of non-corrosive type, shall be kept covered with petroleum jelly.

(*d*) Cells having containers not sealed nor provided with screw-down covers shall have spray arrestors.

(*e*) Celluloid shall not be employed for non-portable batteries.

(*f*) The battery-room shall be well ventilated.

(*g*) As a minimum, the gear controlling the current shall comprise an automatic cut-in and cut-out switch and fusible cut-out, or a circuit breaker with overload and reverse-current trips.

SWITCHBOARDS.

(*a*) Must be placed in dry and well-ventilated situations away from explosive dust or acid fumes.

(*b*) Must be constructed wholly of durable, non-ignitable, non-absorbent materials.

(*c*) If marble or slate be used, all conducting parts shall be insulated with mica or other non-hygroscopic substance.

(*d*) Terminals must be provided for earth connection.

(*e*) Live parts must be spaced or shielded so that an arc cannot be maintained.

(*f*) All connections shall be readily traced.

(*g*) All parts shall be readily accessible, and no fuse shall be fixed at the back of the board.

(*h*) All nuts at back of board must be effectively locked.

(*i*) All circuits, instruments, etc., shall be clearly labelled.

(*j*) Connecting wires to every voltmeter and earth lamp must be protected by a fuse on each insulated pole.

(*k*) The moving parts of switch, in the 'off' position, must be disconnected from the supply.

(*l*) With fuses and switches on same pole, the fuses must be disconnected from supply when their respective switches are in the 'off' position.

MAIN SWITCHGEAR.

Every main switchboard must be fitted with the following switchgear as a minimum :—

1. *Two-wire Systems of Wiring.*

(*a*) When supply is obtained from one generator or a single service main, for these and for each outgoing circuit either a double pole overload circuit breaker or a linked switch with a fuse on each pole. (For earthed system, single pole on the insulated main.)

(*b*) With several generators not running in parallel or with duplicate service mains, change-over switches must be used, in addition, on each outgoing circuit.

(*c*) With generators in parallel, a double-pole circuit breaker (single-pole for earthed system) fitted with overload and reverse-current trips. For compound-wound machines an additional single-pole equaliser switch interlocked so that equaliser must be closed before and opened after the main circuit breaker.

2. Three-wire Systems of Wiring.

Each generator or each side of service mains and each two- or three-wire outgoing circuit double-pole apparatus as for two-wire system. No fuse or unlinked switch on neutral. When neutral is known to be directly earthed, a two-conductor earthed circuit may have single-pole overload circuit breaker or switch and fuse in outer conductor.

3. Two-phase Three-wire Systems of Wiring.

Each generator or service main and each outgoing three-conductor circuit a triple-pole circuit breaker with overload trips on each phase or a triple-pole linked switch with a fuse on each conductor except the neutral. Each outgoing two-wire circuit, double-pole circuit breaker with overload trip on at least one conductor or double-pole switch and fuse.

4. Three-phase Three-wire Systems of Wiring.

For each generator or service main and each outgoing three-conductor circuit, either a triple-pole circuit breaker with overload trips on at least two phases, or a triple-pole linked switch with a fuse on each conductor. For each two-wire outgoing circuit these to be double-pole.

5. Two-phase Four-wire Systems of Wiring.

Each generator or service main and each outgoing four-conductor circuit, either a four-pole circuit breaker with overload trip coil on each phase or a four-pole linked switch with a fuse on each conductor. For each two-wire outgoing circuit double-pole circuit breaker with overload trip on at least one conductor or double-pole switch and fuse.

6. Three-phase Four-wire Systems of Wiring.

For each generator or service main, a triple-pole circuit breaker with overload trips on each phase (at least on two phases for outgoing three-conductor circuit), or a triple-pole linked switch with a fuse on each phase. For each outgoing two-wire circuit supplied from one phase and directly earthed neutral, single-pole gear as above connected in the phase conductor. (Double-pole with unearthed neutral.) For four-wire outgoing circuits supplying a distribution board, triple-pole gear as above, but no fuse or unlinked switch in neutral conductor, except for testing.

INSTRUMENTS.

Every main switchboard not supplied from an external source must have the following minimum :—

Two-wire Systems of Wiring.

For a single generator an ammeter and voltmeter. For generators not to be run in parallel, one ammeter for each machine and a voltmeter to be fitted with multiple-way switch or plug. For parallel running, an ammeter for each machine and two voltmeters, one being connected to bus-bars and the other arranged for use on any generator. Alternators to have synchronising device. The ammeter in the circuit of compound wound machines to be connected in opposite pole to equaliser connection.

Three-wire Systems of Wiring.

An additional voltmeter to be connected between neutral and each outer bus-bar and a central-zero ammeter for D.C. or central-zero wattmeter for A.C. in main neutral conductor.

Two-phase and Three-phase Systems of Wiring.

For a single generator an ammeter on each phase and one voltmeter. For each generator running in parallel, an ammeter in each phase; one voltmeter on bus-bar and one on multiple-way switch, for use on one phase of any generator. A synchronising device.

Instruments should conform to British Standard Specification No. 89–1929.

Earth Testing.

Except for extra low pressure plant of less than 5 KW. capacity, the switchboards of private installations must have suitable means for indication insulation.

Switches and Circuit Breakers.

(*a*) Must be able to carry working current continuously with a temperature rise above the air of not more than 36° F. (20° C.), if rated at less than 100 amperes, and 54° F. (30° C.), for ratings of 100 amperes or more.

(*b*) Must not arc over when breaking 50 per cent. excess current at a pressure 50 per cent. above that of the supply. Fuse switches and circuit breakers must fulfil regulations for fusible cut-outs. (See British Standard Specifications 109—1923 and 110—1923.)

(*c*) Accidental closing impossible.

(*d*) Provision for renewal of main arcing contacts.

(*e*) Handles must be robust and must not be operated through unprotected slots. Operator must be protected from live metal or any injury from adjacent apparatus.

(*f*) Bases to be of durable, fireproof, non-absorbent insulating material. Slates to be planed all over, free from metallic veins, and if of slate must be treated (including holes) with damp-proof medium after drying. All bolts fixing slate or marble slabs must be insulated from slab, and the latter similarly from metallic frame by non-hygroscopic insulating bushes and washers.

(*g*) The live parts of switches not mounted on a switchboard must be enclosed by metal or fireproof insulating covers, guarded from mechanical injury, and giving proper clearance from live parts and protection against arcing.

(*h*) When placed out of doors or in damp places, must have weather-proof cases and proper provision for leading-in cables. Suitable glands are given in British Standard Specification No. 94—1920.

(*j*) Operating current must be adjustable on electromagnetic circuit breakers. and latter must be incapable of being held in against this current.

(*k*) Arrangements and position must avoid all risk of fire.

Fusible Cut-outs.

A. *For Extra Low Pressure.*

(*a*) Temperature rise of any part of the fitting above air not to be more than 54° F. (30° C.), with normal current continuously.

(*b*) Fusing current to be double the current capacity of the smallest cable controlled by the fuse when fusing time is one minute (two minutes for a lead-tin alloy fuse). No fuse to blow at less than 7 amperes need be inserted in final sub-circuits.

(*c*) The base to be of durable, fireproof, non-absorbent insulating material, and all construction must avoid arcing and scattering of metal.

(*d*) No fuse to be placed in ceiling roses, wall plugs, or sockets, or in switches other than fuse-switches of regulation patterns with metal covers. A fuse rated at not more than 5 amperes may be used in projecting wall socket adapters taking the pins of a smaller plug.

(*e*) Cut-outs not fixed on switchboard must be grouped on distribution boards or contained in regulation cases unless completely enclosed.

(*f*) Removable carriers to be used except where the covers provide against scattering of metal, and the maximum power in the building does not exceed 1,000 watts.

B. *Low-pressure Cut-outs must in addition :*

(*a*) Be provided with safe insulating carrier for the fuse, with convenient contacts for the wire.

(*b*) Base contact to be unaffected by vibration.

(*c*) Risk of contact with any live metal to be avoided when handling a carrier.

(*d*) Cut-outs and carriers to be graded ' Ordinary Duty ' and ' Heavy Duty.'

Maximum working current.	Maximum short-circuit current for ' Ordinary Duty ' cut-outs.
10 amperes	1,000 amperes
30 ,,	2,000 ,,
60 ,,	4,000 ,,
100 ,,	6,500 ,,

' Heavy Duty ' cut-outs to be used where ' Ordinary Duty ' cut-outs are inadmissible.

C. *Medium-pressure cut-outs must fulfil conditions* A (*a*) *to* (*f*) *and* B (*a*) *to* (*e*).

(See British Standard Specification No. 88—1919 for Low-pressure Electric Cut-outs.)

Section and Distribution Boards.

A. Must generally comply with all regulations for switchboard, circuit breakers, and fusible cut-outs, except for final sub-circuits carrying less than 20 amperes.

B. Unless current-carrying parts of all accessories are permanently protected, they must have a protecting case, which with earthed concentric wiring systems must provide, if of metal, for attachment to case of all external conductors; if of wood, an interposing metal sheet between it and the support not less than $\frac{1}{16}$ in. thick, to which all external conductors are connected.

C. Arcing under short-circuit conditions must be impossible.

D. Cases of soft wood to have fire-proof insulating lining, and all boxes not provided with backs shall be so shielded from the supports. A glass front must have 1 in. (2·5 cm.) clearance from live parts.

E. When placed out of doors or in damp places, must be weatherproof with proper provision for leading-in.

F. Dimensions must allow of easy access for connecting.

G. Cut-outs must be grouped vertically with fire-proof insulating material between opposite poles.

Conductors of Cables.

(*a*) All conductors, other than the outer conductors of earthed concentric systems, shall be of annealed copper.

(*b*) The sizes of conductors set out in the table on p. 2206 are recognised as standard. The standard sizes and resistances of conductors for flexible cables and flexible cords are set out in tables on pp. 2207 and 2208.

(*c*) No cable having a conductor of nominal sectional area less than 0·0015 sq. in. (1/·044 in.) shall be used except for wiring fittings.

(*d*) All conductors having a nominal sectional area exceeding 0·003 sq. in. (1/·064 in.) shall be stranded.

(*e*) For lighting, the drop from the consumer's terminals to any and every point in the installation shall not exceed 1 volt plus 3 per cent. of the pressure at the consumer's terminals when the conductors are carrying the maximum demand under the practical conditions of service. The current shall not exceed that in tables on pp. 2209–2210. For flexible cables the permissible currents are given in tables on pp. 2208 and 2211.

Insulation and Protective Covering of Conductors.

The following types have been approved :—

A. *Vulcanised Rubber-insulated Cables*—(*a*) insulated with a layer of pure rubber, an intermediate layer of vulcanising rubber, and an outer jacket of vulcanising rubber and compounded or, alternatively, a homogeneous dielectric of vulcanised rubber free from corrosion of tinning—if the latter is used as protective covering it must conform to the requirements of the tough rubber compound (see p. 2244); (*b*) taped as (*a*) and braided; (*c*) sheathed with a closely fitting seamless covering of commercially pure lead, having a smooth exterior surface and of uniform radial thickness; (*d*) lead-covered as above and bedded and armoured, with or without serving or braiding over the armour; (*e*) bedded and armoured, with or without serving or braiding over the armour; (*f*) encased in a closely fitting covering of brass, copper, or equally hard incorrodible metal; (*g*) sheathed with a closely fitting seamless covering containing not less than 95 per cent. of commercially pure lead; (*h*) covered with tough rubber compound.

B. *Paper-insulated Cables*: as (*c*), (*d*), (*f*), and (*g*).

C. Of the types in A, the following shall not be used for a.c. except in connection with an earthed concentric system in which the sheathing forms one conductor; single cables armoured with steel wire or tape or encased in a ferrous sheath, or single, unarmoured, lead-covered cables having a conductor of area exceeding 0·25 sq. in.; or brass, copper or equally hard incorrodible metal with conductor above 0·1 sq. in.

Twin Flexible Cords.

(*a*) Twin twisted flexible cords shall be used only for fixed wiring, fixed fittings and portable lamp standards; in all other positions and for all other purposes, flexible cords made up to a circular or oval section shall be employed—the use of circular or oval section flexible cords is recommended for all portable fittings.

(*b*) The maximum weight carried by a twin-twisted flexible cord shall be as follows :—

Number and diameter of wires in conductor.	Maximum weight.
14/·0076 ins.	3 lbs.
23/·0076 ,,	5 ,,
40/·0076 ,,	10 ,,

Installing and Fixing of Conductors and Cables.

Bare conductors may be used as collectors on trolley wires for cranes, etc., and for battery connections, supported on insulators and spaced so that risk of accidental contact is reduced to a minimum. At the ends of each conductor, straining gear with double insulation to be used. The supply circuit must be protected as for insulated conductors. Lightning arresters on each pole or phase to be used where necessary. Wall supports for span wires must not be within 12 ins. of any gas pipe. Except as above, bare conductors shall only be used in positions not ordinarily accessible to unauthorised persons and under conditions sanctioned by fire offices.

Taped and Braided Cables (Class L) may be used without conduit or casing provided that they are:—

(i) Open to view throughout their length and not installed under floors or buried in plaster.
(ii) Kept away from structural metal work.
(iii) They are protected where within 6 ft. above the floor or when liable to mechanical damage.
(iv) Kept away from gas and water pipes.
(v) Secured by porcelain cleats, clips, saddles, or clamps to prevent the cables coming into contact.
(vi) In damp situations, not less than ½ in. away from wall.
(vii) Protected by non-absorbent, non-ignitable conduits when passing through floors, walls, or ceilings.
(viii) When passing through party walls or fireproof floors, the conduits to be close-fitting and holes plugged with non-ignitable material.

Metal-sheathed Cables (Class M1) may be used without conduit or casing provided they are in accordance with condition (iv) above and
(ix) Secured by clips, saddles, or clamps to prevent appreciable sagging or damage to cable.
(x) Vertical cables are fixed in the same way as horizontal. When inaccessible, 10 ft. allowed between supports.
(xi) All metallic envelopes of cables to be effectively earthed and made electrically continuous throughout by means of soldered joints or bonding clamps or joint boxes.
(xii) The resistance of the metallic envelope in a complete installation, between the main switch and any other point in the installation must not exceed 2 ohms.
(xiii) If liable to mechanical damage they are to be adequately protected.
(xiv) In damp and exposed situations, saddles and fixings to be of non-rusting material.
(xv) Bushed holes to be used when passing through steel or iron structures.
(xvi) Holes through party walls or fire-resisting floors to be plugged with non-ignitable material.
(xvii) When run under floors or behind partitions, all connections to be made in boxes of ample capacity and of non-absorbent, non-ignitable material.

Hard Metal-sheathed Cables (Class M2) may be used without conduit or casing provided they are in accordance with conditions (iv) and (ix) to (xvii) inclusive.

Armoured Cables (Class R) may be used without conduit or casing provided they are in accordance with conditions (iv), (ix), (x), (xiii), (xiv), (xvi), and (xvii). When lead sheathed, such sheathing shall comply with (xi) and (xii), and when not lead sheathed the armouring shall so comply.

Cables covered with Tough Rubber Compound (Class S) may be used without conduit or casing provided they are in accordance with conditions (iv), (ix), (x), and (xiii) to (xvii) inclusive.

Conduits Screwed (Class T1). All approved classes of cable may be enclosed in steel conduits provided that the conduits are in accordance with conditions (iv), (xiii), (xiv), (xvi), and (xvii), and in addition:

(xviii) The conduits and fittings are made in accordance with British Standard Specification No. 31–1923 and if used on circuits of medium pressure are of heavy gauge. Metal bosses must be secured on both sides to conduit by screwing or nuts.
(xix) The conduits are mechanically and electrically continuous across all joints and are earthed.
(xx) The resistance of the conduit in a complete installation, between the main switch and any other point in the installation, does not exceed 2 ohms.
(xxi) Ventilating outlets are provided at the highest and lowest points of each circuit.
(xxii) The conduits of each circuit are erected complete before the cables are drawn in (see table on p. 2246).
(xxiii) Abrasion of covering of cables emerging from conduits must be prevented.
(xxiv) The end of conduits where terminating at accessories and fittings are screwed thereto or provided with lock-nuts, or are led into separate blocks, preferably of non-ignitable material.
(xxv) No elbows or tees, unless of the inspection type, are used except at the ends of conduits immediately behind fittings or accessories; and no bend has a radius less than 2½ times the outside diameter of the conduit.
(xxvi) In damp or exposed situations, the conduits are welded, brazed, or solid drawn.

Metal Conduits not Screwed (Class T2). All approved cables may be enclosed in conduits of steel or other metal provided that the conduits are in accordance with conditions (iv), (xiii), (xiv), (xvi), (xvii), (xix) to (xxiii), (xxv) and (xxvi), and (xxvii). The ends of the conduits where terminated at accessories and fittings are adequately clamped thereto, or are led into separate blocks, preferably of non-ignitable material.

NOTE.—Plain slip sockets do not comply with the above regulations—some form of screwed or grip joint giving ample and permanent conductivity and rigidity throughout being necessary.

Non-metallic Conduits (Class T3). All approved cables may be enclosed in conduits of non-ignitable, non-absorbent damp-proof material, provided that such conduits are mechanically continuous and strong, and are in accordance with conditions (iv), (xiii), (xiv), (xvi), (xvii), (xxi) to (xxiii), (xxv) and (xxvii).

Wood Casing (Class W). All approved cables may be enclosed in wood casing provided that

(xxviii) It is used in dry situations only.

(xxix) It is not buried in plaster or cement nor fixed in contact with gas or water pipes, nor immediately below water pipes.

(xxx) The capping is secured by screws.

(xxxi) If the casing forms part of ornamental woodwork, ready access to the cables is provided.

Flexible Cords (Class Z). High insulation twin or multicore flexible cords may, in addition to being used for pendants and portable appliances, be used provided that conditions (iii) and (vi) are complied with, and in addition:

(xxxii) They are for low-pressure sub-circuits for currents not exceeding 6 amperes.

(xxxiii) If insulated with pure rubber, they are not used in damp situations.

(xxxiv) Insulating cleats not more than 3 ft. apart are used and placed so that the cords do not come into contact with walls, ceilings, or structural metal work.

(xxxv) They are open to view.

(xxxvi) The premises do not come under the Factory and Workshop Acts and the Coal Mines Regulation Acts.

(xxxvii) They are not used in shops, warehouses, or places of public resort.

(xxxviii) Where passing through walls or floors, they are protected by non-ignitable, damp-proof conduits.

(xxxix) Where issuing from fittings and unavoidably passing into ceilings they are enclosed in non-ignitable tubes terminating in non-ignitable junction boxes.

Bunching of Cables.—When installed in wooden casing, cables carrying direct or alternating current may, if desired, be bunched whatever their polarity, provided that the number of cables bunched is not more than:

10	if the sectional area of each does not exceed				0·007	sq. in.
6	,,	,,	,,	,,	0·0025	,,
4	,,	,,	,,	,,	0·1	,,
3	,,	,,	,,	exceeds 0·1 sq. in.		

The size of the casing must not exceed that of the maximum number of cables permissible.

When installed in metal conduits, cables carrying direct current may, if desired, be bunched whatever their polarity; but if carrying alternating current, they shall always be bunched.

NOTE.—Where large cables are bunched, the rating should be reduced to prevent overheating.

Bell and Telephone Circuits in a building must not be run in casing or conduits used for the distribution of electricity supply throughout the building.

Cable Sockets and other Connections.—(*a*) The ends of all conductors exceeding 0·04 sq. in. shall be provided with a soldering socket.

(*b*) The dielectric shall not be removed farther than is necessary. Dielectric damaged by heat shall be cut away.

(*c*) The braid, lead, or other covering over the dielectric, including the tape, shall be cut back at least half an inch from the end of the dielectric.

(*d*) With paper-insulated cables, the exposed conductor and dielectric shall be protected from moisture by suitable sealing with insulating compound.

(*e*) The ends of stranded conductors unprovided with cable sockets shall be made solid by soldering in the case of paper insulation, and in the case of rubber when exposed to damp.

Connections between Cables other than flexible cords shall be made either by soldered joints or mechanical connectors.

(*a*) Every joint shall be easily accessible and mechanically and electrically sound.

(*b*) Every mechanical connector shall be enclosed in a non-ignitable box and made impervious to moisture.

(*c*) Connections between cables and flexible cords, or between lengths of flexible cords, shall be made by mechanical connectors shrouded in non-ignitable insulating material contained within suitable receptacles.

(*d*) Joint boxes shall be constructed wholly of durable, non-ignitable, non-absorbent materials.

Main Distribution.

Control of Main Supply.—Every installation shall be adequately protected by suitable controlling apparatus easily accessible to the consumer.

(*a*) If the normal current exceeds 100 amperes, there shall be provided, in addition to a fuse or circuit breaker with overload trip, an automatic device which shall operate in the event of a leakage to earth. The leakage current must not exceed 100 amperes.

(*b*) There shall be a circuit breaker or a switch and fuse on each insulated conductor, and all such poles shall be linked.

(*c*) No fuse or unlinked single-pole switch shall be inserted in a main circuit in that conductor which is direct earthed at the supply.

(*d*) The neutral conductor shall never be interrupted while the other conductors are closed.

(*e*) Wherever single-pole switches are required, they shall be on the same pole throughout the installation.

Subdivision of Circuits.—(*a*) The maximum number of points that may be connected in parallel to a final sub-circuit shall be as follows:

Where the total rating of the points supplied from the sub-circuit does not exceed

6 amperes	. . . . .	10 points
7 ,,	. . . . .	6 ,,
10 ,,	. . . . .	4 ,,
20 ,,	. . . . .	2 ,,

(*b*) Every final sub-circuit shall be connected to a sub-distribution board.

(*c*) Every sub-distribution board shall be connected to a separate way on a main distribution board.

Earthing.

Conditions where Earthing is Necessary.—(*a*) For all pressures of supply, earthing of metal objects other than the conductors shall be effected in the following cases:—In bathrooms, lift shafts, near running machinery, and in all places where even a slight shock might lead to serious accident, all exposed metal liable to become alive, or situated so that there is risk of contact with earthed metal, shall be earthed. The metal sheathings of cables shall be earthed.

(*b*) Where the pressure of supply exceeds the limits of extra low pressure, any damp plaster, concrete, or metal shall be earthed which is liable to become alive and touched by a person making contact with earth. All metal conduits shall be earthed.

Position of Metal in Bathrooms.—All exposed metal liable to become alive shall, in addition to being earthed, be placed out of reach of a person standing in the bath. Lampholders shall have their exposed metal parts efficiently earthed, or, alternatively, all parts liable to be handled when replacing a lamp shall be constructed of insulating material.

Earthing.—(*a*) The combined resistance of the earthing lead and system should be low enough to let enough current flow to operate the fuse or earth leakage trip.

(*b*) Water pipes used as an earthing system shall have metal joints throughout.

(*c*) Pipes conveying gas or an inflammable liquid shall not be used as an earthing system.

(*d*) An earthing lead shall be of high conductivity copper protected against mechanical injury and corrosion of not less than 0·0045 sq. in. (7/·029 in.). for the main connection. For flexible cords 0·0048 sq. in. and smaller, earth lead to be the same size as live conductors.

(*e*) All connections of the earthing lead shall be easily accessible.

(*f*) All domestic appliances, whether portable or fixed, for pressures exceeding 100 volts direct or 30 volts alternating current shall be provided with a terminal or other suitable means for earthing all exposed metal.

Fittings.

Portable Fittings which have to be earthed shall be connected to earth by means of a third conductor in the flexible cord.

Ceiling Roses shall not be used for pressures exceeding 250 volts, and not more than two pairs of flexible cords shall be attached to one ceiling rose, unless it be designed for multiple pendants.

Lampholders shall comply with the appropriate British Standard Specification. Switch lampholders shall be provided with further means of control in the same room. Lampholders in open-type portable fittings must be earthed as above or insulated from fitting.

Plugs and Sockets.—(*a*) Sockets shall be so constructed that they cannot be accidentally short-circuited whether the plug be in or out, and so that a pin of the plug cannot be made to earth either pole of the socket.

(*b*) Plugs connected to apparatus for currents between 1 and 10 amperes shall be constructed with (i) a hand shield, the entry for the flexible cable being at the side of the shield remote from the hand, and, if desired, a switch being fixed adjacent to the socket, or (ii) the plug so interlocked with a switch on the socket that it is impossible to insert or withdraw the plug when the

switch is in the 'on' position, provided that every socket, or group of sockets, carrying more than 300 watts shall have a switch in an accessible position.

(*c*) Plugs having a rated capacity exceeding 10 amperes shall, in addition to a hand shield, be provided with a switch immediately adjacent to the socket and preferably interlocked.

(*d*) The dimensions and clearances shall be in accordance with B.E.S.A. Report No. 372—1930.

MOTORS.

Control of Motors.—(*a*) Every motor shall be protected by efficient means suitably placed and so connected that the motor and all apparatus in connection therewith may be isolated from the supply, except in the case of the earth point of an earthed system. For motors of less than 1 h.p. a plug and socket will be considered to be an efficient method of insulation from the supply.

(*b*) Every motor shall be provided with an efficient switch or switches for starting and stopping, so placed as to be easily operated by the person controlling the motor. Every motor rated over ½ h.p. shall also be provided with (i) means for automatically opening the circuit if the supply pressure falls sufficiently to cause the motor to stop; (ii) in the case of d.c. motors a starter or switch for limiting the current taken when starting and accelerating; (iii) in the case of a.c. motors, such starter or switch for limiting the current taken, when starting and accelerating, to the value (if any) required by the supply undertaking.

(*c*) In every place in which a machine is being driven by a motor there shall be means at hand for either switching off the motor or stopping the machine if necessary to prevent danger.

Electric Lifts.—Lifts to be operated from a circuit independent of lighting installation. Control and motor leads to be in separate conduit, and cables except trailing to be armoured or in metal conduits.

HEATING AND COOKING APPLIANCES.

Control of Heating and Cooking Appliances.—(*a*) Appliances shall be protected by a fuse on each insulated pole.

(*b*) Appliances, whether portable or fixed, shall be controlled as a whole by a switch, which in the cases of portable appliances shall be fitted on a wall.

(*c*) Where a switch or switches are fixed on the frame of a portable luminous heating appliance, at least one section of the heating element shall not be controlled by such switches, so that the luminous heating element is permanently connected to the wall-plug or similar device in order to indicate that the circuit is not broken and that the current is still flowing.

(*d*) The support and frame of every appliance shall be provided with a suitable terminal to which the earthing lead may be connected.

ALTERNATING CURRENT TRANSFORMERS, CHOKING COILS, INDUCTION COILS, STATIC CONDENSERS AND RECTIFIERS, EXCEPT RADIO APPARATUS.

(*a*) Construction shall be in accordance with B.E.S.A. specification.

(*b*) Live parts shall be guarded to prevent accidental contact.

(*c*) Suitable terminal for earthing lead shall be provided.

(*d*) Shall be placed in well-ventilated space and not exposed to risk of damage from external causes.

(*e*) All inflammable material within 24 ins. vertically above, 12 ins. vertically below, or 6 ins. in any other direction, shall be protected with non-ignitable material.

(*f*) An auto-transformer for lamps or domestic appliances shall not be used on a pressure of more than 250 volts or with earthed concentric public mains.

(*g*) In step-up transformers the primary and secondary windings shall be separate throughout; high-voltage parts shall be shielded by earthed metal, or be inaccessible to unauthorised persons. High-pressure wiring shall be a minimum, and conductors conform to B.E.S.A. specification. A multipole linked switch shall provide for the isolation of the supply to the transformer.

TESTING OF COMPLETED INSTALLATION.

NOTE.—The following tests are intended to ensure that the installation is in a satisfactory state at the time of completion.

The value of systematically inspecting and testing apparatus and circuits cannot be too strongly urged, and such periodical tests are essential if the installation is to be maintained in a sound condition and undue deterioration thereof detected.

All defects thus discovered should be made good without loss of time. The attention of consumers should be drawn to the importance of maintaining all apparatus and fittings in a clean and dry condition.

Tests to be Carried out.

Before an installation is permanently put into service the following tests shall be carried out:—

Insulation Resistances.

(*a*) The insulation resistance shall be measured by applying a direct-current pressure of not less than twice the working pressure, between earth and the whole system of conductors or any section thereof with all fuses in place and all switches on. The working pressure is deemed to be that between outer or phase conductors and neutral, where latter is earthed.

(*b*) The insulation resistance of the lighting circuits measured as in (*a*) above shall not be less in megohms than 25 divided by the number of points on those circuits, except that the insulation resistance of any final lighting sub-circuit need not exceed 1 megohm.

(*c*) The insulation resistance between the case or framework and every live part of each individual dynamo, motor, heater, arc lamp, or other appliance complete with its switch and control gear, regulating resistance, and similar accessories, shall not be less than half a megohm when measured as in (*a*) above.

(*d*) All lamps to be in place except on earthed concentric wiring systems. Heating and power circuits may be tested with appliances removed, but lamps (if any) in place.

Note.—In addition to the foregoing tests, it is advisable wherever practicable to take an insulation test between all the conductors connected to one pole or phase of a system and those on the other pole or phase.

Continuity of Metal Sheathing.

The metal conduits or metallic envelopes of cables in all cases where such methods are used for the mechanical protection of electrical conductors shall be tested for electrical continuity, and the electrical resistance of such conduits or sheathing, measured between a point near the main switch and any other point of the completed installation, shall not exceed 2 ohms.

Additions to an Existing Installation.

It must be ascertained whether the ratings of the circuits concerned is sufficient for the increased current.

Radio Apparatus Connected to Supply Mains.

(*a*) All live parts shall be guarded to prevent accidental contact.

(*b*) Cases for enclosed apparatus shall be substantial and constructed of mahogany, teak, oak (English), walnut, metal or non-ignitable material, or of other material if a non-ignitable and non-hygroscopic lining is used; shall be earthed if of metal. Air temperature inside main container not to exceed 120° F., and local temperature rise of no part of apparatus such as to impair its durability. Cables holes must not cause abrasion of cables.

(*c*) Apparatus to be protected by D.P. fuses (see fusible cutouts). A minimum size may be No. 25 S.W.G. lead-tin alloy for working current less than 2 amperes.

(*d*) When a conductor of any cable connected to radio apparatus is in direct connection to supply mains, such cable to be of type specified and installed in accordance with foregoing regulations.

(*e*) Connection between a conductor connected to mains and earthing lead of radio apparatus is permitted only through a condenser incorporated with or close to the radio apparatus.

(*f*) With D.C. supply mains, the aerial shall only be connected to the apparatus through a double wound high-frequency coupling transformer tested to 600 volts, or through a condenser in series with and adjacent to aerial terminal. On a.c. mains when a transformer is not used as above, the condenser capacity shall be not greater than 0·001 mfd. The insulation resistance test specified in (*j*) shall be applied to the H.F. coupling transformers or to the condenser, for either D.C. or A.C. supply.

(*g*) Head telephones and loud speakers shall be connected to the radio apparatus through a double-wound transformer or through a condenser on each conductor.

(*h*) Condensers referred to in (*e*), (*f*), (*g*), to conform to B.E.S.A. specification 271—1926.

(*i*) Every 'mains' transformer to be double wound with an earthed core. The winding connected to the mains to be separated by earthed metal screen or by insulation tested at 1000 volts (A.C.). All windings to have an insulation resistance of not less than 20 megohms at 500 volts (D.C.) or twice the supply pressure, whichever be the greater.

(*j*) Aerial, earth, and telephone terminals on radio apparatus, transformers, or condensers referred to in (*e*) and (*f*), where external to the apparatus, shall have an insulation resistance of not less than 2 megohms from the 'mains' input terminals measured as in (*i*).

(*k*) Batteries connected to radio apparatus and to supply mains shall have insulation resistance to earth of not less than 2 megohms tested as specified in (*i*).

The Electrical Equipment of Ships.

REGULATIONS ISSUED BY THE INSTITUTION OF ELECTRICAL ENGINEERS.
SECOND EDITION, JULY, 1926. (*Amended*, 1929.)
(*Abbreviated.*)

General.—These regulations apply to all sea-going ships except ships of war. They relate to the use of electrical energy for all purposes except the propulsion of ships, and comprise the main requirements for ensuring satisfactory results.

Nature of Supply.—Standard systems of distribution are two-wire D.C. or A.C., three-wire D.C., three-phase three- or four-wire. Standard pressures are 110, 220, 440 volts for parallel constant voltage systems; 110 volts single-phase A.C. Standard pressures have not been fixed for polyphase currents, but must not exceed 150 volts for lighting and 250 volts for power and heating, except for oil ships. On tugs, trawlers, small yachts, fishing and similar small vessels the standard pressures are 12, 50, and 110 volts. The standard frequency is 50 cycles per second.

Generating Plant.—Generators shall conform to the British Standardisation Rules, except that they shall be capable of sustaining an overload of 25 per cent. for two hours in temperate climates and cool situations on board ship. Generators shall be over-compounded 5 per cent.; they shall be placed where they do not affect the compasses, with their axis fore and aft, and the frames shall be efficiently earthed. Standard capacities for steam prime movers are 5, 10, 15, 20, 25, 30, 40, 50, 75, and 100 kW. Steam pressures for single engines 100–120 and for compound engines 150 lb. per sq. in. Excluding turbines, the momentary and permanent speed regulations respectively must be within 10 and 5 per cent. for engines up to 50 kW., and within 10 and 3 per cent. above 50 kW. For internal combustion engines, these figures are 10 and 3 per cent. up to 10 kW. and 10 and 2½ per cent. above 10 kW. Standard capacities are 2, 3, 5, 7½, 10, 15, 20, 25, and 30 kW.

Switchboards.—The requirements for conductors and distribution are in general those specified in the Regulations for the Electric Equipment of Buildings—see p. 2231, but switchboards must be constructed wholly of durable, non-ignitable, non-absorbent materials. The maximum voltage drop in wireless mains shall not exceed 1 volt plus 1 per cent. of the bus-bar pressure when carrying main and battery loads simultaneously. When the load on a conductor is intermittent, the size of cables for such ratings is given in the following table :—

Rating of Conductors Intermittently Loaded.

Nominal Area of Conductor.	Permissible Current in Amperes.					
	Rubber Cables.			Paper Cables.		
Rating :	Half-hour.	One-hour.	Continuous.	Half-hour.	One-hour.	Continuous.
0·0145	38	37	37	60	57	57
0·0225	47	46	46	79	75	75
0·03	56	54	53	94	89	87
0·04	68	65	64	113	105	104
0·06	92	85	83	151	138	135
0·075	113	101	97	180	162	157
0·1	142	124	118	225	199	191
0·12	160	138	130	252	220	210
0·15	191	164	152	303	261	246
0·2	247	204	184	376	320	296
0·25	295	244	214	453	377	343
0·3	315	283	240	523	435	385
0·4	452	357	288	663	543	464
0·5	534	422	332	804	648	540
0·6	641	499	384	960	767	624

0·85	900	680	512	1,325	1,045	815
1·0	1,036	803	595	1,548	1,211	932

Cables in machinery spaces or exposed to weather or the action of salt water shall be either lead covered, with or without further protection, or be run in conduit. Cables in cold-storage chambers shall pass normally through the walls or lagging with continuous lead tube flanged at each end. Such cables must be lead covered in full view throughout their length and supported by porcelain, hard wood, or other non-metallic, non-hygroscopic material. All metallic-covered

cables must have such covering earthed at both ends, except for sub-circuits, which are earthed at the supply end only.

Cables passing through decks or watertight bulkheads shall be provided with suitable glands or deck tubes—see B.E.S.A. Specification No. 94—1920. Where unarmoured cables pass through beams and non-watertight partitions, the holes must be bushed with lead or other soft non-ferrous metal. Flexible cords with silk or cotton covering must not be used in crew or cargo spaces, or where exposed to mechanical damage.

Maximum Spacing of Clips securing Lead-covered or Armoured Cables.

Overall Diameter of Cable.	Lead-covered.	Armoured.
Under 0·3 inch . .	8 inches	10 inches
0·3 to 0·5 inch . .	10 ,,	12 ,,
0·5 to 0·75 inch . .	12 ,,	14 ,,
0·75 to 1·25 inch . .	14 ,,	16 ,,
Over 1·25 inch . .	16 ,,	18 ,,

Earth Connections.—Only steel ships shall be wired on the single-conductor system. Earthing connections carrying current shall be of the same size as the corresponding insulated conductor. Earthing connections not normally carrying current shall be of copper of the same size as the working conductor (but not less than 0·003 sq. in.) up to 0·007 sq. in., and above that size not less than 0·007 sq. in. for every 50 amperes of working current or part thereof, but need not exceed 0·1 sq. in. Earth connections shall be accessible and secured by screws not less than $\frac{3}{8}$ in. in diameter.

Interference with Compasses.—Dynamos, batteries, and all apparatus producing an external magnetic field shall be fixed at such a distance from the compass that the magnetic field produced thereat has a negligible value. No single-conductor cable carrying continuous current shall be fitted within 30 ft. of standard and steering compasses. Conductors in the vicinity of the compass shall be twin, or as close together as possible. Incandescent lamps used for lighting the compass shall not consume more than 0·6 ampere, and no live part shall be less than 7 ins. from any part of the magnetic system. Effect of switching must be noted during adjustment of compass.

Navigation Lamps.—Each navigation lamp is to be separately wired and controlled by a separate switch and fuses, and to have an automatic indicator in circuit to give warning of the failure of the light. Metal filament bayonet cap vacuum lamps fixed vertically of not less than 60 watts to be employed.

Storage Batteries.—The cells shall be so constructed that the electrolyte cannot be spilled, with strong containers (not celluloid). They should be in a single tier and mounted on oil insulators. The deck must be lined with lead or other acid-resisting material, and all exposed metal protected with acid-resisting paint. The battery compartment must be well ventilated. Switches and fuses must be fixed outside the battery room. All connections in an acid battery room are to be of bare metal or lead-covered cables.

Fittings.—Fittings are to be so designed and fixed that dust and moisture cannot accumulate within them, and are not to be mounted on surfaces liable to become damp. In exposed positions they are to be weatherproof and waterproof; open type fittings must not be used near inflammable goods or where inflammable dust or gases can occur. Switches, etc., must not be installed in bunkers or where inflammable gases may be present. Weatherproof portable lamp fittings with metal frames must have all metal parts connected to earth by a third conductor in the flexible cord, and must be provided with hooks to hang them up with. Lampholders in weatherproof portable fittings must be earthed, and in open type fittings they must be insulated and protected with insulating shields. Plugs and sockets must be so constructed that they cannot be readily short-circuited or earthed or allow an arc to be maintained. Plugs must be provided with hand-shields or interlocked with switches in the sockets. Weatherproof plugs and sockets must be employed in exposed positions. See B.E.S.A. Specifications Nos. 97—1926, 98—1919, 67—1929, 372—1930, 52—1927.

Lamps.—Arc lamps must have the whole of their live parts insulated from the frame, and must be provided with wired globes or other protection; they must not be fitted near combustible goods or where gases can accumulate, and each circuit must be controlled by a switch and fuse on each insulated pole. Navigation lamps must be of the carbon or metal filament type of 32 candles.

Motors.—May be of any type enumerated in B.E.S.A. Specification No. 168—1926, or of submersible type. When larger than 1 b.h.p. they must strictly conform. Working parts must be accessible, and construction must allow of dismantling in space where fitted, unless readily removable. The carbon brush gear must be adjustable. For brushes see p. 2295 and B.E.S.A. Spec. No. 96—1922 for standard terminals. Lubrication must be automatic. Motors should be placed in well-ventilated compartments, with axis of rotation in a fore and aft direction and clear of inflammable material: otherwise they must be of flame-proof or forced-draught type with pipes taken outside compartment. Where temperature exceeds 120° F. motors to be pipe-

ventilated, induced- or forced-draught type connected to inlet air at less than 120° F. Motor starters above 3 b.h.p. must have no-volt release and replaceable resistance elements. Motors essential to the safety of the ship in the event of damage must be capable of running for a reasonable period after the compartment has been flooded.

Control Gear.—Regulators and controllers are to be of incombustible materials and guarded or enclosed in incombustible cases; contacts shall be renewable, and all live parts enclosed by metal covers, and so designed that they cannot be touched by the operator. Resistances shall not rise to an excessive temperature, and no accessible part of the apparatus may rise above 130° F. Internal connections shall not be soldered. Control gear shall not be placed where inflammable gases can accumulate, unless it is flameproof; in exposed situations it shall be totally enclosed. Resistances shall be placed in well-ventilated compartments and away from combustible material.

Heating and Cooking Apparatus.—Appliances shall be so constructed that parts which are handled cannot exceed a temperature of 130° F. The elements shall be readily replaceable; live and highly heated parts shall be guarded. Connections between the elements and switches or external leads shall be made without solder, and their temperature shall not exceed 200° F. All appliances for pressures exceeding 150 volts shall be efficiently earthed. Whether portable or fixed, appliances shall be controlled by fixed switches; portable appliances shall have at least one section of the elements controlled only on the live side of the wall plug or other connection with the fixed portion of the circuit.

Internal Communications.—Transforming apparatus and batteries shall conform with the rules for lighting and power plant. If the working pressure exceeds 25 volts, all parts of the apparatus shall be made and fitted in accordance with the rules for lighting and power circuits. Communication cables shall be made and fixed in accordance with the rules for light and power cables, and shall be kept as far as possible separate from the latter, with separate grooves when run in wood casing. Fuses need not be fitted in branch circuits for pressures not exceeding 25 volts, or in circuits supplied from primary batteries.

Lightning Conductors.—Conductors shall be fitted to all vessels having wooden masts, of copper tape or rope having not less than 0·15 sq. in. sectional area. When in dry dock, ships' lightning conductors shall be connected to an efficient earth on shore.

Oil ships.—On oil ships the pressure for all purposes shall not exceed 110 volts with A.C.; with D.C., for power 220 volts, for lighting and heating 110 volts. No part of the system shall be earthed, and double-pole linked switches shall be used on every circuit or sub-circuit. All cables shall be lead-covered, with or without armour. Distribution shall be on the two-wire, two-conductor system. No wiring shall be taken into oil-holds or coffer-dams, which must be lighted by lamps entirely outside the space and separated from it by an airtight glass bowl. Lamps in dangerous spaces shall be in gas-tight fittings, and the switches shall be outside the spaces; no portable lamps other than self-contained battery-fed lamps (mining type) may be used in dangerous spaces.

Constant-current Series System.—Special requirements include automatic circuit closer for short-circuiting generator in the event of an open circuit anywhere in the system, and forbid the use of open-type machines. All bare conductors (including heating elements) to be totally enclosed in metal cases with conductors accessible only when disconnected, and no part of the system shall be earthed.

Trials.—The insulation of the whole system, with all lamps and fuses in place, is to be tested before putting into service with direct current at twice the working pressure between the system of conductors and earth, and shall not be less in megohms than 10 divided by the number of lamps (on lighting circuits), but the insulation resistance of any final lighting sub-circuit need not exceed one megohm. The insulation resistance of every piece of apparatus, with switch or control gear, etc., shall not be less than half a megohm. The installation shall be run for six hours and all the apparatus operated, not necessarily simultaneously.

Disturbances to Wireless Installations, Direction Finders, and other Thermionic-Valve Apparatus.—Disturbances arising from commutator machinery may cover a wide area and may be reduced by employment of lead-sheathed cable for deck motor circuits, such circuits being well removed from chart-room or wireless cabin. A condenser of 2 mfd. capacity insulated to withstand four times the supply voltage may be connected with short leads across the brushes of a disturbing motor. Commutators must be kept in good condition. In motor-boats equipped with wireless, braided-metal cable should be used for sparking-plug connections, the braiding earthed at both ends and at least at one intermediate position. The low-tension earth wire should be earthed in at least two places.

Plugs and Sockets.

British Standard Specification for 5-, 15-, and 30-ampere, 2-pin wall plugs and sockets for domestic purposes (without earthing connection), No. 73—1927, gives details of materials to be used, sizes and spacing of all insulating, current-carrying, protecting, and fixing parts, together with gauges and tables of dimensions. Heavy Duty, Flame-proof type plug and socket are dealt with in Specification No. 279—1927, and Reversible Protected-type two-pin plugs and sockets with earthing connections in No. 196—1927. Charging plug and socket for vehicles propelled by Electric Secondary Batteries are dealt with in Specification No. 74—1917. Three-pin wall plugs and sockets, hand-shield and side-entry pattern (two-pin and earth type), for domestic purposes are dealt with in Specification No. 317—1928.

Cable Soldering Sockets.

Specification No. 91—1930 of the British Engineering Standards Association gives the standard dimensions of cast and wrought lug sockets, clamp sockets, and clamps, for cables from 0·003 to 1·000 sq. in. sectional area. Cast lug sockets are of brass containing 70 per cent. of copper, and tubular lug sockets are of solid-drawn copper tubing; clamp sockets are of brass or other suitable non-ferrous metal. Sweating surfaces are to be drilled and tinned, and contact surfaces machined.

Watertight glands for Electric Cables are dealt with in Specification No. 94—1920.

Cables for Installation Work.

As far as electrical installation work, and particularly conduit work, is concerned, the type of cable with which the contractor has mostly to deal is that known as a rubber insulated cable. The real properties of rubber insulated cables are more or less obscure, and the question as to what constitutes a good cable is almost impossible to answer with any degree of accuracy. To give some indication as to the quality of the rubber compound covering, a careful chemical test is required, and this combined with a stretching test will give a distinct clue as to the possible durability of the material.

Government Department Specification for Rubber-Covered Cables J, K and L Classes for Power and Light.

Designation.—Cables shall be designated by the nominal sectional area of the conductor and a letter prefix as follows: 'J Low' and 'J Low Twin,' 'J Medium' and 'J Medium Twin' for 250-volt and 660-volt respectively for V.I.R. taped and braided. 'K' and 'K Twin' for V.I.R. taped, and lead sheathed (660-volt) and 'L' and 'L Twin' for V.I.R. taped, lead-sheathed and armoured (660 volts).

Material.—The conductor shall comply in all respects with B.E.S.A. specification No. 7, and be free from all mechanical defects.

Tinning.—Each wire shall be tinned uniformly with pure tin free from lead in a bath free from contamination with copper. Before stranding, a sample shall be bent into a loop of radius not less than 12 and not more than 15 times its diameter, cleaned to remove grease and immersed for 1 minute in hydrochloric acid specific gravity 1·088 at 60° F., washed and examined under a lens for blackening. Average number of times of immersion to produce visible blackening shall not be less than 8 times for wire 0·029 to 0·048 inches diameter, 7 times for diameters above 0·048 up to 0·0808, and 5 times for diameters over 0·0808 inches. A further sample to be wrapped round a rod of diameter four times that of the wire and submitted to the above for one cycle.

Jointing.—Not more than one joint to be allowed in any wire forming 1000 yards of conductor nor a joint to be within 12 inches of another in same layer, nor in conductor after stranding. Joints shall be brazed, silver soldered or electrically welded.

Stranding.—To be uniform throughout length. 3-stranded wires to have a left-hand helical lay, 7 strand to have straight centre wire with six left-hand helically laid wires, the stranding for other numbers of wires to have alternate left-hand and right-hand lays.

Resistance of Conductors.—To conform to B.E.S.A. specification No. 7. Compensation for the laying up of twisted twin cables to be agreed between contractor and inspector.

Dielectric.—Conductor shall be covered with one layer of British plantation pure rubber applied helically or longitudinally, then a covering and jacket of vulcanised rubber consisting of pure rubber mixed with sulphur, non-hydroscopic mineral matter and wax if required. The dielectric shall contain not less than 45 per cent. by weight of pure rubber. After vulcanisation the acetone extract shall not exceed 5 per cent. by weight, of which rubber-resins are not greater than 2 per cent. and free sulphur 0·75 per cent. Maximum amount of organic matter in residue after acetone extraction not to exceed 1·0 per cent. of total dielectric. Sulphur content in rubber not to be less than 1·25 or greater than 1·75 per cent. of total dielectric. No re-manufactured rubber or rubber substitutes to be used. Cable to be rejected if blackening is shown on pure rubber or tin, or if pure rubber adheres to conductor.

Thickness.—To be in accordance with B.E.S.A. specification No. 7.

Taping and Vulcanising.—To consist of helical binding of fine cotton tape (red and black or blue for twin cables) of specified thickness, rubber proofed. The whole to be vulcanised into homogeneous body, after which rubber layers shall be inseparable but tape removable without tearing rubber.

Mechanical Tests.—After removal of the conductor, an outer covering a length of 2 inches marked on the dielectric shall be maintained stretched to 6 inches for 24 hours at an ordinary temperature not exceeding 65° F. After release, the length shall not be greater than 2½ inches, no signs having been shown of the rubber cracking or elongating irregularly. Tensile strength not to be less than 800 lb. per sq. in.

Heat Tests.—Separate samples after removal of conductor shall withstand without material deterioration a dry heat of 270° F. for 1 hr. and a moist heat of 320° F. for 3 hrs. After three days interval samples to be stretched as above from 2 ins. to 5 ins. for 6 hrs., the distance becoming not greater than 2½ ins. on release.

Electrical Tests.—(*a*) High voltage test as B.E.S.A. Specification No. 7 after vulcanising and before outer protective coverings are put on. (*b*) Insulation resistance shall not be less than that given in tables and to be measured immediately after test (*a*). Cable to be immersed in water

and measurement made with not less than 500-volt direct current after 1 minute negative electrification. The electrification must proceed regularly.

Twinning.—For circular twin, the complete cores shall be twisted with a right-hand lay, wormed with tanned jute and wrapped to approximate circular section with rubber-proofed cotton tape. For flat twin, the two cores side by side are tape-wrapped to form symmetrical cable.

Mechanical Protection.—The specification gives particulars for braiding, identification cotton, lead sheathing, bedding and serving, galvanised steel wire and steel tape armouring, tests on finished cables and packing, together with tabulated data and a temperature correction table for insulation resistance.

The foregoing details give some indication of the main features which are to be looked for in a high-class rubber insulated cable. As regards the conductors, the conductivity question is one of considerable importance, but it should be mentioned that trouble in this direction very seldom arises, because there is little difficulty in maintaining a standard purity in electrolytically refined copper. The phrase ' to show no sign of sulphide of copper after vulcanising ' refers to the appearance of the wire when it is stripped of its insulating covering. It should then present a clean, bright appearance, free from blackening.

The building up of the rubber dielectric in three layers represents the usual English practice, and the wording of the specification is designed to exclude the use of adulterants and deleterious substances, these being practically synonymous so far as the life of the rubber insulation is concerned.

The specifying of a minimum percentage of rubber in addition practically leaves no room for anything but legitimate compounding ingredients, the choice of which is left to the experience and skill of the cable manufacturer.

There is, perhaps, no industry so greatly dependent on detailed experience and skill in applying that experience as that of the manufacture of rubber, and when electrical conditions are involved this is doubly true.

Generally speaking, therefore, where considerations of quality and durability are paramount it will always be best to purchase rubber-insulated cables, either to a specification such as that instanced above, or to agreed standards such as those of the Cable Makers' Association.

The provision of suitable outer coverings for rubber-insulated wires and cables which are exposed to abnormal conditions is a point which should not be overlooked. Conversely, in a given situation, a certain method of installing may be unsuitable. For instance, condensation effects, which occur in tubes and pipes, are notoriously bad for rubber cables, and in such situations either the method of installing should be varied or special coverings, such as a bitumen sheath, should be applied to the cables. Many cable makers are prepared to advise as to the best type of covering and method of running or fixing cables under abnormal surrounding conditions.

A second quality of vulcanised rubber cable has been placed on the market to meet the demand of those users who are satisfied with a cheaper grade of cable. Such cable, known as ' non-Association ' cable, is quite satisfactory when properly manufactured, and may be safely used in cases where only a moderate length of life combined with good mechanical properties, is required, and where the conditions do not require a permanent maintenance of high elasticity of the dielectric.

Revised Specification for Cab-Tyre Sheathed Cable.*

The following specification for this class of cable is based on the British Admiralty Specification Tests for Cab-Tyre Sheathing :—

The cab-tyre sheathing shall contain not less than 35 per cent. and not more than 40 per cent. of first-grade plantation rubber or other rubber of not less good quality.

The surface of the sheathing shall not be treated or dressed without the consent of the Admiralty Overseer.

The acetone extract of the vulcanised sheathing shall not exceed 5 per cent. calculated on the weight of the complete sheathing as manufactured.

Bending Test.—A test length of the complete cable containing the conductor shall be bent round a hard rod having the same diameter as the external diameter of the cable to form a loop. The unbent portions of the test-piece shall be bound together so that the two parts touch one another closely throughout their length from their ends up to the beginning of the loop.

In cables of large size when this method is not practicable the test-piece shall be bent in a loop so that the maximum extension of the external surface at the curvature at the bend reaches 50 per cent.

The sample in either case shall be left untouched for a period of 48 hours and at the termination of this time shall show no signs of cracking.

Immersion Tests. (*a*) *Chemical.*—Test-pieces 6 ins. long shall be prepared, and after the conductor and dielectric have been removed they shall be dried at a temperature of 100° C. for one hour in an air oven ; they shall then be cooled in a desiccator for two hours, and at the end of this period shall be weighed. The ends of the test-pieces shall be plugged with rubber bungs and sealed with paraffin wax for a length of half an inch from each end. The test-pieces thus prepared shall be completely immersed in a vertical position in the following solutions for a

* Referred to in I.E.E. Rules as ' tough rubber compound ' covering, p. 2234.

period of 48 hours at normal temperature; they shall then be removed and washed in running water for a period of two hours, afterwards being wiped dry and the wax and plugs removed. The samples shall then be dried in an air oven for one hour at a temperature of 100° C. and shall be cooled for two hours in a desiccator; they shall then be reweighed. The difference in weights before and after immersion shall be calculated as grammes per 100 sq. ins. of surface exposed to the solution.

(1) *Acid Test.*—The solution shall be hydrochloric acid having a specific gravity of 1·045. The figure calculated as stated above shall not exceed 1·0.

(2) *Alkali Test.*—The solution shall be sodium hydrate having a specific gravity of 1·116. The figure calculated as stated above shall not exceed 1·5.

(*b*) *Oil Test.*—A test-piece shall be prepared 6 ins. long; one end shall be sealed so as efficiently to prevent access of oil to the interior. The test pieces shall be immersed in pure rape oil of the best quality to such a depth that not less than 2 ins. of sheathing is exposed to the action of the oil. The immersion shall be continued for six hours, the oil during that time being maintained at a temperature of 100° C. After immersion the sample shall be removed and rolled dry between blotting paper; the seal shall then be removed and the sample re-weighed.

The difference in weights shall be calculated as grammes per 100 sq. ins. of surface exposed and the figures so obtained shall not exceed 15.

The cable should be generally in accordance with *St. Helens Cable & Rubber Company's* original Patent No. 3996/1911.

Cab-Tyre Sheathed Cables are now made in C.M.A. 'Nonazo' (non-Association) quality, as well as in C.M.A. Association grade.

WIRING SYSTEMS.

Conduits and Fittings for Electrical Installations.

Conduits, with the exception of the seamless or drawn varieties, are generally made from specially selected steel strip, varying in gauge according to the diameter of the tube. The strips are rolled to a circular section of exact external and internal diameter, by a method which ensures freedom from internal roughness and an even surface to facilitate the drawing of the wires into the conduit, thus preventing injury to their insulation. Exact sizes are essential in order to obtain a tight junction between the conduit and fittings with both socket and screwed junctions.

The conduits are made in two different types, viz. Light Gauge, for socket and continuity junctions, and Heavy Gauge for screwed junctions.

Conduits are usually supplied in two standard finishes, as follows:—

(1) Stove enamelled (black); (2) Galvanised.

For all ordinary installation work in the interior of buildings, enamelled conduits will be found satisfactory in working.

The enamel employed should be flexible, acid-resisting, insulating, and durable.

The conduits must be well cleaned before being enamelled, and subsequently stored at an even temperature until the enamel is set, so that it is not liable to flake or break away when the conduit is bent. The enamel should resist any chemical action which is likely to be found in the plaster of buildings.

Where conduits are subjected to excessive chemical action, especially when buried in cinder-fill concrete, quick-drying chemical plasters, and the like, a more efficient protection is required, and this is afforded by galvanising.

British Standard Specification for Steel Conduits for Electrical Wiring.*

(No. 31—1923.) (*Abstract.*)

Steel conduits shall be either close-joint, brazed, welded or solid drawn as ordered, and shall be of mild steel and free from burrs and internal roughness. The conduit fittings shall be made of steel or malleable iron. All steel shall have a tensile strength of not less than 18 tons nor more than 24 tons per square inch of section, and an elongation of not less than 15 per cent. in a length of 8 inches. Malleable castings shall be well annealed and free from internal projections.

The conduit shall be manufactured in straight lengths of ten to fifteen feet.

For all fittings made out of *tube*, the minimum thickness of the fittings shall be equal to that of the corresponding conduit with which they are used. In no case shall 'close joint' tube be used for these fittings.

Two classes of steel conduit for electrical wiring are recognised as Standard:

Class A.—Plain.
Class B.—Screwed.

Class A consists of light gauge conduit of the thickness and dimensions given in the Table (p. 2246). Class A conduit is either close-joint, brazed, welded or solid drawn. The coupler joining the lengths of tubing is a sleeve, and neither the ends of the conduit nor the coupler are screwed.

* By permission of the British Engineering Standards Association.

In the close-joint tubes, the edges of the steel strip, though brought tightly together in the process of manufacture, are not metallically joined in any way.

Class B consists of heavy gauge conduit of the thicknesses and dimensions given in the Table. Class B conduit is either brazed, welded or solid drawn. Both ends of the conduit are screwed.

Unless otherwise specified with the order, all conduits and fittings shall be stove enamelled jet black or galvanised by the hot process both inside and out.

TABLE OF STANDARD DIMENSIONS OF STEEL CONDUITS.

The Henley Wiring System.

(W. T. Henley's Telegraph Works Co., Ltd.)

In this system the cables carry their own metallic protection, which is of a flexible nature; it is consequently very easily and speedily erected. The wires and cables are of very small dimensions, and when painted, distempered, or stained and varnished to match existing decorations, they are to all intents and purposes indistinguishable. If desired, the cables may be buried in plaster and concealed generally. The cables may be run under floorboards, in lofts or cupboards, and dropped down between the faces of lath-and-plaster partition walls. The chasing of walls or cutting away of joists is very much less than is required with tubing.

The cables employed are of flat section of one, two, or three conductors, each conductor composed of tinned copper wires, insulated with pure and vulcanised rubber, taped with proofed tape of a distinctive colour for each core, the whole then vulcanised together, cores laid side by side, sheathed with a solid drawn tube of special alloy to protect the cores from mechanical damage. These cables may be used on either direct or alternating current.

TABLE OF SINGLE-CORE, TWIN, AND TRIPLE CABLES.

0·002	3/·029	1,250	7·8	0·274 × 0·574	10·00
0·003	1/·064	2,000	12·9	0·276 × 0·580	10·36
0·003	3/·036	1,250	12·0	0·294 × 0·634	11·43

Test Pressure.—1,000 volts alternating for 15 minutes after 24 hours' immersion in water at 60° F. (15·6° C.).

For the purpose of bonding the sheathing at switch and light points the Universal Bonding Clamp is provided. This clamp, fig. 3, has been designed so that one clamp only, instead of several, may be used at any point, thereby reducing to a minimum the necessity for stocking various sizes of clamps for various numbers and sizes of wires, etc.

When erecting it will be found more economical in many instances to run both switch and light feeds to a three-plate ceiling rose, looping from there to the next light. In the case of electroliers controlled by two switches, in many instances it will be found economical to use a four-plate ceiling rose, taking both switch and light feeds to this rose, the switches being connected by means of a triple cable. This three-core cable can be used to advantage in many other instances, which will be readily apparent when the work is planned out.

Straight through and tee joints, etc., are made by means of the boxes provided under the system.

For fixing the cables, the 'Link' clip, fig. 4, is specially convenient. These clips are made from tinned brass, and may be fixed either with nails or countersunk-headed screws.

Fig. 2 shows a form of Tee Joint Box for the twin system. These Boxes are manufactured from brass heavily tinned; the internal connectors are of the porcelain type, and are made in various forms according to requirements. The continuity of the metal sheathing of the cables is preserved by means of mechanical clamps that bond the lugs on the boxes to the cables.

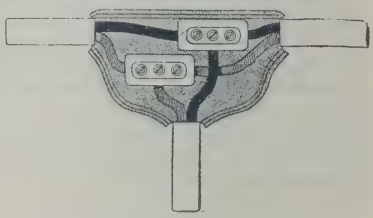

FIG. 2.

Another form of Tee Box—the 'Super' Box—is shown by fig. 5, p. 2250. In this Box the loose bonding clamps used with the box illustrated in fig. 2 are dispensed with; the cover is held in position by one unlosable self-centring nut which is fixed in the cover, and the porcelain connectors are substituted by a moulded terminal block.

The latest addition to the system is a Box of the 'Universal' type, which is illustrated in fig. 6, p. 2250. This Box works on the same principle as the Universal Bonding Clamp illustrated in fig. 7, and can be used as a straight through, tee, or four-way box as required. As with the 'Super' Box, the cover is secured by one unlosable nut. The joint is made by means of porcelain connectors.

The fixing of link clips, saddles, protective covering, or other articles, to plaster, brick, marble, slate, stone, etc., is best effected by the use of "Rawlplugs" (see p. 420).

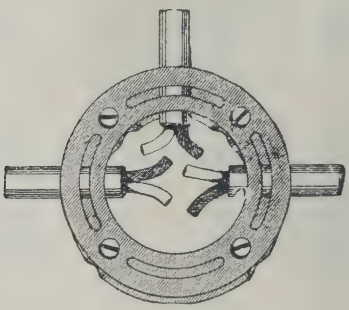

FIG. 3.

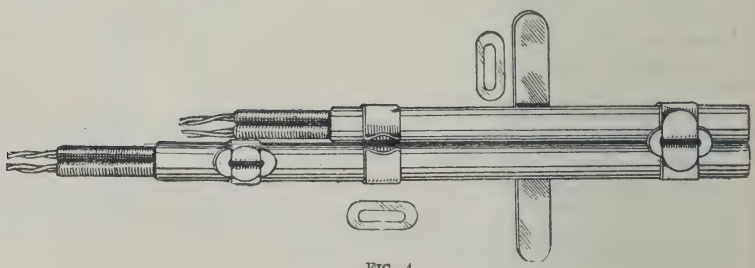

FIG. 4.

The Henley 'Nomet' (Regd.) Wiring System.

This system, whilst not new, employs Henley C.T.S. cables, and has been developed:

(*a*) To meet the wishes of customers who prefer a non-metal covered system.

(*b*) For use in abnormal situations where metal-covered wiring may be undesirable.

It is strongly recommended that, wherever possible, a metal-covered system be used, this being an economical and efficient means of electric wiring, and also a relatively safer method than any non-metal covered system.

Table of Single-Core, Twin, and Triple Cables.

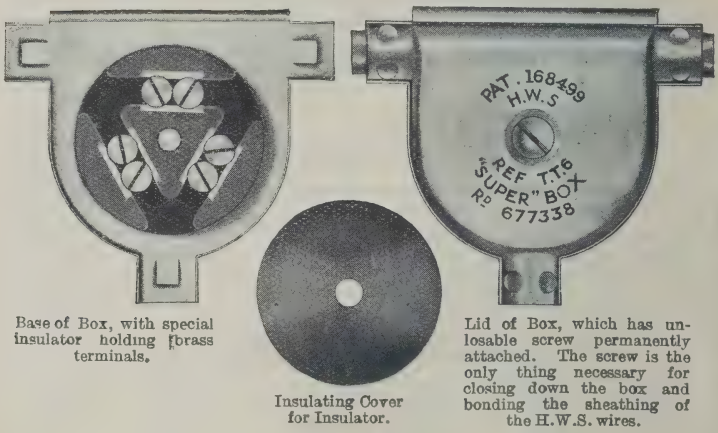
0·003	3/·036	1,250	12·0	0·274 × 0·582	3·30

Test Pressure.—1,000 volts alternating for 15 minutes after 24 hours' immersion in water at 60° F. (15·6° C.).

The 'Nomet' Wiring System cables, like the Henley Wiring System cables, are small in dimensions and carry their own mechanical protection. The cables can be easily erected, painted or otherwise treated, and the complete range of accessories (which are stocked) facilitate the wireman's work and enable a neat and satisfactory installation to be made.

THE HENLEY WIRING SYSTEM.



Base of Box, with special insulator holding brass terminals.

Insulating Cover for Insulator.

Lid of Box, which has unlosable screw permanently attached. The screw is the only thing necessary for closing down the box and bonding the sheathing of the H.W.S. wires.

FIG. 5.

FIG. 6.

The J. and P. Wiring System.

(Johnson and Phillips, Ltd.)

This system consists of single, twin (fig. 7), or three-core (fig. 8) rubber-insulated cable protected by a metallic sheathing of a special lead alloy. The cables are of flat section, and are intended for the wiring of domestic and other building interiors without further protection.

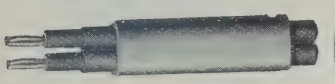


FIG. 7.

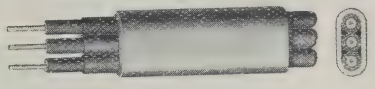

FIG. 8.

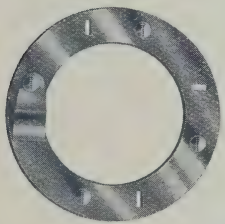

FIG. 9.

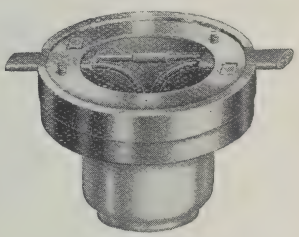

FIG. 10.

When fixed with the special fittings provided, they are neat and unobtrusive in appearance, as they lie flat against the wall or ceiling and do not sag. If used for surface fixing, they can be coloured to match the paintwork or distemper, and are then practically indistinguishable from their surroundings.

The system fully complies with the I.E.E. Wiring Rules, and with the requirements of fire insurance companies and electricity supply authorities.

The bonding fixtures are a special feature of the J. & P. wiring system. By means of bonding and bonding clips a perfect bond can be secured with the greatest ease.

The bonding ring (fig. 9) is fixed behind a wooden pattrass (fig. 10), where connections are made to switch points, etc. The ring is supplied with four ways, one or more of which may be used as required, suitable for cables up to 3/·036 twin core.

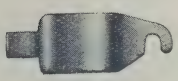

FIG. 11.

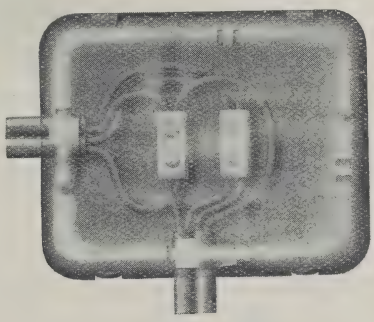

FIG. 12.

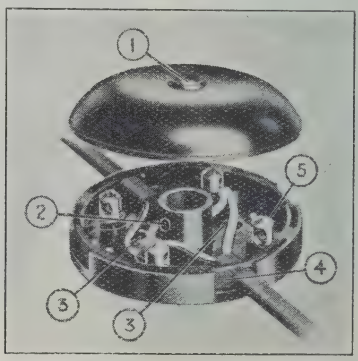
To fix, the tail of the clip, fig. 11, is simply inserted in the slot provided in the ring, the cable is placed under the clip and the notched end of the latter pushed under the screw. When this is tightened up, the metal cable sheath is securely held, the cable cannot pull out, and absolute electrical continuity is attained.

Fig. 12 shows a joint box in which twin cables can be inserted on any one or two sides if it is desired to do so.

The J. and P. 'Non-Metal Sheathed System,' designed to supplement the Metal Sheathed system described, uses C.T.S. cables which are of the same overall size as the corresponding metal-sheathed cables, and the same fixing clips and saddles, protective steel covering, etc., can be employed. C.T.S. cable is more flexible than the metal sheathed cable, and although this extra flexibility reduces the risk of kinking the cable during installation, a little more care is needed to avoid sagging on long straight runs. An ornamental wood moulding, designed to cover the cable and clips, and shaped so that it cannot be misused as a picture rail, is available for use where the appearance of a moulding would harmonise better with the decorations.



1. Blanked hole for flex.
2. Hole in pillar for flex.
3. Blanked holes for back entry cable.
4. Sliding Shutter.
5. Terminal post.

FIG. 13.

Only one size and type of Joint Box (fig. 13) is used with this system. It is hot moulded in bakelite, and has a very fine finish. Four apertures are provided for side entry cables, the apertures being reduced in size to fit any cable used for domestic installations, or closed completely by means of sliding shutters. Two blanked holes in the base can be knocked out cleanly and easily to accommodate back entry cables, and by knocking out another blanked hole in the cover the box can be used as a neat ceiling rose. The flex is passed through the central pillar, and is gripped firmly when the cover is screwed down. Loose connectors are not required with this box, four terminal pillars being moulded into the base.

The Callender 'Kalibond' Wiring System.

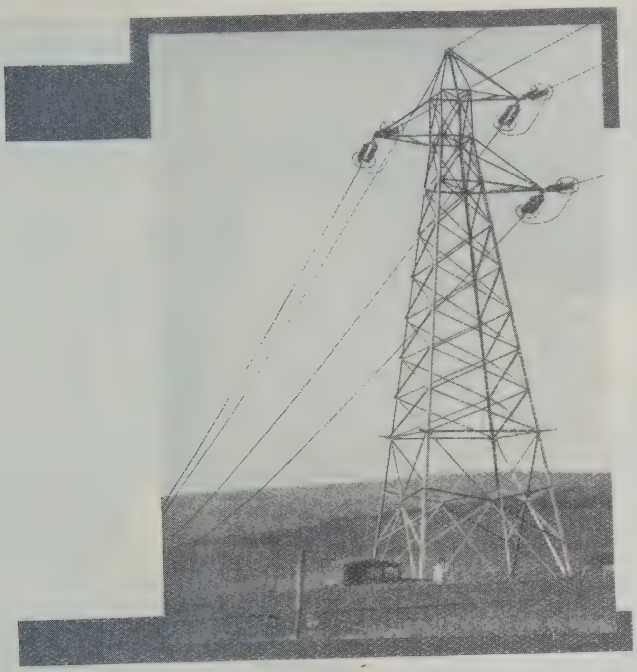
(Callender's Cable and Construction Co., Ltd.)

The system consists of single, twin, and three-core wires composed of pure copper conductors insulated with vulcanised indiarubber, sheathed with a special metal alloy, and provided with an uninsulated tinned copper bonding wire laid in intimate contact with the inner surface of the metal sheathing, together with patent metal junction boxes and all-porcelain connectors. There are no hygroscopic tapes on the wires, nor screws in the junction boxes—the system is all rubber, metal, and porcelain.

Before despatch from the works, each length of insulated core is immersed in water for at least 24 hours, then subjected for a period of 15 minutes to a pressure test of 1,000 volts alternating afterwards being tested for insulation resistance with a battery having a pressure of not less than 500 volts.

Callender 'Kalibond' metal sheated wire, although stiff enough to prevent sagging between fixing clips properly spaced, is easily bent round mouldings and cornices, and being of small dimensions has a particularly neat appearance when in position. The single core is insulated with drab rubber, the twin cores with one drab and one black, the three cores with one drab and two black.

By the use of 'braided' 'Kalibond' wire, which is made in various styles of decoration, a rearrangement of the electrical equipment of a room may be made at any time without spoiling the effect of an artistic scheme of decoration, or losing the wiring efficiency.



CALLENDER 132 KILOVOLT OVERHEAD TRANSMISSION

S.E. England Grid Scheme

The photograph shows a Single Circuit Tower at Sweet Hill, Patcham, near Brighton, being part of the Overhead Transmission Line erected by Callender's Cable and Construction Co., Ltd.

The company invite enquiries from users of electrical plant for Overhead Transmission work for small or extensive schemes in any country.

The Callender Junction Box.

(Pat. No. 276172.)

These boxes (made in three sizes) are of tinned brass. Push-in sections are provided at the sides of each box for the entry of cables, and pillars of tinned brass are provided for bonding the wire of the cables to the box. There are no bonding rings, screws, or loose parts to be assembled, or cutting tools to be used. The cable connections are made in the usual way with Midget all-porcelain connectors, or with standard porcelains if preferred. The bonding wires of the cables are twisted round the bonding pillars and secured by means of Midget connectors which form effective bonding clamps.

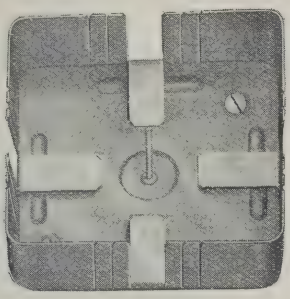

Fig. 14.

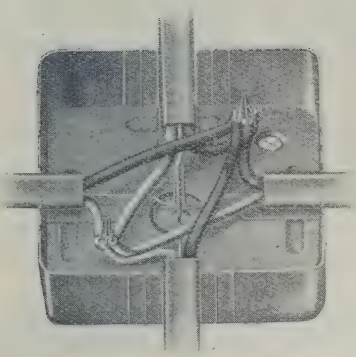

Fig. 15.

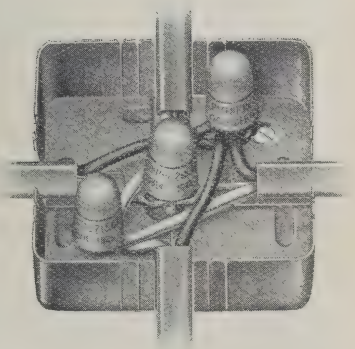

Fig. 16.

Fig. 14 shows one of the boxes with the sections pushed down to receive four twin cables, and fig. 15 the four cables brought into the box and connected up. Fig. 16 shows the twisted ends of the conductors covered with Midget connectors, which are made entirely of porcelain, and consist of a small cone having an interior thread which narrows sharply towards the apex: these connectors will joint up to three conductors each 3/·029 in size, by the simple action of screwing the connector on to the wire-ends.

Before the cables are introduced into the box a layer of a special preparation called 'Kalanoid'—an insulating and waterproof compound which remains plastic indefinitely—is placed in the box, and then, when the cables are introduced and the connectors screwed on, a further quantity of the 'Kalanoid' is worked thoroughly into the box to completely cover all the connections, and a final layer added. A cover placed over the whole is secured by means of its own natural spring without the aid of screws or clamps.

The C.T.S. Wiring System.

The cab-tyre sheath type of protected cable was originated by The St. Helen's Cable & Rubber Co. Ltd., Slough. It is generally known as C.T.S. It was designed for use in positions where ordinary protected cables often give trouble, principally as trailing or portable cables, and has since been found of value in all kinds of dangerous situations. (See also p. 2337.)

The conductors are usually insulated in accordance with the standards of the C.M.A., the whole then being sheathed with the same tough rubber material as is used in the manufacture of cab tyres. The principal characteristics of this rubber are durability, non-corrodibility, and non-absorbence. This type of cable is, therefore, now used in the numerous places where corrosion, moisture, hard wear, climatic or temperature changes are likely to be met with.

An advantage for some classes of work is that the elastic flexibility of the material prevents it from being kinked.

This class of cable is being largely used for general wiring. Being a portable solid system not needing any further protection, it is easily and cheaply run.

The use of C.T.S. without further protection of any kind is authorised by the Wiring Rules of the Institution of Electrical Engineers. In these Rules, C.T.S. is referred to as ' tough rubber compound covering.'

The Macintosh Wiring System.

(The Macintosh Cable Co., Ltd.)

The highly flexible properties, tough nature, and high permanent dielectric strength of this insulating material, known as ' Maconite,' have led to its adoption for nearly all classes of electrical conductors. The fact that twin cables of the now well-known 8 section can be mounted on the surfaces of walls, ceilings, etc., (either with or without the special wood fillet supplied) without being conspicuous, and at low cost, renders it particularly suitable for the wiring of small houses, flats, and working-class dwellings. Many housing schemes have utilised it for this purpose. Its insulation resistance is equal to high quality vulcanised rubber, but in the case of ' Maconite ' it is more constant and is unaffected by prolonged immersion in water or in a saturated solution of caustic soda. Resistance to breakdown pressure is also stated to be very high.

The following are details of tests to which Maconite has been satisfactorily subjected. Except where specifically mentioned, no tests of less duration than some thousands of hours are given :—

Extremes of temperature.—

(1) Freezing Maconite Cable in a block of ice for several days, and testing at 1,000 volts a.c. for 30 minutes. Then thawing out in running water and again testing at 1,000 volts a.c.

(2) Boiling in water and for 3 hours in a weak solution of caustic soda.

(3) Exposure for several months in temperature of 100° F. above boilers and brass furnaces.

In all these cases, not only did the cable withstand the tests, but its flexibility was found to be absolutely unimpaired at the end.

Exposure to Chemical Action.—

(1) Immersion in dilute uric acid.
(2) ,, copper pickling acid.
(3) ,, 50 per cent. solution of sulphuric acid.
(4) ,, 5 per cent. solution of nitric acid.
(5) ,, 50 per cent. solution of hydrochloric acid.
(6) ,, slaked slag water.
(7) ,, two samples of corrosive pit waters.
(8) Immersion in saturated solution of caustic soda.
(9) ,, saturated solution of common soda.
(10) ,, 10 per cent. solution of ammonia.
(11) ,, saturated solution of common salt.
(12) ,, sea-water.

In all cases the cables withstood the tests, the cables carrying direct current at 250 volts, two cables being on test in each solution, and being connected to the positive and negative poles of the system respectively. This was done in order to be certain that the material would withstand osmotic action.

The general results of the tests indicate that cables insulated with ' Maconite ' are particularly suited for installation in chemical works, steelworks, dye works, long railway tunnels, etc., etc., where corrosive fumes or liquids are always present.

The material may prove to be suitable as a sheath for cables in the place of lead alloys or bitumen. It is already being used as a sheath for a surface wiring system which requires no bonding or earthing.

Failures only occur at the points where it is jointed to other apparatus, such as junction boxes, switches, lamp fittings, and distribution boards. *The Macintosh Cable Company* have therefore produced a complete system embodying gas-tight fittings of the above nature, using patented ' Maconite ' glands which will ensure that no destructive gases or elements reach the metal fittings necessary for junction purposes.

A further use for which ' Maconite ' has proved highly efficacious is in the construction of multi-core cables for telephone and signalling purposes : its resilience and flexibility prevent destruction by the mechanical strains to which the cores of such cables are subjected. The same feature is also leading to its adoption for trailing and similar cables for colliery work, etc.

PRIMARY CELLS.

'SIEMENS' DRY CELLS.

These cells (*Siemens Bros. & Co., Ltd.*), originally known as the 'Obach,' have the exciting agent in the form of a damp paste. The following table gives the details of a few of the rectangular sizes. The outputs in ampere-hours are for continuous discharges through an external resistance of 10 ohms, until the P.D. across the terminals of the closed circuit has fallen to 0·75 volt.

Size.	Approximate Overall Dimensions (including terminal).	Approximate Weight.	E.M.F.	Initial Internal Resistance.	Output.
		Lb. Oz.	about	about	Amp. Hours.
M	$4\frac{7}{16}$ ins. × $4\frac{7}{16}$ ins. × $8\frac{1}{4}$ ins. high	10 0	1·5 volt	0·15 ohm.	260
N	$3\frac{5}{16}$ " × $3\frac{5}{16}$ " × $7\frac{1}{4}$ "	5 4	1·5 "	0·15 "	110
O	$2\frac{13}{16}$ " × $2\frac{13}{16}$ " × $6\frac{3}{4}$ "	3 0	1·5 "	0·20 "	40
P	$2\frac{1}{4}$ " × $2\frac{1}{4}$ " × $6\frac{1}{4}$ "	1 14	1·5 "	0·25 "	25

An improved form of high-tension dry battery comprises large cells capable of giving satisfactory service with multi-valve wireless receiving apparatus at a normal anode current not exceeding 10 milliamperes. Three sizes only are standardized, viz., 18 volts, 36 volts, and 72 volts. Spring clip terminals are fitted and tappings provided at suitable intermediate voltages.

SIEMENS INERT CELLS.

These cells, originally known as the 'Dura' cells, have the exciting agent in the form of an inert powder, which by the addition of ordinary clean drinking water becomes a paste, thereby giving a cell all the characteristics of a 'dry' cell, as described above.

Batteries and single cells are made up in this form, and the special utility of the construction is that the cells before being charged keep for an unlimited time in any climate, without deterioration, and may be converted at any time, as required, into a newly-made, so-called, 'dry' cell, with equivalent E.M.F. and output. This form is particularly suitable for use in those countries where it is essential to keep considerable stocks and where deterioration would be serious.

SIEMENS 'SACK' LECLANCHÉ CELLS.

These cells are wet cells using sal-ammoniac as the exciting agent, and are modifications of the porous-pot form, the depolarising material being enclosed in fabric instead of a porous-pot. This enables a lower internal resistance and higher output in ampere-hours to be obtained.

Improved results can also be obtained by using Siemens 'Siebrosal' as the exciting agent in place of sal-ammoniac crystals.

G.E.C. 'EXTRA SEC' DRY CELLS.

The cell only requires to be filled with water, without any exciting element, and the excess of water emptied out. Specially suitable for use in tropical climates as the cell can be stocked for considerable periods without deteriorating, and only becomes active when charged with water.

G.E.C. 'POROUS POT' LECLANCHÉ CELLS.

Specification.—Porous pot of high porosity, thoroughly tested and filled with a mixture of best selected peroxide of manganese and crushed carbon; positive plate of carbon throughout; without lead cap; well-amalgamated, solid drawn zinc rod of 98 per cent. purity; E.M.F., 1·5 volts.

Directions.—Place porous pot and zinc in glass jar and fill two-thirds full with solution of sal ammoniac, 2 ozs. to the pint of water.

G.E.C. 'CARSAK' LECLANCHÉ CELLS.

Specification.—Positive element consists of a porous sack which surrounds the carefully selected granules of carbon and manganese peroxide, which are very tightly packed. The 'pot' is practically unbreakable and its cylindrical form is maintained by a cap and base of hard material. The zinc is a semi-circular plate of ample dimensions, well amalgamated. 'Carsak' cells have a very low resistance, are thoroughly reliable and constant, and have a long life. They are particularly suited for telegraph, telephone, bell and signal circuits and for all positions where a low resistance Leclanché cell is required.

The 'Carsak' cell is designed to withstand severe transit conditions, and is therefore particularly suitable for export.

ACCUMULATORS.

Compiled from information supplied by the Hart Accumulator Co. and the Chloride Electrical Storage Co.

Storage cells should be placed in a well-ventilated room, preferably with louvres at the top to allow of the free escape of the gases evolved during charging; and the room should also be well lighted, both naturally and artificially, provision being always made for a hand inspection lamp to enable cells to be examined individually. The best working temperature is 50° to 80° F. Windows should face north to avoid direct sun rays. The room should not be exposed to undue draughts, as this promotes evaporation of the electrolyte, and it then becomes necessary to add an abnormal amount of water to keep the plates well covered with electrolyte.

Insulation.

Good insulation is essential. The cells should be mounted on insulators unless the boxes, if glass, are provided with feet. Above 100 volts the stands should be mounted on insulators also.

Assembly.

Cells with a capacity of less than 1,000 ampere-hours are assembled in glass boxes. The smaller sizes may be provided with feet or are mounted on separate insulators with lead discs, indiarubber washers or wood strips intervening. The larger sizes are mounted on wooden trays filled with sawdust. Above 1,000 ampere-hours capacity, cells are assembled in lead-lined wooden boxes.

The battery should be mounted on strong wooden racks or stillage protected with acid-proof paint with sufficient space between each cell to allow for insulation and cleaning.

The cells should be placed with the edges of the plates to view (if in glass boxes) and should only be arranged in double rows when they are accessible from each side.

Polarity.

The positive pole is painted red and is that to which the brown plates are connected: the negative pole is painted black and is that to which the grey plates are connected. The positive pole of each cell must be connected to the negative pole of the next cell throughout the battery, so that there will be a disconnected positive terminal at one end and a disconnected negative terminal at the other end of the battery. These are the battery terminals, which are

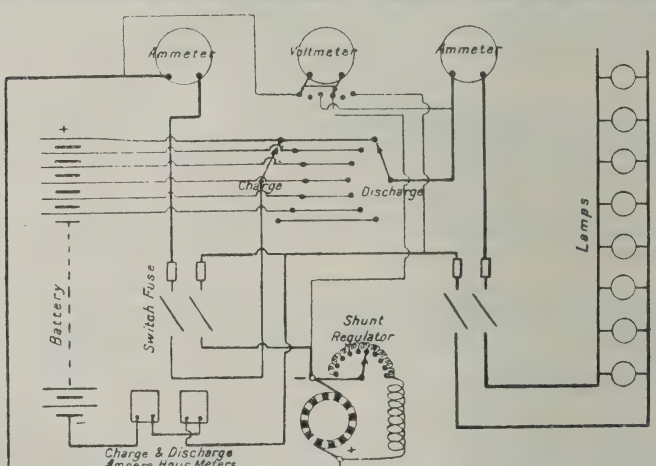

FIG. 17.

connected to the dynamo as indicated in the diagram of connections in fig. 17. Cells should never be connected in parallel so as to form single cells of larger capacity; but if necessary they may be formed into batteries, and the batteries connected in parallel by coupling their ends.

Regulating cells should be at the negative end of the battery.

An automatic switch should be provided in the charging circuit.

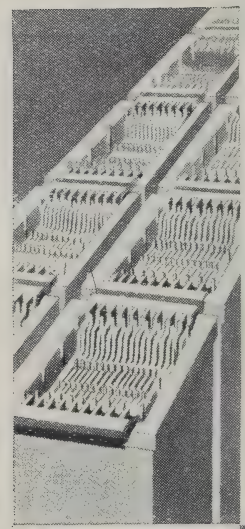
efficiency of the cell



BECAUSE you know the cell's efficiency depends on the chemical re-action inside, you take great care as to the battery-plates. But remember that the electrolyte is an equal co-partner in the action. The world's leading engineers rely on BAA—it is made from fine, natural Brimstone only, and distilled water. And it is most carefully tested.

Dynamo.

The dynamo used for charging should be shunt-wound, and the electromotive force required will be 2·6 volts for each cell in series. Before connecting up the dynamo it should be tested for polarity, which may be done as follows: Place two clean strips of sheet lead in a stone jar filled with dilute acid; separate them about two inches by means of a block of wood; connect one strip to one terminal of the dynamo and the other strip to an incandescent lamp which has its second terminal connected to the second terminal of the dynamo. After the dynamo has been running for a few minutes one of the lead strips will become brown, showing that the dynamo terminal connected to this strip is the positive terminal.

Instruments.

In addition to the voltmeter and to the ammeters in the charging and discharging circuits, it is very desirable to have in circuit a pair of ampere-hour meters, one to record the charge and the other the discharge. These may be connected in series as shown in the diagram of connections, and fitted with pawls which will prevent backward running, so that there will be a continuous record of both charge and discharge.

Water.

The water used for the cells should be distilled, as this avoids any danger of impurities entering the cell.

Acid.

The electrolyte in all storage batteries—lead-acid type—is dilute sulphuric acid with a specific gravity of 1·200/1·215. The method of manufacture is immaterial provided the finished article when diluted does not contain more than 0·001 grammes per 100 c.c. of chlorine or copper, twice that amount of iron, or one-third that amount of arsenic.

On the continent, sulphuric acid prepared by the catalytic process is largely used, but as this acid is usually prepared from iron pyrites the iron contents are higher than that made from natural brimstone. In this country *Messrs. F. W. Berk & Co., Ltd.*, the manufacturers of the well-known B.A.A. Accumulator Acid, prepare it from distilled water and the best brimstone, producing thereby an acid of the highest purity and best quality.

Preparing Electrolyte.

To dilute concentrated sulphuric acid it must be mixed with about 4½ times its volume in a suitable acid-proof vessel. The acid must be added to the water, never the water to the acid on account of the heat generated. Careful stirring is necessary. Correction for temperature must be made when testing the specific gravity to the extent of one point added to the hydrometer reading for every 2·7° F. above 60° F. The mixture must be allowed to cool before using it.

Filling up.

When everything is ready for charging, the acid must be put into the cells to a height of not less than one inch above the plates. Charging must proceed as soon as possible afterwards.

Charging.

Before the battery is switched into circuit with the dynamo care should be taken that the field-magnets are properly excited and the proper E.M.F. generated. The initial charge should be continued for not less than 36–40 hours at the normal charge rate specified by the makers for the battery in use. It has been recommended that the first 12 hours' run be continuous. Some makers, *e.g.*, The Chloride Electrical Storage Company Limited, now supply their batteries in a short first charged condition, which entails only 15 hours' initial charge at a prescribed rate, or alternatively two runs of 8 hours each. During the early portion of the initial charge the specific gravity will drop 20 to 50 points, and the charge cannot be considered complete until the specific gravity has maintained a maximum stationary value for at least two hours in the case of short first charge batteries, or five hours in the case of ordinary batteries. As the plates absorb the acid slowly, the level of the electrolyte will fall at first, and to compensate for this, more acid should be added, but any subsequent evaporation should be made good by the addition of water only.

Discharge.

The permissible rate of discharge depends upon the number of hours for which the discharge is required—the longer the time the smaller the rate. The product of rate into time is, however, not constant, but is greater with low rates of discharge than with high. Thus in the Hart Accumulator, 25-plate Lighting Type, the rates of discharge for 5, 7, and 10 hours are 126, 99, and 75·6 amperes respectively, giving discharge capacities of 630, 693, and 756 ampere-hours. The

discharge rates for different times are always given by the makers, and should never be exceeded, the ampere-hours taken out being recorded on the discharge ampere-hour meter. The accompanying tables have been prepared for users of batteries supplied by The Chloride Electrical Storage Company, Limited, and may be considered applicable to all Planté batteries.

CAPACITIES OF PLANTÉ TYPE STATIONARY BATTERIES AT VARIOUS RATES OF DISCHARGE.

Capacity in Ampere-Hours (expressed as a percentage of the ampere-hours available at the 5-hour rate) When Discharging in

Recharging.

To obtain longest life from a battery it should be recharged whenever the cells are about two-thirds discharged, determined by specific gravity and voltage, also by ampere-hours used (where ampere-hour meters are installed). A battery may be charged at any convenient rate between the conventional 'normal' specified by the maker, and half that value. In any case the charge should be completed at the lower rate. The ampere-hours put in should exceed the number taken out by about 10 per cent. ordinarily, but at least once a fortnight the battery should be brought up to a thorough healthy condition regardless of ampere-hour meter readings—all cells uniform and the extent of gassing, the specific gravity of the acid, the voltage, and the colour of the plates. Records should be kept on suitable forms of the individual voltage and specific gravity of each cell periodically and details of each charge and discharge.

Level of Electrolyte.

The level of the electrolyte must never be allowed to fall to less than half an inch above the top of the plates. Any loss due to evaporation must be made up by adding pure distilled water as above explained. Evaporation will be greatly retarded by the use of glass spray arresters covering the top of the plates or by an anti-spray oil film. Spray arresters must be so placed as to be easily removable for the purpose of examining the cells. Acid should not be added, except under the maker's advice.

Specific Gravity.

The specific gravity of each cell should be taken and recorded at least once a week, and if the consecutive readings so obtained are carefully compared, it is possible at once to detect a backward cell and take steps to remedy what is amiss. The hydrometer should be long enough to float in about two-thirds of the total depth of the electrolyte. The specific gravity varies to some extent with the temperature, and during the summer months will be rather lower than during the winter. The standard is taken at 60 deg. Fahr.; for every 2·7 degrees above this 1 degree of specific gravity may be added; for every 2·7 degrees below 1 degree of specific gravity may be deducted.

Weak Cells.

The indications of weak cells are bad colour of the plates, irregularity of gassing, or failure to gas, and a fall of specific gravity of electrolyte (obtained by the hydrometer), or voltage (obtained

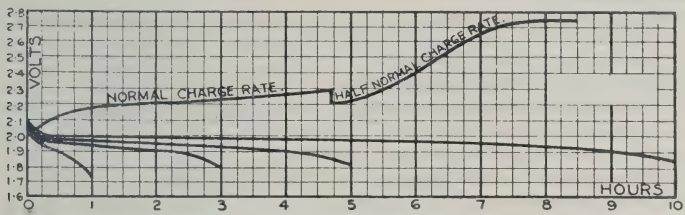

FIG. 18.—Typical Curves of Voltages during charges following 5-hour discharges, and curves for discharges at 1, 3, 5, and 10-hour rates.

by a cell-testing voltmeter) below that of other cells. Weak cells should be inspected for 'short circuits.' These may be caused by the lodgment of material between the plates or by the positive and negative plates touching each other. After removing the short circuit the weak cell should be cut out of circuit for a few discharges and put into circuit again for the following charge. Care must be taken not to allow the negative plates to dry out or heat by exposure to the atmosphere.

Voltage Characteristics.

Fig. 18 indicates the characteristic rise in voltage on charge, and fall in voltage during discharge according to the rate of discharge in amperes. The curves are applicable to any modern Planté battery.

Buckled Plates.

Buckled plates should be removed and straightened by pressing between thick boards. The positive plates are most easily straightened when fully charged, as they are then softer and not so liable to crack. The negative plates should be kept in dilute acid while the positives are being overhauled, as otherwise they may get heated by oxidisation with the air.

Battery Rooms.

SIZE OF BATTERY ROOMS REQUIRED FOR 25, 50, AND 100-VOLT 'HART' BATTERIES.

Capacity in Amp. Hours.	25 Volt.		50 Volt.		100 Volt.	
	Single Tier.	Two Tier.	Single Tier.	Two Tier.	Single Tier.	Two Tier.
	′ ″ ′ ″	′ ″ ′ ″	′ ″ ′ ″	′ ″ ′ ″	′ ″ ′ ″	′ ″ ′ ″
140	6 6×3 9	3 6×4 3	6 9×5 0	7 0×4 3	13 3× 5 0	13 3× 4 3
280	9 3×3 9	5 0×4 3	10 0×5 0	10 0×4 3	12 9× 8 9	9 9× 6 0
420	6 9×5 0	6 9×4 3	13 0×5 0	13 0×4 3	16 6× 8 9	12 6× 6 0
630	9 0×5 0	9 0×4 6	11 6×8 9	9 0×6 6	16 9×12 6	16 9× 6 6
770	10 6×5 0	10 6×4 6	13 3×8 9	10 6×6 6	19 6×12 6	13 3×11 0
1,050	13 3×5 0	13 3×4 6	17 0×8 9	13 3×6 6	25 3×12 6	17 0×11 0

In preparing this Schedule the number of cells is as follows: 25-volt circuit, 13 cells; 50-volt circuit, 27 cells; 100-volt circuit, 54 cells. The height of room in each case should not be less than 8 feet.

Idle Batteries.

When a battery is not required for several weeks it should be thoroughly charged and the plates well covered with electrolyte. The cables should then be disconnected at the ends of each row to avoid any possibility of electrical leakage. Cells will remain in this condition for several months. If a charge can be given once every six or eight weeks it is best to do so; this should be given at 75 per cent. of the normal rate and continued until the full charge is completed, and the plates gas freely. If a battery is to be used at infrequent intervals, it should be given an extended charge once every two weeks.

Brush Gear.—The brush gear is of simple and rigid construction, split horizontally, and is supported by a separate frame. The brush-holders, which are of the direct-acting box type, are bolted to a carrier arm which keeps them in strict alignment, and are easily adjustable. The insulation is micanite throughout. When the brush rocker has been once set in the working position, it remains fixed for all loads up to the maximum permissible overload.

Care of Direct-Current Generators.

Steadiness.—It is important that the machine be firmly fixed to a good foundation. A machine may be run successfully on an upper floor, if supported on solid joists either of timber or iron. The machine will spark and the brushes and commutators wear unduly if there is vibration.

Commutator and Brushes.—These will always repay careful attention. If the brushes are left to wear unequally, and the commutator is not cleaned, the machine will soon commence to spark badly, and both brushes and commutator will wear rapidly. If, however, these parts are attended to in accordance with the following instructions, the wear and tear will be very small.

Adjustment of Brushes.—The brushes must be set truly on a diameter so that the point of one is diametrically opposite the point of the other. Gauze and metal brushes as they wear must be advanced to maintain the same distance, and consequently to bear the same angle on the surface of the commutator. They must be advanced frequently, even though the wear may be very small, otherwise the brush will not bed properly on the surfaces of the commutator when advanced. Each brush must always bed equally well at the point, or toe, and at the heel. If brushes are allowed to wear too much before advancing (but this should not be), they must be taken out and filed to fit truly. In filing a brush, clamp it firmly, and file by taking long strokes with a file always in one direction. If it is the toe that requires filing, after filing to fit take off the sharp edge, leaving the toe always $\frac{1}{16}$ inch thick. One brush often wears faster than its fellow (or fellows), and must be set up accordingly. Moreover, sometimes a whole set of brushes on one side of the commutator will wear faster than those on the other side, and this must be allowed for, or the brushes will cease to be on a diameter, and sparking and flatting of the commutator may result.

Carbon Brushes are usually set radially to the commutator and therefore require no diagonal adjustment. They require periodical inspection, adjustment and cleaning, as the toes or heels usually burn away and a new surface giving the full contact area of the brush must be again obtained. The best results with carbon brushes of ample contact area and good designs fitted with flexible tails are obtained by keeping the brushes absolutely clean and free from dust and the commutator true and polished with polishing paste.

Flats.—The most common source of the formation of little 'flats' upon the surface of the commutator is the brushes being out of adjustment. Another cause is vibration of the brushes, due primarily to vibration of the machine, owing to improper foundations or a badly-jointed belt. Flats are sometimes caused by the pressure of the brushes being reduced to too low a limit.

Pressure.—It is well to have the pressure as light as possible, so long as no sparking and no vibration takes place at the brushes.

Oiling and Cleaning the Commutator.—In the case of metal brushes use a little good mineral oil or vaseline, applied with a piece of rag. Do not on any account apply oil with a feeder, or on a piece of waste. A commutator well looked after will acquire in time a dark-coloured, smooth polish. When this takes place run a piece of No. 0 0 emery cloth on the commutator occasionally before starting to work. In flour-mills and dusty places it is necessary to clean the commutator with a little benzoline every day before starting, or, if run continuously, during the run, taking care not to drench the commutator; also to apply emery cloth about once a week as just directed.

Belting.—Where practicable, the drive should be arranged so that the under side of the belt is the tight or driving side. A flexible belt should always be used. Leather-linked belting, arched on the face next the pulleys and flat on the outside, is very suitable. Such a belt should *not* be taken off after working. Single belting with double edges makes a good cheap belt for ordinary use, and may be jointed with a butt joint, secured by belt fasteners. If an ordinary single belt is used, it should be straight and of good quality. It should be jointed with a laced butt joint, until it has stretched, and then a proper spliced and cemented joint made. A dynamo belt must run evenly. A belt which lashes either up and down, or from side to side, should not be tolerated.

Oiling the Bearings.—Adjust the sight-feed lubricator to give about 3 to 10 drops per minute. The amount required varies with the quality of the oil used and the load on the machine. If the machine has been standing, give it a few extra drops before starting. It is well to use an oil feeder made entirely of copper. Keep the machine clean—free from copper dust and waste oil.

Should the commutator wear out of truth or become very uneven (scored), take out the armature and turn up the commutator in a lathe, being careful to use a fine-pointed tool and not to take heavy cuts; afterwards polish with emery cloth. If the commutator should be only scored, it may be dressed in the machine with coarse, and afterwards fine, emery cloth, finishing with No. 0. Slight 'ringing' does not matter.

ALTERNATING-CURRENT GENERATORS.

While many D.C. machines nowadays are driven by steam turbines through gearing, a similar arrangement is adopted with alternators in spite of the fact that it is not very difficult, either from an electrical or a mechanical point of view, to construct medium-size high-speed turbo-alternator sets. The geared alternator is adopted from motives of economy, as the steam turbine can then be designed for speeds of over 3,000 r.p.m.

The Mather & Platt Geared Alternator.

(Mather & Platt, Ltd.)

This machine is constructed on the following lines:—

The stator consists of a cylindrical core, built up of thin steel laminations of the highest electrical and magnetic quality, insulated from each other, and firmly clamped together in a rigid cast-iron frame.

The windings are fully insulated before insertion in the slots, the latter being usually of the open type. High-tension coils are insulated with moulded mica, and low-tension coils with standard mica sheet mechanically protected by leatheroid. In all cases the insulation forms a complete sealed tube completely enclosing the straight part of each coil, and extending for a considerable distance beyond the stator core at each end. The coils are held in position by hard wood wedges.

In normal machines, the poles are completely laminated, the core and tip being stamped in one piece. The built-up poles are usually bolted to the rim of a cast-steel hub. In special cases, however, the above construction may be modified.

For small machines with few poles, the field coils consist of cotton-covered wire or strip. Each coil is provided with terminals which relieve the last turns of wire from all stress. The coils are thoroughly dried and impregnated in vacuo with an oil- and moisture-resisting varnish. For larger machines copper strip bend on edge is used in all cases where it is practicable.

The shaft is of mild steel of ample size and stiffness. Each bearing is of the pedestal type, with a cast-iron bush of large diameter and length, lined with white metal, and lubricated automatically by two oil rings running in an oil well of large capacity. The oil channels and escape grooves are carefully designed to eliminate oil-flinging and creeping, and the overflow is so arranged that frothing or churning of oil in the oil well does not cause any drip. The pedestal and bearing bush are split horizontally.

The slip rings are of bronze, insulated entirely by mica. The brush-holders are of the direct-acting box type, and the whole brush gear is simple and strong.

ALTERNATING-CURRENT TURBO-GENERATORS.

The G.E.C. Turbo-Alternator

(with combined axial and tangential ventilation).

(The General Electric Co., Ltd.)

The following is the specification of a G.E.C. turbo-alternator of the standard type:—

The alternator is of the enclosed type, with drum-type rotor and forced ventilation. Shaft and exciter are included, but no bearings or coupling, excepting where this is specifically stated.

Stator Frame.—The stator frame is a massive casting of box section, accurately bored to accommodate and clamp tightly the laminations. Stout end-plates are used for this purpose, and are secured in such a way that no bolts pass through the stampings, thereby avoiding a considerable amount of iron loss. All longitudinal ribs are fitted with dovetailed keys to which the stampings are secured. The casing rests on two feet, which are connected to the main body by strong ribs to avoid flexure or vibration.

Laminations.—The laminations are accurate stampings of special low-loss iron, punched out of large plates with carefully ground tools to avoid burrs. They are re-annealed after punching, and insulated as a last operation. No filing or scraping takes place after the laminations are assembled, as this causes much higher iron losses due to eddies than in ordinary machines For the same reason, the insulation between plates is increased by sheets of strong paper placed at suitable intervals.

Stator Winding.—The stator winding consists of a lap winding of the diamond coil type.

The coils are completely insulated before insertion in the slots, which are of the open type. The insulation of the coils is entirely class ' B ' insulation and consists of mica and micanite.

The insu'ation of the slot portion consists of a micanite tube carefully moulded on to the coil by a special process, which eliminates the possibility of air spaces. The end turns are insulated by a suitable number of layers of mica silk tape wrapped round the coil, and the coil is finally finished off with a layer of protective tape.

Clamping of Stator Windings.—The end windings are suitably braced, which prevents any possible movement of the coil under the severe stresses which accrue should a sudden short circuit take place.

Ventilation of Stator.—Fans are arranged at both ends of the rotor, to draw air through channels in the end shields from ducts in the foundations and force it into the space enclosed by the guards of the stator winding. From there, after cooling the overhanging parts of the stator coils, the air is pressed into pockets in the stator casing, and through the vent ducts of the stator core. It enters these vent ducts on the outer periphery of the core, and is guided by suitably shaped spacing pieces first inwards to the teeth and stator coils and then outwards to the outer periphery. The air escapes from the ducts through the stator casing to the outlet opening, a funnel-shaped orifice, through which the cooling air finally leaves the machine. This orifice can be arranged either at the top or below the machine, according to local requirements. The employment of an air-cooler is recommended, but a decision as to the type can only be arrived at in each particular case with a knowledge of the local conditions.

Rotor Winding.—The winding consists of coils which are completely shaped before they are embedded in the slots. Strong and ample insulation is provided between the winding and the rotor, as well as between the conductors themselves, particular care being taken to avoid crushing action due to centrifugal force. The insulation used is practically incombustible.

Clamping of Rotor.—The rotor windings are held in the slots by metal wedges. The overhanging end-connections are enclosed by steel shrouds of ample strength to withstand with safety the centrifugal stresses at maximum speed. These are put on with a moderate shrinkage. The shrouds are located at one end on a spigot provided in the core, at the other end on strong steel end plates carried from the shaft. Balancing grooves are provided at both ends of the rotor. The windings are entirely boxed in and protected from injury.

Ventilation of Rotor.—The cooling air enters the rotor at both ends through channels underneath the stator fans and passes under the rotor end winding into axial ducts arranged below the rotor coils. It escapes from these ducts through radial vent spaces, provided at intervals in the rotor core, into the air gap of the alternator, and leaves the machines through the stator core and casing.

Slip Rings.—The current is supplied to the winding through two steel slip rings shrunk on to an iron sleeve, and insulated therefrom by a moulded-on mica bush. Any danger of distortion or of getting out of truth of the rings is thereby avoided. Particular attention is paid to the leads connecting the rings to the windings. They are sunk into a groove in the shaft and protected by a key-shaped cover.

Terminals.—The terminals are usually arranged at the bottom of the shell, the cables being brought up to them from the basement. They are thus in a naturally protected position without necessitating unsightly boxes in the engine-room. The neutral point of each phase is brought out separately.

Rotor Construction.—The rotor is of the drum type, the winding being distributed in slots all round the periphery. The rotor body and shaft are one solid forging. This design has been adopted because a solid forging gives the strongest possible mechanical construction. The slots are milled out of the solid.

Journals.—The journals are of ample dimensions to run without overheating. They are finished off after the whole of the rotor is completed to ensure a true surface. Ample oil flirts are left at both sides, working in rings supplied with the bearings by the makers of the turbine.

Exciter.—The exciter is carried from the bearings at the slip-ring end. It is specially built for high speeds, and is usually compound wound.

Tests.—Numerous tests are carried out during the process of construction to see that the materials are satisfactory at all stages. Amongst these tests are the following :—

(*a*) Breakdown test for tubes after inserting them in the core.

(*b*) Test between adjacent conductors in a slot, not less than ten times the working voltage between conductors.

(*c*) Between finished coils and between any coil and earth, twice working voltage plus 1,000 volts, but in any case not less than 2,000 volts.

(*d*) Rotor winding tested to earth with 2,500 volts when all connections are made to the slip-rings and after balancing test.

(*e*) Static balancing on flat rails.

(*f*) Dynamic balancing at full-speed.

(*g*) Synchronous run at full speed to measure iron, windage and excitation losses. During this test the open-circuit curve and the short-circuit curve are obtained.

(*h*) Overspeed test at 15 per cent. above running speed.

(*i*) Oscillograph of wave-form on open circuit.

The G.E.C. Fraser & Chalmers Turbo-Alternator Set.

(*The General Electric Co., Ltd.*)

In fig. 19 is shown a close-up view from the alternator end of a G.E.C. Fraser & Chalmers Turbo-Alternator, being one of five 22,500 kVA. alternators installed at Nechells Power Station,

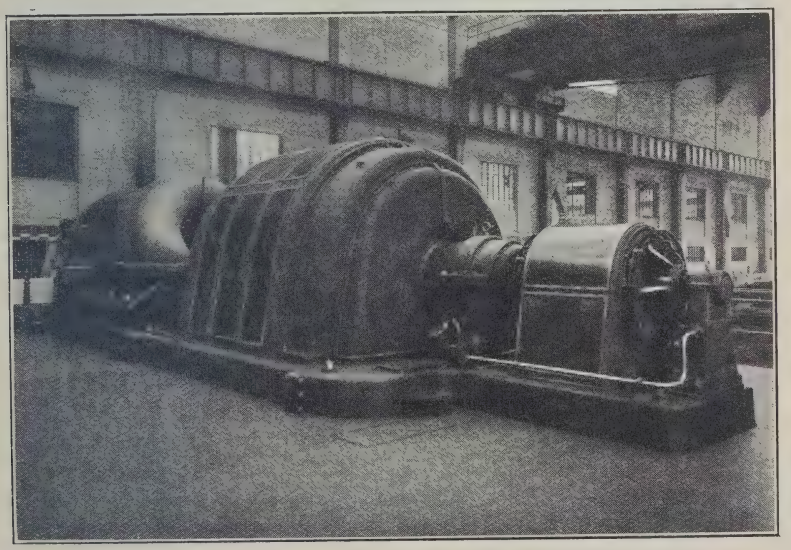

Fig. 19.—Fraser and Chalmers Turbo-Alternator Set.

Birmingham. Each set is capable of a maximum continuous output of 22,500 kVA. when running at a speed of 1,500 r.p.m. and with power factor ·66.

The G.E.C. Fraser & Chalmers Geared Turbo-Alternator Set.

Fig. 20 shows two 1,250 kVA. G.E.C. Fraser & Chalmers geared Turbo-Alternators. The turbines are of the back pressure type running at 6,000 r.p.m., and drive through gearing, two alternators, which run at 1,500 r.p.m., giving a supply at 400 volts, 3 phase, 50 cycles.

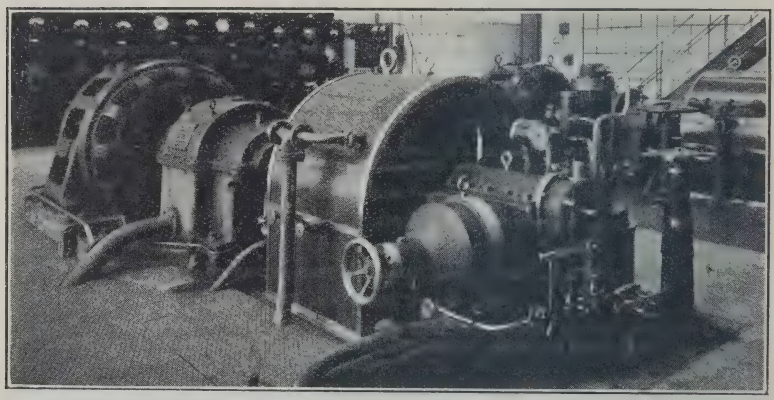

Fig. 20.—Fraser and Chalmers Geared Turbo-Alternators.

The Tirrill Automatic Voltage Regulator.

(The British Thomson-Houston Co. Ltd.)

Fluctuating loads, and the time-lag inseparable from manual control of generator voltage, may cause serious variation in a generating station voltage. This regulator (fig. 21) automatically

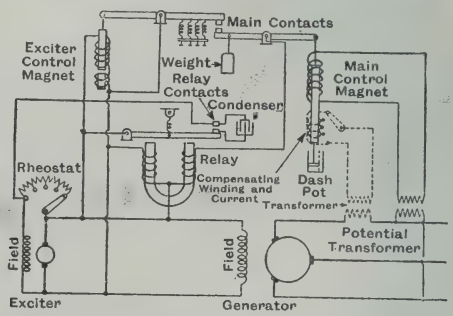

Fig. 21.—Elementary Diagram of Type T A Regulator, connected to Three-Phase Alternator, showing (in dotted lines) Compensating Coil and Current Transformer.

and instantaneously regulates the voltage of either alternating- or direct-current generators. In fig. 21, the rheostat in the field circuit of the exciter results in the alternator generating only about 60 per cent. of its normal P.D.; when it is short-circuited, the P.D. of the alternator greatly exceeds the normal value. The action of the Tirrill regulator is to vary the duration of the periods

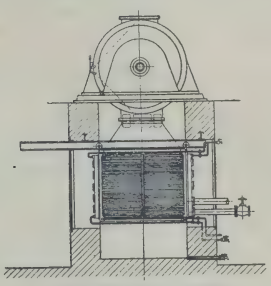
of open- and of short-circuit of this exciter field resistance. In the diagram, the two main or floating contacts are fixed respectively to two pivoted levers. The top contact lever tends to be kept depressed by springs, which are opposed by the downward pull of the exciter control magnet. The bottom contact lever has a counterweight balancing a core which is acted upon by the main control magnet energised from the alternator terminals. The pivoted armature of the relay carries one of the rheostat short-circuiting contacts which the spring tends to keep closed. The middle point of the relay winding is connected to an exciter terminal, one end to the other exciter terminal permanently, and the other end intermittently through the main contacts. When these contacts are closed there is no magnetic effect in the relay, because the two portions of the winding neutralise each other and the exciter rheostat remains short-circuited. The rising generator voltage then increases the current in the main control magnet sufficiently for the core to rise and open the main contacts. The relay magnet now becomes strongly excited, and, its armature being attracted, opens the short-circuiting contacts across the exciter field rheostat terminals, the condenser reducing sparking. The regulator is thus in a constant state of vibration and responds instantaneously to changes in alternator P.D. The function of the compensating winding on the control magnet (energised through a current transformer) is to eliminate circulating currents between alternators in parallel by reducing the excitation of an over-excited generator and *vice versâ*.

Air Coolers.

The 'Heenan' Patent Closed Circuit Air Cooler.

(Heenan & Froude, Ltd.)

This cooler, figs. 22-24, which is designed for the ventilation of turbo-alternators, comprises a tubular air cooler built generally on the lines of a surface condenser arranged in the alternator foundations and coupled up to the bottom discharge of the alternator by suitable ducting.



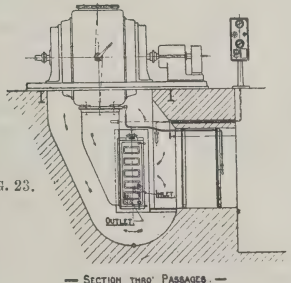


Fig. 23.

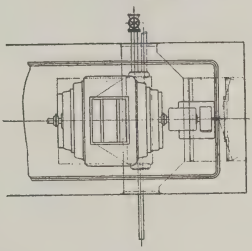

Figs. 22 & 23.—Arrangement of 'Heenan' Closed Circuit Air Cooler.

The arrows show the direction of the air.

Fig. 24.

After passing through the cooler the air returns to the alternator *via* the end shield, the fans circulating the air being carried on the rotor.

With this system the same air is continually recirculated through the windings of the alternator, so that the only dirt that can be deposited is that contained in the initial volume of air, thus the necessity for air filtration is obviated.

With an unfailing and clean supply of water the circuit can always remain a closed one, but under actual working conditions it has been found necessary to provide for cooling in the event of a failure of the water supply or other eventuality, and the arrangement, therefore, embodies a system of dampers and emergency air doors which cut out the air cooler and permit external air to enter the foundations, the hot air in this case being discharged direct to atmosphere.

Dampers are fitted to the top and bottom discharges of the alternator, which are interconnected and operated by one lever, and arranged so that if one set is closed the other set is open. Connected to the same lever is the trip gear for the emergency air doors, which are balanced and which open automatically, due to the difference in pressure, immediately the catch is released. As soon as the trouble has been diagnosed and rectified the emergency doors are closed and the alternator dampers changed over for closed circuit running.

A thermostatic alarm device is fitted in conjunction with the system, which gives visible and audible warning to the attendant should the temperature of the air leaving the cooler reach a predetermined figure. This alarm device consists of a dial type thermometer with a klaxon horn, red lamp and relay, arranged on a panel either for wall or floor fixing. The thermometer is connected to a bulb in the foundations, and as soon as the dial hand reaches a certain point the relay brings into operation the klaxon horn and lights up the red lamp, so warning the attendant that the air temperature is rising.

In regard to the construction of the coolers, this follows condenser practice in so far as the coolers consist of a nest of tubes held between tube plates, the joints being formed by screwed ferrules and packing. The water headers fitted with division plates and branches for inlet and outlet water connections are also in line with condenser practice, but the tubes in these coolers are gilled at close pitch, the gills being soldered to the tubes in one operation for each length of tube, this construction giving the highest heat transference efficiency, which has, of course, been ascertained chiefly by experimental work.

Another departure from an ordinary condenser is the addition of secondary tube plates in front of the main tube plates, so that a dead air chamber is formed at either end of the cooler into which any leakage from the main tube plates would drain instead of being carried over with the air into the windings. Rubber bushes are used in these secondary tube plates to form an air- and water-tight joint with the tubes.

Air cocks are fitted to the top of the water headers and drain pipes to the dead air chambers. The tubes are of brass (Admiralty mixture), solid drawn and tested to an internal pressure of 2 tons per sq. in.

The tube plates are also brass, of ample thickness to allow for a suitable stuffing box and screwed gland. The water headers are of cast iron of ample thickness to withstand any pressure they are likely to be subjected to, and are fitted with hinged doors, so that the tubes and tube plates can be cleaned from time to time without breaking the joints of the main header or pipes.

The gills are of thin copper, and both gills and tubes are tinned in the process of soldering the gills to the tubes, so that the danger of corrosion is well catered for.

Figs. 22-24 show the arrangement of a cooler in the foundation, from which it will be noted that the cooler itself is carried on rollers, which bear on the flanges of a steel joist, the latter being extended and supported outside the foundations, so that the complete cooler unit can be removed for overhaul or cleaning when necessary, with a minimum amount of trouble.

Inspection doors are provided on either side of the foundations to permit the removal of the cooler and also to give access to the foundations.

Air Filters.

The 'Heenan' Patent Air Filter.

(Heenan & Froude, Ltd.)

The overload capacity of turbo-alternators and generators is dependent to a considerable extent upon the supply of suitable volumes of cool air for carrying away the heat generated by electrical loss. The usual method is to mount fans on the rotor shaft, arranged to extract air through a supply system in which a combined air filter and cooler is inserted.

The 'Heenan' Patent Air Filter receives ordinary unfiltered air from the neighbourhood of the generating station, and brings it into very thorough and intimate contact with wet scrubbing surfaces, which are kept thoroughly wetted by water issuing from jets. After cleansing the scrubbing surfaces the water gravitates to a tank, from which it passes through strainers to a centrifugal circulating pump and thence to the distributing jets. The atomisation of water, forming part of certain air-filtering systems, is entirely avoided. The air leaves the filter in an entirely natural condition, containing no trace of loose moisture.

NEW TECHNICAL BOOKS

The Strength of Shafts in Vibration

By Captain J. MORRIS, B.A., A.F.R.Ae.S. (late R.A.F.). Formerly Scholar of Corpus Christi College, Cambridge. 200 pp., Illustrated. Crown 4to, cloth ... ... *Net* 30s.

An original work on a subject of outstanding importance to engineers and students. The results of rigorous applied mathematics reduced to relative simplicity by a suitable choice of notation and by the methods of attack adopted. The work constitutes an extensive monograph on resonant vibration in shafts, much of which is now published for the first time.

Railway and Seaport Freight Movement

Comprising Modern British and American Practice. By GEORGE BULKELEY, A.M.I.Mech.E.; Port Manager, Mombasa and Kenya Coast; formerly on Personal Staff of the General Manager, Great Western Railway, England; Author of "Mechanical Appliances for Handling Railway Traffic." With an Introduction by His Excellency Sir EDWARD GRIGG, K.C.M.G., K.C.V.O., D.S.O., M.C., Governor of Kenya and High Commissioner for Transport in Kenya and Uganda. Profusely Illustrated with Photographs and Diagrams. 240 pp. Royal 8vo, cloth ... ... *Net* 28s.

Design of Merchant Ships and Cost Estimating

A Treatise on Ship Design and Cost Estimating, giving up-to-date methods of arriving at correct proportions, form and power to attain minimum Capital Cost with maximum service efficiency. The work is intended for the use of Naval Architects, Marine Surveyors and Consulting Engineers, Ship Draughtsmen, Students and all who are interested in the advancement of Shipbuilding and the Mercantile Marine. By ALEXANDER KARI, M.Sc. (Dunelm), A.M.I.N.A., Associate Member of N.E.C. Institution of Engineers and Shipbuilders. Third Edition. Revised. 320 pp. 112 Illustrations. 104 Tables. Also Diagrams and Charts. Royal 8vo, cloth ... ... *Net* 36s.

Naval Architect's and Shipbuilder's Pocket-Book

Of Formulæ, Rules, and Tables, and Marine Engineer's and Surveyor's Handy Book of Reference. By CLEMENT MACKROW, M.I.N.A. Thirteenth Edition, Revised, by LLOYD WOOLLARD, M.I.N.A., Royal Corps of Naval Constructors. 744 pages. Diagrams. Fcap. 8vo, limp ... ... *Net* 21s.

Modern Bridge Construction

By F. JOHNSTONE TAYLOR. Author of "Water Power Practice," "River Engineering," etc. 232 pp., with 118 Illustrations. Demy 8vo ... ... *Net* 15s.

CROSBY LOCKWOOD & SON

Stationers' Hall Court, London, E.C. 4.

F. 2269

The filtering efficiency of this apparatus is extremely high, both heavy and fine dust being eliminated. The cooling effect in hot summer weather in temperate climates is often as high as 20° or 30° F. In tropical climates the latter figure is sometimes exceeded. The consequent reduction in air temperature is of great value in permitting the generation plant to run on heavy overloads without overheating.

Visco Air Filter.

(The Visco Engineering Co., Ltd.)

The Visco Air Filter (devised in 1916) is used in conjunction with turbo alternators, pipe ventilated motors, and general ventilating plants. It works on the principle that the air volume is divided into a large number of thin streams which are passed through a layer of specially prepared filter bodies, the surfaces placed irregularly to each other, so that the direction of the air flow is changed suddenly and a great number of times. The filter bodies are thin copper-plated steel rings $\frac{7}{16}$ in. diameter and $\frac{7}{10}$ in. long, coated with a thin film of viscinol, which is a specially prepared blend of highly viscous mineral oils. When the direction of the air flow is changed, the dust particles continue in the original direction and are thrown against and retained by the viscinol-coated surfaces.

The filter is standardised in units 20 by 20 ins. square and 3½ ins. deep, consisting of frame and cell, which latter is simply hooked on the frame. The capacity per unit is 600 cu. ft. per minute. Pressure loss is practically steady at ⅜ in. water gauge. Average consumption of oil, 1 gallon per unit per annum. Cleaning is done by rinsing in hot soda water on the average every eight weeks, depending on the original dust content and length of daily run. There are practically no other running costs.

The filter units are assembled in a convenient shape to make up any capacity, and are preferably built into the alternator foundations (thus taking up no valuable space) or as self-contained units in any position.

The *advantages* claimed are: No moving or wearing parts, all metal, fireproof, no attention, foolproof, small space.

The Ventex Air Filter.

(Ozonair, Ltd., 96, Victoria Street, London, S.W. 1.)

The latest variety of the dry or viscous type of filter is known as the 'Ventex.' It consists of a large number of specially corrugated plates spaced uniformly in a frame or holder. Owing to their form, the plates expose a large surface to the air, which in its passage between them is buffeted from side to side, thus bringing any suspended particles into contact with the viscous surfaces. The cleaning efficiency is claimed to be almost 100 per cent., whilst the resistance set up by the filter at standard air velocity is only ¼-in. water gauge. Trials made with the Ventex Filter at 50 per cent. above the normal working capacity showed that it is absolutely silent. All the parts are rigidly fixed and the coating fluid cannot flow, so that there is no danger of the filter becoming dry even at the highest velocities.

Portable Electric Blower.

(The Consolidated Pneumatic Tool Co., Ltd.)

This blower, fig. 25, is largely used for keeping the windings of motors and dynamos free from dust. Weighing, complete ,about 15 lbs., and suitable for use on either a direct or alternating

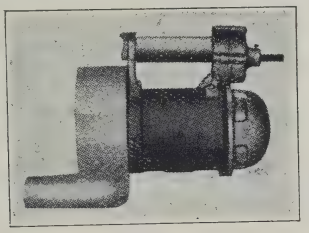

Fig. 25.

current circuit, it will maintain a steady air blast through a 1¼-in. orifice, with a pressure of about 12 ins. of water. It is very convenient to handle, and can be attached to any ordinary lamp socket.

CONVERTERS.

SYNCHRONOUS (OR ROTARY) CONVERTERS.

The G.E.C. Synchronous Converter.

(The General Electric Co., Ltd.)

The following is a specification of a Synchronous Converter of standard type :—

Frame.—The frame is constructed of cast iron or steel of high magnetic permeability. It is split horizontally and bolted together by strong steel bolts. The construction permits the top half to be readily removed for inspection or repair.

Main Pole-Pieces.—The main pole-pieces, which are bolted to the frame from the outside, are built up of laminations in order to reduce eddy-current losses in the pole faces to a minimum. The design is such as to permit the removal of a field coil without disturbing the armature or yoke. In exceptional cases cast steel poles with laminated shoes may be employed.

Armature.—The armature is built up of best quality stampings of high permeability and low iron loss.

Except in very small sizes they are mounted on a cast iron spider, and held tightly in position by heavy end-plates. The laminations are accurately punched before assembling, and are covered with a special insulating compound, which is effective in reducing eddy-currents to a minimum.

The core is held together between the end-plates by means of bolts, which do not pass through the active portion of the core. Ventilating ducts, adequate in number and ample in dimensions, are provided at frequent intervals. Similar ducts are included at the two ends between the core and end-plates.

The general construction of the armature is such as to afford a current of air to the field coils for ventilation and cooling.

The armature is composed of former wound coils, taped, varnished, and baked before assembly. The slots are lined with several layers of non-hygroscopic insulating material. Special care is taken to make the leakage surfaces as large as possible. The top of the slot is closed by an impregnated wooden wedge driven in tightly. There are no binding bands on the armature core itself, that part of the winding being retained in position by the wooden wedges.

The end windings are so shaped that the surface exposed for cooling is as large as possible. After winding, a black finishing varnish is sprayed by compressed air on to the armature until it is completely coated. A large number of equalising connections is provided to ensure that out-of-balance currents, if any, shall not pass through the brushes.

Prior to assembling in the frame the armature is balanced statically, and the final balancing is obtained dynamically.

Commutator.—The commutator is built up of hard-drawn copper segments, insulated by best mica insulation, and held tightly between two V-shaped clamping rings in such manner that the inevitable expansion of the copper and iron, due to temperature rise, may take place without in any way affecting the commutator surface. During its construction the commutator is subjected to several baking processes, with the result that there can be no possibility of moisture remaining in the mica insulation, and when completed, the whole commutator gives a true ring, which indicates that the entire mass has been formed into one rigid body. In addition, the construction is such that ' breathing ' is reduced to a minimum, and the possibility of moisture permeating the insulation is eliminated. A considerable distance to the iron parts is allowed at the front and back of the commutator in order to secure a high insulation resistance to earth, and to prevent any leakage to the iron. The radial depth of the segments is ample for the size of the commutator, and varies somewhat with the size of the machines. Before leaving the works, the mica between the segments is grooved to a suitable depth to promote good commutation. To assist in cooling, the commutator lugs which connect the segments to the armature windings are given a considerable width, and thus provide a large cooling surface.

The shunt field coils are wound to leave a clearance between the inside of the coils and the poles. Sheets of a material with high insulating properties are fixed on the inner sides of the coils and packing blocks are secured in such a manner as to maintain an air passage between the coils and the poles. It is thus ensured that the inner surfaces of the coils are efficiently cooled. Double cotton-covered wire is used, and the coils after being wound are put into a heated impregnating chamber where they are dried for several hours under vacuum, the vacuum pump drawing off all moisture. After removal from this chamber they are flooded in a duplicate chamber (while still under vacuum) with a heavy pressure at the same temperature, the insulating compound being forced right through the layers of the coils.

Series coils are wound with bare copper strip and painted with a finishing varnish. Ample leakage surfaces to the frame are provided.

The connections between the coils on adjacent poles, both for shunt and series windings, are of great mechanical strength.

Commutating Poles.—G.E.C. Rotary Converters are fitted with commutating poles of a design which permits sparkless collection of current at all loads with fixed brush position. The face of the pole is specially shaped to give an even commutating flux. For traction rotaries, and others designed for heavy overloads, the poles are made with specially high reluctance to ensure stability at all times.

The coils are wound with bare copper strip and painted with a finishing varnish. The micanite spools are moulded direct on the poles and ample leakage surfaces are provided.

Damping Winding.—A substantial damping winding is fitted to the field poles. This is instrumental in strongly opposing any tendency to hunt, whether that tendency may arise from changes in load or from any low-frequency oscillations originating in the generating plant. It consists of a pair of heavy copper rings bolted together by copper bolts between the poles and connected up by drawn copper rods passing through the pole faces and fixed at each end to the rings. In order that any pole winding may be removed, the rings are divided up between the poles and jointed in a manner which permits the joint to be readily unmade for the removal of the pole or winding, and at the same time in no way impairs the mechanical strength or the electrical conductivity of the rings. A damping winding of high conductivity and great rigidity is thus obtained which completely damps out all oscillations.

The damping winding is also necessary for improving the starting characteristics of the converter when started from the alterating current side, from transformer tappings.

Booster.—The booster, if provided, takes the form of an alternating current generator, with a stationary field. The booster armature is mounted on the main shaft side by side with the armature of the rotary converter, and is constructed on the same principle as the armature of the rotary. The current passes from the converter slip-rings through the booster armature to the armature of the rotary. The booster field-frame is split horizontally into two parts, and mounted on the bedplate by the side of the main frame. The booster field may be excited either by shunt or series windings, or both.

Six-phase and Four-phase Connections.—Rotary converters intended to work on a three-phase supply are usually wound as six-phase machines, drawing a six-phase supply from three-phase transformers in order to take advantage of the greater output and more even heating of a six-phase armature as compared with a three-phase. Similarly, converters for operating on a two-phase supply are wound either four-phase or six-phase, the latter being made possible by using a double Scott connected transformer.

D.C. Brush Gear.—The direct current brush holders are fixed to a strong cast iron arm projecting radially inwards from the brush rocker. The rocker is carried in a spigot in the yoke and can be turned by means of a screw adjusting gear. The rocker is split across the horizontal diameter so that the halves can be readily removed for inspection or repair. The copper rings connecting the brush sets of the same polarity are bolted direct on to the cast iron arms, the surface of the joint being copper plated to ensure a good contact.

Provision is made for separating the halves of the rings should it be desired to remove one-half of the brush rocker for any reason.

Each carbon brush is contained in a separate box-type holder to avoid rubbing, and a spiral spring exerts pressure on the brush. The pressure on the brush is adjustable by means of a steel lever which engages in one of a large number of slots in a quadrant.

A.C. Brush Gear.—The alternating current brush holders are mounted on semi-circular arms, which are carried on heavy insulated spindles projecting from the pedestal bearing on the slip-ring end of the rotary converter. Each brush is contained in a separate box-type holder, and a helical spring exerts radial pressure on the brush.

The pressure on the brush is maintained by means of a lever, terminating in a special pawl which wedges against corrugations on the inside of a brass tube. The pressure can be easily adjusted by slightly canting the lever, moving it up or down the brass tube and releasing it, when the pawl will automatically engage in other corrugations.

Each brush and brush holder can be easily adjusted independently of the rest of the brush gear for pressure and wear on the slip rings.

Terminals for the incoming cables are provided and fixed directly on to the arms.

Slip-rings.—The slip-rings are of phosphor bronze, and so designed as to ensure efficient cooling. The rings are given a large radial wearing depth.

A cast-iron sleeve, which is securely keyed to the shaft, forms the base for the slip-ring structure This sleeve is insulated throughout its length with compressed mica ground to shape, the slip-rings being shrunk on to this.

The connections from the armature to the slip-rings consist of solid copper bars strongly bolted into the slip-rings at one end and supported at the other by a steel ring shrunk on to the sleeve, similarly to the slip-rings. These connecting bars are covered with insulating materials, and are efficiently protected from breakdown to the other slip-rings through which they have to pass. Ample clearances are provided for cleaning.

Wherever possible, each tapping of the armature winding is brought to the rings separately in order to avoid unbalanced current. Thus the slip-rings themselves act as balancing rings.

Shaft.—The shaft is of such strength that it will carry the armature without undue flexure or vibration, and is supported by two main bearings. The tensile strength of the material is 35 tons per sq. in.

Bearings.—The bearings are either of the cylindrical or of the roller type, the former being self-lubricated by means of rings which dip into oil chambers of large dimensions. The bushes are of cast iron, lined with best quality white metal, and are split horizontally. A glass level gauge, with draw-off tap, is fitted to each bearing. The general design of the bearing is such as to preclude any oil flinging.

Roller bearings are used mainly to reduce the torque required during starting. They consist of large roller bearings of the best possible workmanship. They are supported by pedestals, and are arranged to allow the necessary axial play for expansion of the shaft. They are lubricated by grease charged through a suitable nipple.

Bedplate.—A strong bedplate of box section is provided, having heavy ribs connecting the sides at various points.

Its general construction is substantial, and ensures complete freedom from vibration.

The bedplate is grouted solid into the foundation blocks without any bolts.

Speed-Limiting Device.—All large rotary converters (and small ones, if desired) are equipped with a speed-limiting device, which will shut down the machine if by any chance the normal speed should be exceeded by a predetermined amount. This device works on the centrifugal principle. A plunger which tends to move under the action of centrifugal force is mounted on the shaft and

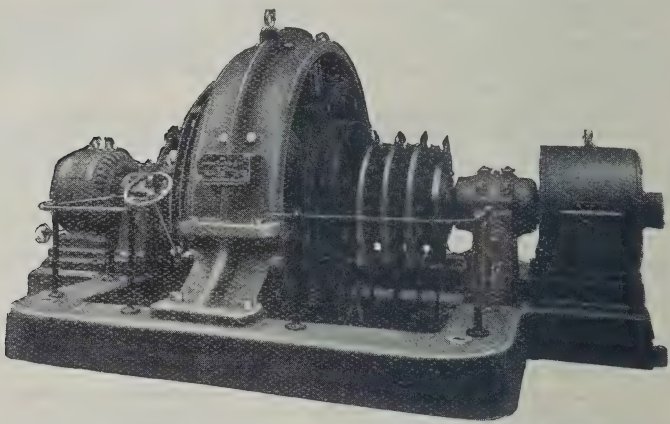

FIG. 26.—1,000 kW. G.E.C. Rotary Converter; 550–570 volts, 50 cycles, 750 r.p.m.

revolves with it. This plunger is held in position by means of an adjustable spring loaded trigger which releases at the predetermined speed. When released the plunger flies out and trips a switch device, which makes contact in a circuit, and thereby opens the direct current circuit breaker, or, if desired, cuts out resistance from the converter field circuit. The plunger automatically returns to its normal position when the machine shuts down.

Oscillating Gear.—When definitely specified, an oscillating device is supplied for moving the armature to and fro longitudinally while it is running. As the armature rotates, it is alternately pushed out of the magnetic centre and then released, thus causing a smooth oscillation. This device is not required for the satisfactory working of the machine and is not recommended.

Temperature Rise.—The rotary converter is capable of developing its full rated load continuously, with a rise in temperature of 72° F. (40° C.), in accordance with B.S.S. 172.

Overload Capacity.—The rotary converter will give an overload of 25 per cent. for 2 hours, and 50 per cent. for 15 minutes. It will also withstand overloads of 100 per cent. momentarily.

Starting Motor.—If the rotary be supplied with a starting motor, the latter is mounted on an extension of the bedplate. The motor is of large capacity, and is adequate in size to run the converter up to speed in a short time. The motor is usually of the solid rotor type. The starting

torque is sufficient to permit rapid acceleration in the first moments of starting, even though the supply voltage is below normal, as may be the case after a shut-down at the main power station.

Tests.—All material is subjected to tests at various stages of its manufacture, to ensure that no faults exist in the completed machine. Tests for static and dynamic balance are also carried out before the machine leaves the works. Standard final tests on rotaries for 650 volts direct current or under include a 2,000 volt flash test with alternating current for one minute, and six hours run on full load to ascertain the efficiency and temperature rises.

Starting, Self-Synchronising, and Controlling Synchronous Converters.

G.E.C. Methods of Starting, Self-Synchronising and Controlling Synchronous Converters.

It is usually required that synchronous converters shall be of the self-synchronising type, as the running of sub-stations is thereby facilitated. The practice can be considered standard. In the G.E.C. patented method of starting and self-synchronising, the starting current is not allowed to pass into the armature until the field is excited. Consequently, when the armature is switched on through the choking coils, the current is not strong enough to reverse the field, so that the polarity of the converter is always correct.

Fig. 27 shows the scheme of connections. The essential features are the synchronising switch and the choking coils. The rotary converter is provided with a starting motor, which is started by closing the triple-pole circuit-breaker shown at the right of the figure. This brings the set up to approximately synchronous speed. Meanwhile the switch shown in the figure is closed in its starting position, where the blades make contact on the long synchronising contacts. Under these conditions the slip-rings of the rotary are connected to the source of alternating-current supply through the choking coils, which limit the current taken by the machine. This current, however, is sufficient to pull the set into synchronism. When this has happened, the synchronising switch is pushed right home, so that the blades go into the full-on contacts. Mechanism is provided which prevents the synchronising switch being pushed at once into its fully-closed position. The device is so arranged that on slightly pulling the switch towards the 'off' position a pin releases a slotted bar, which falls under its own weight, allowing the pin to pass along the slot and permitting the synchronising switch to be pushed right home. When this happens, an

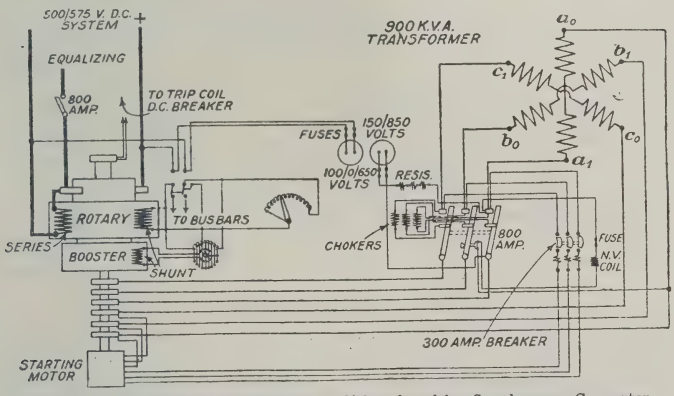

FIG. 27.—Diagram of Connections for Self-Synchronising Synchronous Converter.

interlocking contact is operated, which opens the no-volt coil of the starting-motor circuit-breaker tripping the latter, so that the converter set is left in synchronism with the starting motor disconnected.

The standard starting motor used is provided with a solid rotor. The stator windings are adjusted once for all when the set is first put into use so as to give the best value of slip to the starting motor and so as to necessitate the minimum value of synchronising current.

MOTOR CONVERTERS.

The motor converter combines the advantages of the ordinary rotary converter with those of the motor generator and to a very great extent eliminates the defects of both, while it is particularly suited to the higher frequencies now in commercial use. The machine is of the same general appearance as a motor generator, but its dimensions for a given output are considerably less. The static transformer, which is necessary in order to reduce the voltage for the ordinary rotary converter, is not required, the high-tension current being taken direct to the stator windings.

The switchgear required for the motor converter is of the simplest possible character, while starting and sychronising troubles are entirely eliminated with the use of patented devices, and the efficiency and power factor attain high values even at light loads.

The machine possesses a number of valuable features which are unattainable with any other machine; it can be designed with a voltage regulation on the direct current side of over 25 per cent., and can also without difficulty be compounded or overcompounded to suit the varied requirements met with in practice. Once synchronised a motor converter will not drop out of step, this being mainly due to the rotor being wound with a large number of phases; the exceptionally strong synchronising torque of this type of converting plant is one of its most remarkable characteristics. A motor converter, moreover, is particularly suitable for use on three-wire systems, and when working under these conditions will automatically maintain the voltage difference between the two sides within about 1 per cent. of the voltage across the outers, even with an out-of-balance current of 50 per cent. The air gap on the alternating current side is much larger than would be the case for a similar induction motor, and this advantage is of course accentuated in the larger sizes.

The motor converter consists of an ordinary induction motor with wound rotor, and a continuous current generator rigidly coupled together, the rotor windings of the induction motor and the armature of the generator being electrically interconnected. Fig. 28 shows the diagram

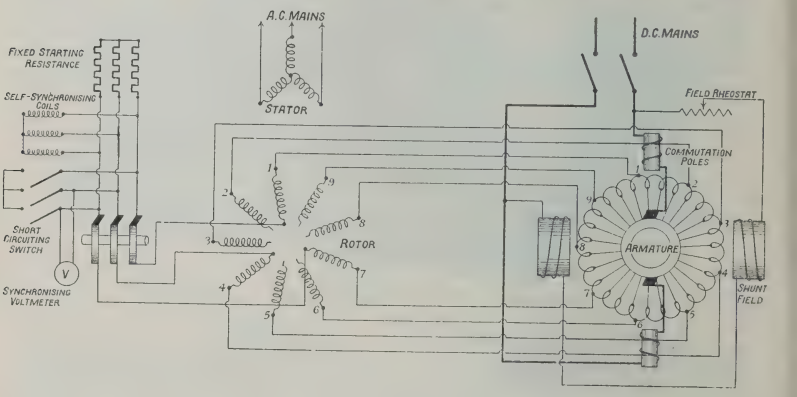

FIG. 28.—Schematic Diagram of Connections of Motor Converter.

of connections of a Motor Converter in its simplest form. The machine differs from a motor generator in that the rotor and armature are interconnected, and from a rotary converter in that the stator is direct connected to the high voltage mains and no transformer is required, although the rotating portions of the machine carry low voltages only. The high-tension stator winding may be star or delta connected, and the rotor winding is generally wound with nine phases connected to nine corresponding points of the direct current armature. Only three phases are used for starting, and only three slip rings are therefore required.

Perhaps the best method of explaining the principle of the motor converter is to consider it in conjunction with a rotary converter. A comparison between the relative merits of the two machines is thereby greatly facilitated.

In the case of a rotary converter, the supply current is first transformed to a suitable voltage by a transformer, fed through slip rings to the rotor, and the machine then runs as a synchronous

motor at a speed depending on the frequency of supply and the number of poles. At the opposite end of the rotor a commutator is provided, from which the direct current is taken, the pressure definitely depending on the pressure at the A.C. end and being adjustable only within narrow limits.

In the case of a motor converter, the supply current is fed direct to the stator winding of the A.C. part of the machine, thus setting up a rotating field.

The rotor of the machine may therefore be considered as the secondary of a transformer, the stator being the primary winding.

Assuming that both ends of the machine have the same number of poles, the rotor when electrically connected to the armature will rotate at a speed corresponding to half the frequency of the supply, that is, with 50 per cent. slip.

The whole arrangement is equivalent to a transformer, the secondary of which is allowed to rotate at half synchronous speed, and this has the effect of reducing the periodicity under which the converter part operates by half.

On account of this rotation, moreover, half of the energy taken from the mains is converted into mechanical energy in the A.C. rotor, and the D.C. armature being mechanically connected to the rotor therefore supplies half its output as an ordinary D.C. generator. The remaining half of the electrical energy drawn from the mains is transferred, as already described, from stator to rotor by transformer effect, whence, the armature being electrically connected to the rotor, it becomes available as direct current energy at the commutator brushes.

The motor converter thus acts partly as a rotary converter and partly as a motor generator.

Owing to the fact that the presure is reduced by transformer effect from stator to rotor instead of by separate transformers, no energy is supplied to the machine through brushes and slip rings which, in the case of a rotary converter of any size, carry very heavy currents on account of the low voltage. The D.C. part of the machine operating partly as an ordinary direct current generator, the output voltage may be varied between much wider limits than would be the case for a rotary converter.

The 'A.C.E.C.' Motor Converter.

The A.C.E.C. are sole licensees for Belgium of the Arnold and La Cour patents relating to motor converters, and since the British master patent has expired they have supplied a large number of these machines for use in Great Britain.

A.C.E.C. motor converters (fig. 29) are arranged for starting up on the A.C. side by means of patented devices which enable the starting and synchronising to be effected simply by closing the main switch; the machine runs up to speed and automatically comes into synchronism with the high-tension supply.

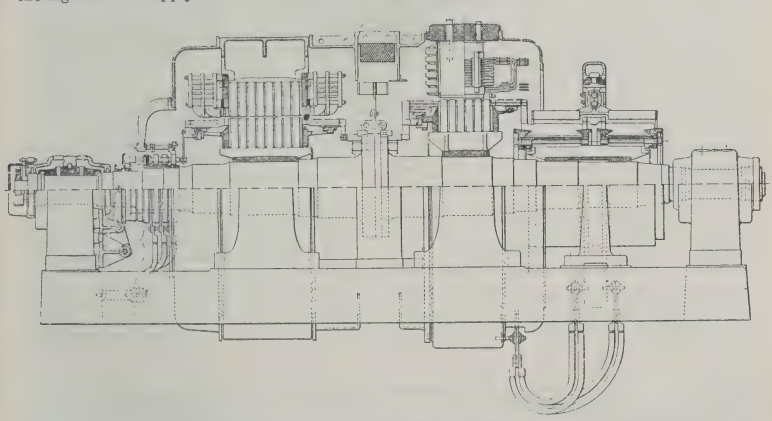

Fig. 29.—Section through Standard 1,500-kW. Double Commutator A.C.E.C. La Cour Motor Converter, showing general construction.

The rotor circuit being closed through a fixed three-phase resistance and the field rheostat being adjusted for maximum field, the high-tension switch is closed and the machine starts up as an induction motor, the current drawn from the mains being approximately one-third of normal full load current.

As the machine speeds up, its direct current voltage gradually builds up, and when this reaches a value equal to approximately two-fifths of the normal voltage, the D.C. field is reduced. Owing to the A.C.E.C. patented synchronising reactances which are connected across the rotor winding the machine then automatically falls into step, and the needle of the synchronising voltmeter comes back to zero. The rotor slip rings are then short circuited by means of a three-pole switch and the short-circuiting device for all the phases of the rotor closed. The effect of the above-mentioned reactances is to produce a resultant retarding torque when the E.M.F. of the rotor is in advance of the E.M.F. in the armature and an accelerating torque in the contrary case, so that once the motor converter has attained synchronous speed it remains in step at that speed. It will be seen that the whole operation is extremely simple, and one which can be performed without difficulty by an unskilled person.

When the motor converter is used on a three-wire system, the neutral point of the short-circuiting switch is connected to the neutral wire of the system.

Efficiency.

The values of the efficiency of a motor converter are considerably higher than those of the motor generator set, particularly at low loads. At full load the efficiency is very slightly lower than that of an ordinary rotary converter, but at three-quarter load and half load the efficiencies of the two types of machine are practically the same.

Power Factor.

Being a synchronous machine, the motor converter runs with a high-power factor at all loads, a notable advantage over the ordinary induction motor generator set. This high-power factor is maintained in spite of the large range of voltage regulation on the direct current side, whereas in the case of an ordinary rotary converter, any extension of the normal range of D.C. voltage involves a drop in the value of the power factor. The motor converter can be designed to run with practically unity power factor at all normal loads for any given value of the D.C. voltage.

As regards the general construction of the A.C.E.C. Motor Converters the *Bearings* are of the self-aligning type with automatic oil and air circulation, and are each capable of holding a large volume of oil. These bearings are so designed that the oil which is lifted by the rings passes along the shaft and falls into another chamber of the pedestal and cannot again be lifted by the rings until it has passed down to the bottom of the pedestal and up again to the surface of the oil ring chamber. The complete rotating element is very carefully balanced, and every precaution is taken to ensure smooth running without vibration.

The *Stator* frame consists of a substantial iron casting arranged with feet for bolting to the bedplate. The core is built up from suitably insulated laminations of high permeability, the slots being of the semi-closed type.

The stator end windings are supported by solid blocks of insulating material securely bolted to the frame. This work is carried out on the same general lines as are now universally adopted in the construction of turbo-alternator stators. Owing to the special methods of insulation and impregnation used, and the application of Creedy windings and Haefely wrappings, the stators can be wound for pressures up to 15,000 volts. The coils are former wound and carefully protected by massive bakelite finger blocks where they emerge from the stator slots, thus avoiding any possibility of breakdown at these points.

The laminations of the *Rotor* core are clamped between substantial end-plates. The ends of the windings are connected at the slip-ring end to short-circuiting contacts, three of them being so connected through slip rings, and at the other end to tapping points on the D.C. armature winding, through the interconnections previously described.

The *Armature* core is built up from high-permeability laminations of similar grade to those used in the rotor and stator, clamped between substantial cast-iron end-plates. The winding is of the drum type, each coil being former wound, and is provided with a number of tapping points for connection to the rotor winding. The coils are held in position in the slots by means of specially treated wedges, the end windings being kept in place by steel bands insulated with mica.

Substantial short-circuiting gear is provided, with adjustable contact blades. It is hand-operated, and so designed that the actuating portion, after pressing the sliding ring into the running position, automatically makes a small movement in the reverse direction so as to release the pressure from the ring while the machine is running. The contact blades engage with solid gun-metal blocks.

Mercury Vapour Rectifiers.

The necessity of converting alternating to direct current in many cases, and the desirability of dispensing with running machinery in sub-stations, etc., has led to the development of the rectifying properties of the mercury vapour lamp for this purpose. Essentially the rectifier consists of an arc *in vacuo* between iron or carbon anodes and a mercury cathode, which allows the current to pass in one direction only, namely, from the anodes to the cathode, as the names imply.

The exclusive use of mercury as a cathode is due to the fact that it can be vaporised, condensed and returned by gravity to the cathode during the operation of the arc, without loss of material; while the electrical conductivity of mercury vapour entails but a small voltage to maintain the arc and enables the anode to be well removed from the cathode, which is essential in order that the anode shall be kept cool.

Efficiency.

The losses within the rectifier chamber are due to the voltage drops at the anode (about 5 volts), the cathode (about 9 volts) and in the arc (about 0·1 volt per cm. of arc length), making a constant total drop of about 20 volts in the rectifier. In consequence, the efficiency of the rectifier is practically independent of the load, while the higher the voltage the higher the efficiency—hence the suitability of such rectifiers for high-voltage d.c. traction.

Transformer.

The greater the number of anodes the larger becomes the transformer for a given output, but the smaller the ripple in the d.c. voltage. Usually 6 anodes are used. The transformer for rectifier supply must be specially reinforced against short-circuits. With an absorption 'choke,' a 6-anode rectifier needs a transformer rated only for a 3-anode rectifier.

Regulation.

The rectifier has no inherent regulation, which depends largely on the connections. With 3-phase star/6-anode connections the regulation is 10–12 per cent. and 4–5 per cent. with and without an absorption choke. Induction regulators are also used to provide regulation.

Load Characteristics.

The rectifier, owing to its nature as a valve in contradistinction to that of a converting machine, is an apparatus with an inherent continuous rating. It has a large overload capacity, since it is free from mechanical inertia. The rating must be reduced where overloads of long duration are required, for although momentary overloads are easily handled, continuous overload will result in overheating with its consequent liability to the development of faults. It can respond quickly to load fluctuations owing to the comparative absence of the electrical inertia introduced by the presence of magnetic fields. A given rectifier will theoretically provide its rated current at *any* desired voltage, so that the kW. rating will depend directly upon the D.C. terminal voltage. In practice, however, the higher the rectified voltage, the greater becomes the tendency for short-circuits between anodes due to heating, and for 'arc-back,' etc., so that output current ratings are progressively reduced as the voltage is increased.

'Arc-back,' or loss of rectifying property, depends largely upon the temperature rise due to a given load. The presence of foreign gases and failure of the vacuum, reduce the voltage that the rectifier will withstand without arc-back. The fitting of an anode guard—consisting of an iron tube with open-mesh grating enclosing the anode—assists in suppressing the tendency to arc-back.

'Flashing' is momentary loss of valve property and is due to various causes such as the condensation of small globules of mercury on the cool anodes.

'Fading' occurs in glass-bulb rectifiers with long arms, and is due to charges on the glass shielding the anodes.

Cooling.

Glass rectifiers are cooled naturally, by air fan, or by immersion in oil; metal-clad rectifiers by the circulation of water. Cooling is very important, since it determines the load, overload capacity, losses, etc. Short-circuits are caused by condensed mercury running down the anodes; by overheating of the anodes; by the effect on the anodes of ultra-violet irradiation from the cathode spot; by insufficient vacuum and continuous abnormal overload causing overheating.

Construction.

(*a*) *Glass-bulb* rectifiers. The first rectifiers were built with glass bulbs, and such are still used for small powers, low voltages, currents up to 250 amperes and few anodes. Glass-bulb rectifiers have a long but unpredictable useful life. They must be discarded when the anodes have been worn sufficiently for the deposited material to hinder radiation and cause fading. The bulbs are evacuated during manufacture, when care is taken to eliminate occluded gases. Little knowledge of the state of the vacuum is possible during operation. Graphite anodes are usually employed, since they do not quickly deteriorate, and tend to absorb stray gases. Molybdenum or platinum must be embodied in the lead-in arrangements to form an efficient seal. The temperature of glass-bulbs is limited to about 110° C.; above this temperature the internal arc drop increases very rapidly. The arms of glass rectifiers are usually given a right-angle bend to protect the anodes from ultra-violet rays from the cathode and from contact with condensed mercury, both of which tend to cause short-circuits. Starting may be effected by tilting the bulb.

(*b*) *Metal-cased* rectifiers are used for large outputs and high voltages because large volumes of mercury vapour are concerned; the state of the vacuum must be continuously determinable by vacuum gauge; periodic inspection and renewal of the anodes is necessary. The cylinder is usually of steel, closed by a top anode plate which supports the main and excitation anoded and the condensing chamber. The cathode consists of a pool of mercury from which the arc rises through arc funnels and anode shields. The casing and condensing chamber are cooled by water jacket. The main anodes of special steel are insulated by porcelain bushings. Ignition (*i.e.* preliminary striking of the arc to initiate electronic emission) is accomplished by means of a plunger maintained a short distance above the cathode surface on a rod depending from the top of the condensing chamber, and capable of being lowered momentarily by the energising of a solenoid. Excitation anodes are connected to a dead load sufficient to maintain the arc when the main load falls below a critical value. The vacuum is maintained continuously or intermittently by a vacuum pump. Since it is usual to earth the negative side of a d.c. system, the rectifier must be insulated as a whole from earth, and the cooling-water connections made by long rubber pipes.

Operating Features.

Parallel operation is governed by the same principles as with D.C. generators, but no reversal of power flow is possible. The operation is independent of frequency fluctuation, so that rectifiers can safely be run in parallel from separate unconnected A.C. systems, without need of synchronisation. Automatic control is more easily applied to rectifiers than to rotary machinery. Rectifiers can be worked in parallel with converters or batteries.

Applications.

The rectifier can be widely applied, but has naturally been found pre-eminently suitable for loads undergoing considerable fluctuations, such as tramways and railways. The absence of inertia enables any load within the rating to be supplied as demanded. The traction field is at present the widest, after which come power and light, rolling mills and electro-chemistry. The rectifier is definitely out of the experimental stage, and by reason of its high efficiency is becoming a serious rival to the synchronous converter. Its limitations in size have as yet scarcely been approached. Already currents up to 20,000 amperes and voltages up to 16,000 volts have been obtained in single units.

The advantages of the rectifier may be summarised as follows :—

1. The efficiency is high at all loads.
2. Little auxiliary apparatus is needed.
3. Wear and tear is small.
4. Synchronisation is unnecessary.
5. Little floor space is needed and the sets require no solid foundations.

The disadvantages are :—

1. Ripples in the rectified wave form are objectionable in some services.
2. Larger transformers than for converting machines are required.
3. No control of the power-factor is available.
4. Reversibility is impossible.

The 'Tungar' rectifier, which is suitable for charging small storage batteries, is more closely allied to the 'valves' used in wireless telegraphy, the cathode being an incandescent filament.

MOTORS.

DIRECT-CURRENT MOTORS.

Shunt-wound Motors.

The shunt is the most common type of field winding, and is generally applied to motors designed for operating at constant speed under constant or varying loads. Nearly all commercial applications, particularly those of large capacity, require this type of motor. When

necessary, considerable speed variation can usually be secured by means of a rheostat in the field circuit, increased resistance resulting in an increased speed.

On many shunt-wound commutating-pole motors a stability winding is used on the field for the purpose of insuring stability under all conditions of operation. This is, in effect, a light series winding, which, however, does not change the speed-torque characteristics from those of an ordinary shunt-wound motor.

SERIES-WOUND MOTORS.

These are variable-speed machines particularly adapted to such uses as railway and crane service. The characteristic features of a series-wound motor are its great torque at starting and low running speeds possible.

COMPOUND-WOUND MOTORS.

For some special classes of service, in which it is necessary to start under heavy load and later operate at approximately constant speed, a series winding is added to assist the shunt field at the low-speed points. A compound-wound motor combines the characteristics of both shunt and series-wound motors. In most cases, however, the series winding has comparatively little effect except during the starting period, and may be short-circuited, if desired, at higher speeds.

Starting Motors.

Except very small machines, all direct-current shunt and compound-wound motors are started by first giving the shunt field full excitation and then connecting the armature, with a starting resistance in series, to the circuit. The resistance is then cut out in steps as the motor accelerates, the time required to attain full speed varying from about 15 seconds for small, to one minute for large motors. These limits should be used with discretion, since more time is required to start with heavy load than with light load.

After all connections are made according to instructions and all mechanical preparations are complete, see that all the field adjusting resistance (if used) is cut out and that the starting resistance is all in circuit. Close the circuit-breaker (if used), then the line switch, and lastly cut out the starting resistance step by step, allowing enough time for smooth speed acceleration. Too rapid starting results in excessive starting current and possibly flashing at the brushes. The motor should generally start when the armature circuit is first closed through the starting resistance, and failure to start when the second or third step of resistance is cut out is a signal to open the line switch or circuit-breaker at once and find the cause of the failure.

Stopping Motors.

Never move a starter or controller handle to the off position under any circumstances if by doing so the shunt-field circuit of the motor is opened. The high inductance of the motor field may generate voltage enough to puncture the insulation. If it is necessary to open a shunt-field circuit it should be done very slowly, allowing the field current to die out, through the resistance of the arc across the switch terminals. If a field circuit must be opened in this manner often, a field switch should be installed, so that a local circuit is closed through the field before the latter is disconnected from the line. Starting rheostats are usually so arranged that the field circuit is always closed through the motor armature. If the starter or controller is provided with a low-voltage release, the line switch or circuit-breaker should always be opened first for stopping; the motor speed will then decrease until the starting resistance is automatically cut into circuit.

Brushholder Adjustments.

The correct position for the brushes in either direction is clearly marked before the machine is shipped, and before starting up the position should be checked. Sparking at the brushes when the machine is operating with load can frequently be entirely removed by shifting the brushes slowly from or towards the neutral point. In any case the correct distance of the brushes from the neutral point is very slight, and the movement should be made with great care, for shifting the brushes too much will cause violent sparking.

Care of Commutator and Brushes.

Carbon brushes are used on all direct-current machines nowadays. The chief considerations in caring for such machines are to keep the commutators clean, the brushes properly adjusted, and the contact surface of the brushes good. The last condition, once fulfilled, will usually take care of itself until the brushes are worn out, provided the other conditions are complied with. At intervals depending on the service and the location, the commutator contact surface and end should be thoroughly wiped with clean cloth that is free from lint.

A few drops of oil on the cloth or a piece of paraffin rubbed lightly across the commutator surface will give all the lubrication necessary. Lubricant should be used very sparingly on a commutator, and no grease, oil, or dirt should be allowed to accumulate on the commutator or the brushes.

The ideal appearance of a commutator surface is polished dark brown or chocolate colour. Such a commutator needs no attention other than cleaning when necessary. If the surface has a raw copper colour with gradual roughening, it should be smoothed with sandpaper or, if very rough, with a piece of sandstone; emery paper or cloth should not be used for this purpose. The sandpaper should be held against the commutator by means of a block having the same curvature as the commutator. The sandstone likewise should be curved to fit the commutator. The brushes should be lifted from the commutator surface when using sandpaper or stone, and should not be placed in contact again until the commutator surface is thoroughly cleaned of all gritty particles.

Bedding the Brushes.

When making proper contact with the commutator, the face of the brush is glazed. If the glazed portion does not extend over very nearly all the brush face the brushes should be ground in by wrapping a long strip of fine sandpaper closely around the commutator with the rough side toward the brushes and then rotating the commutator and the sandpaper slowly through perhaps one revolution. Shorter pieces of sandpaper held close to the commutator surface and drawn a few times back and forth under each brush or set of brushes will answer the same purpose. The commutator surface should be wiped clean after the brushes are ground in, and lubricated with a few drops of fresh oil on a clean cloth.

Field Coils.

An open-circuited shunt field coil can be detected by touching the terminals of a voltmeter to the terminals of the individual coils while full voltage is applied to the field circuit. The voltmeter will show no deflection until the defective coil is reached and will then indicate the full voltage.

A short-circuited shunt field can be found by the same test, the voltmeter deflection being least on the defective coil. The short-circuiting of one field coil may result in burning out one or more of the others if full voltage is applied to the circuit.

In replacing a field coil make sure that the polarity of the pole differs from that of either adjacent pole. The polarity can be tested with a small bar magnet or a piece of steel wire suspended from its centre by a string. In holding the magnet near the poles successively it should reverse at each pole, *i.e.* no two successive poles should attract the same end of the magnet.

Cautions.

Never allow the load to be entirely removed from a series-wound direct-current motor while operating, or to be reduced enough to cause a dangerously high speed. A series motor should not be belted, on account of the possibility of the belt running off, thus permitting the motor to race.

Never open the shunt-field circuit of a motor in operation, otherwise the motor may race and produce serious damage.

When the shunt-field circuit of a motor or a generator is excited, never open it quickly unless a path for the inductive discharge is provided. The circuit can be opened slowly, if desired, the arc at the opening serving to reduce the field current gradually. *Do not permit any part of the body to bridge this opening*, or a serious shock will be received.

Always follow a fixed regular order in closing and opening switches, unless there are special reasons for departing from this order. A routine method will aid in avoiding mistakes. Keep all switches open when the motors are idle. Close switches carefully, keeping firm hold of the handle until completely closed.

A routine method of making inspections, replenishing lubricants, etc., will also prevent oversights and possible damage.

SPECIFICATION FOR DIRECT-CURRENT MOTORS.

(The English Electric Co. Ltd.)

These machines are of the two end-shield type, and are supplied with standard shaft extension, but without pulley, coupling, sliding base, or foundation bolts, unless otherwise ordered.

Commutation poles are fitted as standard on all sizes from C.B. 7 upwards.

C.B. machines are usually supplied in the Protected or in the Enclosed-ventilated type, but they are also made as Pipe-ventilated, Drip-proof, or Totally-enclosed machines.

The *Protected type* motor is so designed that the internal rotating parts and live parts are protected mechanically from accidental or careless contact, a perforated metal cover being fitted to the cylindrical opening over the armature fan.

The *Enclosed-ventilated* type is similar to the Protected type, but a perforated metal cover is fitted over both cylindrical openings in the frame.

The frame is circular, of cast steel. The four main poles are bolted to the frame and are laminated except in the smallest sizes, C.B. 5 and C.B. 6, which have solid poles. Commutation poles, when fitted, are of solid wrought iron.

End shields are in the form of end plates bolted to facings on the magnet frame and form substantial supports for the bearings.

Ball or roller bearings, or in certain cases a combination of both, are used, and are of ample proportions. On the larger machines a ball-thrust bearing is fitted.

The bearings are enclosed in dust-proof housings.

This type of bearing has stood the test of lengthy experience in practical use. It requires practically no attention. As the bearings will work equally well in any position, provided the shaft is horizontal, the motor may be fixed to wall or ceiling without altering the position of bearings or end shields, as is necessary with ring-lubricated oil bearings.

The field coils of all sizes are former wound, thoroughly impregnated and taped all over. All coils are heavily insulated from the poles and the frame, to safeguard against earthing.

The armature is slotted and drum wound, and is specially designed to give thorough ventilation of the windings, core, and field coils. The core plates are keyed directly to the shaft, and are held in position by two end flanges. The windings are carefully impregnated.

The commutator is built up of segments of hard-drawn copper which are held in position by end flanges fitting into deep V grooves in the segments.

The brush rocker which carries the brush spindles is mounted on a turned seating on the end-shield. The brush holders are substantial castings, and the brushes are easily replaceable.

A terminal box is arranged on the magnet frame, and is provided with a cast-iron cover. A flange is provided on the terminal box to receive screwed conduit.

The standard direction of rotation is counter-clockwise when viewed from the commutator end; if the opposite direction of rotation is required, this must be stated on the order.

The following accessories are supplied as extras, if required :—

Pulley for rope or belt (standard or otherwise) or half-coupling or flexible coupling.
Sliding base with adjusting screws and four bolts for fixing the machine to the base.
Foundation bolts.

Speed Regulation of Direct-current Shunt-wound Motors.

There are three commercial methods of varying the speed of direct-current shunt-wound motors: (1) by altering the terminal voltage; (2) by a resistance in series with the machine; (3) by a resistance in series with the shunt circuit. The first method is not employed as a rule with the ordinary industrial motor, but is only used in connection with self-contained plants such as winding, and certain printing press control equipments. The second method is sometimes adopted where a small speed reduction is required. With it, fine regulation is difficult to obtain, while the power consumption of the motor remains practically the same throughout the whole range of speed, an amount of the power proportional to the speed reduction being dissipated in the resistance. The method is convenient where it is desired to regulate the speed down to about half for very short periods, such as for crane and haulage work. The third method of control is one which has received a good deal of attention during the last few years, and motors have been developed which are capable of speed regulation by field resistance up to 4 : 1, and in certain cases up to 6 : 1, the torque being maintained constant over the whole range.

Such large variations of speed generally require some special device to compensate for the cross magnetisation of the armature due to armature reaction, and for this purpose interpoles or auxiliary poles are employed. The poles are placed mid-way between the main field

poles and carry either the full armature current or a percentage of it. The interpole flux therefore varies directly as the load and as the armature reaction, and as the tendency of the motor to spark increases as the load, so the compensating flux increases proportionately.

The size of motors with shunt regulation is determined by the minimum speed and the maximum b.h.p., although it may be necessary for the motor to give a much lower output at the minimum speed. This is clear when it is considered that minimum speed requires maximum flux and maximum speed requires minimum flux, that the magnetic circuit must be large enough to carry the full flux, and that the dimensions of the armature are also determined by the number and size of the armature conductors. The only variable, therefore, is the field flux. The efficiency does not largely vary throughout the range of speed at a given load, owing to the fact that at the minimum speed the electrical losses are a maximum, whereas the friction and windage losses are

APPROXIMATE COMMERCIAL EFFICIENCY OF DIRECT-CURRENT MOTORS PLOTTED AS A FUNCTION OF THE BRAKE H.P.

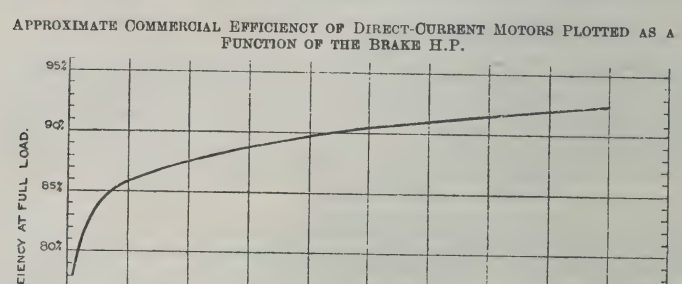

FIG. 30.

a minimum ; but at the maximum speed the electrical losses are a minimum and the friction and windage losses a maximum. The curve shown in fig. 30, giving the full-load commercial efficiency as a function of the brake horse-power, is typical of constant speed motors running at the normal speeds recommended by the British Engineering Standards Association. Motors with series resistance regulation have their sizes determined by the maximum speed and maximum output, and although the torque can remain constant throughout yet the output or power will be reduced in proportion to the speed.

Direct-Current Traction Motors.*

DIRECT-CURRENT SERIES-WOUND TRACTION MOTORS.

British Standard Specification for Traction Motors (Direct-Current, Series-wound). No. 173—1928 (*Abstract*).†

Types of enclosure are : (1) Totally enclosed, there being no air circulation between inside and outside of case ; (2) ventilated, having free circulation between inside and outside of case ; (3) self-ventilated, having air-fan ; and (4) forced ventilated (draught) type, in which air is forced through by external means.

Classes of Rating.—If excitation can be varied independently of armature current, the rating shall be associated with a stated condition of excitation and corresponding speed. (1) Nominal one-hour rating to be the h.p. output at motor shaft, at the rated voltage and constant current, which the motor can produce for one hour, the limit of temperature-rise measured by resistance being 100° C. for Class A and 120° C. for Class B insulation, and 90° C. on commutator. (2) Continuous rating is defined as the output at the motor shaft after working continuously with covers, etc., arranged as in service, the temperature-rise measured by thermometer not to exceed 85° C.

* For 'Electric Traction' see Section XIV., p. 669.
† By permission of the British Engineering Standards Association.

on commutator, and on insulated windings measured by resistance 85° C. and 105° C. for Class A and Class B insulation respectively. Class A includes enamelled wire and cotton, silk, paper, etc., when impregnated or oil immersed. Class B, asbestos and built-up and cemented mica insulation. In ventilated motors, the rating shall be the output at rated motor voltage; in totally enclosed motors the output at half the rated motor voltage.

The motor must be run in both directions with fixed brush position under specified test conditions. The statement of efficiency to be made on result of direct measurement corrected to 75° C. and not on the basis of addition of losses. The new machine must withstand, at the conclusion of the one-hour test, an alternating voltage of 1,000 plus twice the line voltage (minimum 2,500 volts R.M.S.), applied for one minute, between the windings and frame. The insulation resistance in megohms, when the high-voltage test is applied, to be not less than line volts/(1,000 + Rated B.H.P.). The specification lays down methods of carrying out performance and voltage tests, and the information as regards type, voltage, speeds, weight, and characteristics, to be supplied by the maker.

G.E.C. 'WITTON' D.C. INTERPOLE TRAMWAY MOTORS.

(The General Electric Co. Ltd.)

These tramway motors are designed for direct voltages 500 to 600 volts, and outputs from 30 to 90 b.h.p. They can be adapted for operating at 1,200 volts. The weight per b.h.p. has been reduced 28·3 lbs. While the majority of machines in this range are intended for car driving-wheels 33 in. in dia. (new), special motors are available for wheels 24 to 27 ins. in dia. The motors are designed within a minimum track gauge. Among the points of advantage incorporated are :—

1. Strongly proportioned box frame construction of high permeability cast steel.

2. Positive axial ventilation of the 'parallel flow' type (Oerlikon system), a double fan at the pinion end drawing two distinct streams of air through the motor.

3. Hoffman roller armature bearings with lubrication and grease sealing, and reliable locking.

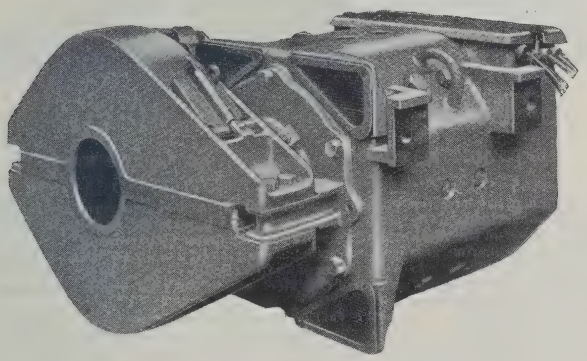

FIG. 31.

4. Armature laminations and commutator mounted on steel spider to avoid restriction of ventilation and to facilitate removal from the shaft.

5. Extensive use of mica insulation of armature coils, with mica, bakelite and porcelain brush-holder insulation.

6. Special care has been given to the design of the lubrication system and facilities for inspection of the motor.

7. Large diameter commutator tightened from the front and permitting of renewal of any segment without removal of commutator.

8. Exceptionally high efficiency.

A general view of the G.E.C. traction motor is shown in fig. 31 and the performance curves in fig. 32.

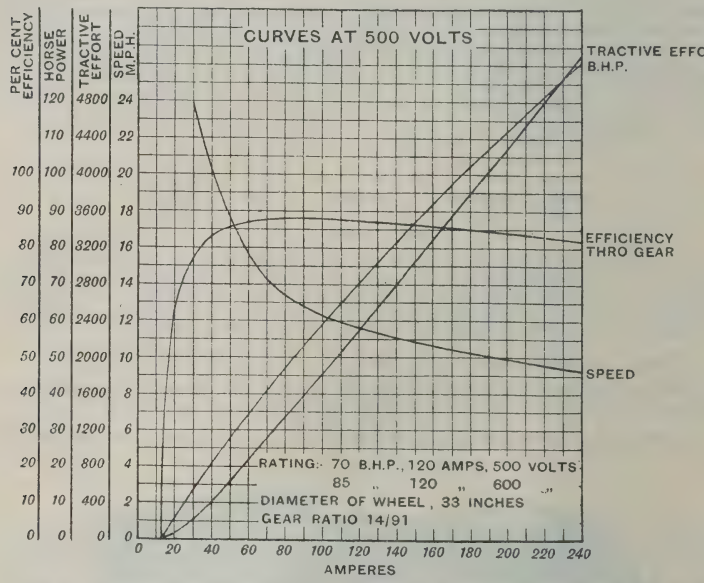

FIG. 32.—Characteristic Curves of G.E.C. 'Witton' D.C. Traction Motor, Type W.T. 32 R.

THE B.T.H. CO.'S SELF-VENTILATED, INTERPOLE TRACTION MOTOR.

(The British Thomson-Houston Co., Ltd., Rugby.)

As an example of the most modern type of light-weight direct-current series motor made by the B.T.H. Co. may be mentioned the motor rated at 52 h.p., 88 amperes at 525 volts, for a temperature rise by thermometer on the windings not exceeding 25° C. on an hourly rating. The weight of the motor complete with gearing, gear case and axle linings is 1,865 lbs. for use with wheel diameters of 24 to 27 ins. and 1,990 lbs. for wheel diameters of 30 to 33 ins.

Magnet Frame.—The magnet frame is of cast steel, and is provided with machined seatings for the pole pieces and brush holders.

Armature Bearings.—The armature is carried in roller bearings, designed to take end thrust, in addition to the radial load. The bearings are arranged for lubrication with grease; greasers are fitted with non-return valve, and screw threads for the connection of the grease gun.

Pole Pieces.—The four exciting pole pieces are built up of soft iron laminations, mounted on a steel key, into which are screwed the bolts for holding the poles to the magnet frame. The interpoles are made of drop forged steel.

Armature.—The armature is built up of soft steel laminations, assembled and pressed together hydraulically, and keyed to ensure that no rotational movement takes place with respect to the shaft. The shaft can readily be removed without disturbing the windings; the commutator can also be removed independently if necessary.

Ventilation.—The motor is self-ventilated by the parallel method. A double-sided fan is provided at the pinion end of the armature which draws air into the frame at the commutator end, expelling it at the pinion end. Air flows in two streams, one stream passing over the surface of the armature and field coils, while the other passes through the armature, by means of longitudinal ducts in the commutator shell and core punchings.

Axle Bearings.—The axle caps are of cast steel, tongued and bolted to machined surfaces on

the magnet frame. The caps have liberal-sized oil boxes designed for lubrication by means of oily waste. Auxiliary wells are provided for filling and for gauging the supply of oil.

Gear Case.—The gear case is made of malleable cast iron, bolted to the frame at three points, and provided with a door in the upper half, spring closed, for inspection and for lubrication of the gearing.

The English Electric Co.'s Direct-Current Traction Motor.

(The English Electric Co., Ltd.)

The direct-current series-wound traction motor gives in result the effect of the change-speed gear of a motor-car engine, which enables a small-powered motor to exert a big effort when required for acceleration or for climbing gradients. It is capable of working both large and small units both for short distances and main line traffic. The three features of design which have contributed to give the d.c. motor its present wide range in traction work are :—

(*a*) commutating poles ; (*b*) ventilation ; (*c*) high-tension design.

(*a*) *Commutating Poles.*—The coils are connected in series with the armature, and their effect is to counterbalance, under the brushes, the field set up by armature reaction, so that commutation under all conditions of loading is practically sparkless, even with the field shunted, thus giving a range of economical speed to traction equipments.

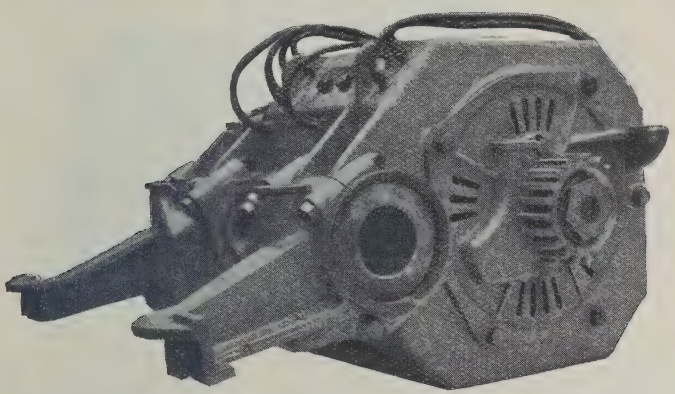

Fig. 33.—English Electric Co.'s Direct-Current Traction Motor.

(*b*) *Ventilation.*—Through the introduction of ventilation, it is now possible to transmit up to 450 h.p. on a single axle, on standard gauge, with 50-in. wheels, on the one hour rating of the motor.

All traction motors manufactured by *The English Electric Company*, ranging from 30 h.p. to 400 h.p., are fitted with commutating poles and are either self- or forced-ventilated. Self-ventilated motors range from 30 h.p. to 330 h.p. Ventilation is effected by means of a fan which forms part of the armature spider at the pinion end. The air is drawn in through apertures at the commutator end of the motor, and expelled at the pinion end. The fan is provided with two sets of blades, one of which draws the air through ventilating ducts in the armature, and the other over the surface of the armature and round the fields. Forced-ventilated motors range from 180 h.p. upwards, the ventilating air being supplied by motor-driven fans.

(*c*) *High-tension D.C. Motors.*—High-tension D.C. motors have been supplied in connection with the following schemes, amongst others :—L.M.S. Railway (England) and Cataluña Railway (Spain), both with a line voltage of 1,200 ; Midi Railway and Paris-Orleans Railway (France) ; Midland Railway (New Zealand) ; Imperial Government Railways (Japan) and The Great Indian Peninsula Railway : the last five having a line voltage of 1,500 ; Montreal Harbour (Canada), line voltage 2,400. Motors of similar design are also being supplied for the Morocco Railways for a line voltage of 3,000.

An experimental line at 3,500 volts gave entirely successful results.

The high-tension motors are specially insulated, mica and mica compound being used throughout for the insulation of armature, field coils, and brushes, so that the dielectric strength of the machines is not affected at high temperature.

On the larger sizes, such as 350 h.p. motors supplied to Chemin de Fer de Midi, the motors drive on the axles through twin gearing, the teeth of the pinions at each end of the armature being staggered to assist in giving uniformity of turning moment.

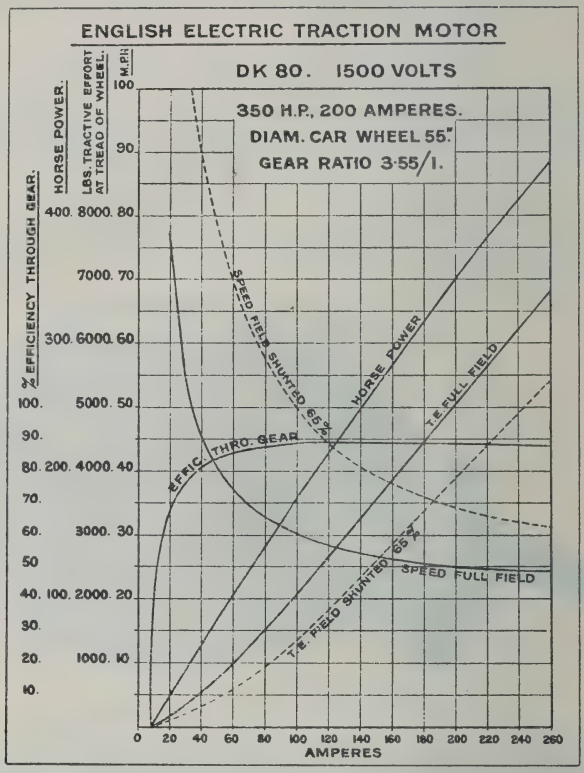

FIG. 34.

Fig. 33 shows a typical English Electric 350 h.p., 1,500 volt, traction motor, of which the characteristic curve is shown in fig. 34.

ALTERNATING-CURRENT MOTORS.

Alternating-current Motors may be divided into the following classes:—Synchronous, Induction, Induction-type Synchronous, and Commutator Motors.

Synchronous Motors.

An alternating-current generator will, if brought up to speed, excited, and connected to a suitable alternating-current supply, run as a motor at a speed in revolutions per second equal to the frequency divided by the number of pairs of poles. Such motors are called synchronous motors, and they will operate only at synchronous speed. They will not start under load, and have to be started by auxiliary means. If overloaded beyond a certain point they will fall out of step with the supply system and come to a standstill. Their sphere of usefulness is limited, and they are most commonly employed as phase regulators on transmission lines, or for driving direct-current generators.

The English Electric Co. Synchronous Motor.

(The English Electric Co., Ltd.).

The following is a specification of a synchronous motor (Class G.L.), made by the English Electric Co.

These machines are made in various standard types as follows: The Engine Base Type, the Sole Plate Type, the Bedplate and Two-Pedestal Bearing Type, the Bedplate and Three-Pedestal Bearing Type, and the Engine Shaft Type.

The *Engine Base Type* consists of a stator frame with feet, core, coils, terminals, and shrouds, one pedestal bearing, a rotor with poles and field coils, shaft, slip-rings and coupling, complete collector gear, screws for fixing stator frame and pedestal to the engine base and screws for adjusting the height of the frame.

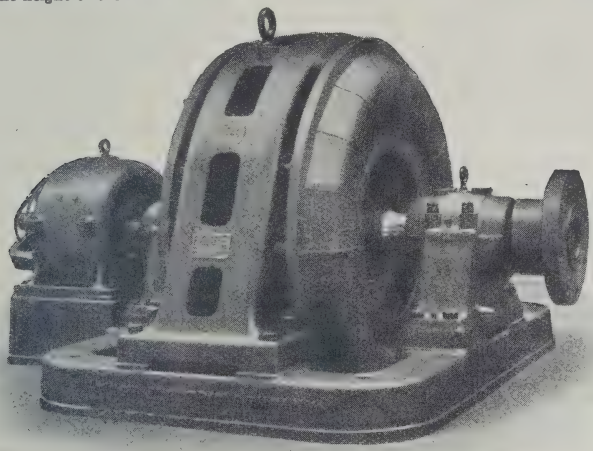

Fig. 35.—English Electric Co.'s Synchronous Motor.

The *Sole Plate Type* is practically the same as the Engine Base Type, with the addition of three sole plates suitable for building directly into the foundations.

The *Bedplate and Two-Pedestal Bearing Type* is similar to the Engine Base Type, but has a second pedestal bearing and a bedplate on which the stator frame and the two pedestal bearings are mounted. The shaft is suitable for drive with solid or flexible coupling or, in special cases, with a gear wheel, or pulley for belt or rope.

The *Bedplate and Three-Pedestal Bearing Type* is the same as the above, but has a third bearing with a correspondingly extended bedplate. The shaft is suitable for fitting with gear wheel or pulley for belt or rope.

The *Engine Shaft Type* differs from the Sole Plate Type by the omission of the shaft, coupling, and the pedestal, together with its sole plate, the rotor being suitably bored for forcing directly on to the engine shaft.

Stator.—The cast iron stator frame is of substantial design and great stiffness, the feet forming an integral part of the casting.

For the small machines the frame is cast in one piece, but on account of transport limitations the larger sizes are cast either in two or four pieces, which are held together by bolts.

Machines of small and medium size can be supplied with either high or low height of centres.

The core is built up of best quality core plate stampings of high permeability and low iron loss, effectively insulated from each other to reduce eddy currents to a minimum. In the smaller sizes the stampings are complete rings, in the larger sizes they are in segments.

The outer circumferences of the laminations are located on steel dove-tail keys, and the laminations are firmly held in position by means of heavy clamping rings. Ventilating ducts are provided at frequent intervals to allow free circulation of air.

The inner circumference of the core is slotted for the reception of the stator winding.

Semi-closed slots are used whenever possible, as they afford a mechanical support for the coils and tend to reduce the excitation loss and the eddy current loss in the pole tips.

The stator winding is usually of the hairpin type held in place in the slots by means of wedges of insulating material. The coils are amply insulated and thoroughly impregnated before being put into place.

The outhanging portions of the coils are protected from mechanical injury by shrouds secured to the frame. In all cases where the pole pitch is large or the duty gives rise to forces likely to distort the windings, these portions of the winding are supported by special brackets so as to give as strong a mechanical construction as possible.

Terminals.—Connections from the stator windings are brought out as heavily insulated flexible leads which pass through a cleat board supported on the frame. This arrangement of terminals presents the safest and simplest means of connecting the machine to the external circuit.

Rotor.—The rotor consists of a cast wheel of steel or iron to which the poles are attached.

For the largest sizes the wheel is cast in two or more pieces, the sections being held together by shrink keys and bolts. The hub is held together by shrink rings.

The hub is provided when required with register and bolt circle suitable for bolting direct to the engine makers' coupling or with a sleeve extension for bolting direct to the engine makers' flywheel. In small and medium-sized rotors, the centre, sleeve and coupling are cast in one piece.

The poles are rectangular in shape, being either steel castings or built up of steel stampings, in either case of high permeability material. They are secured to the wheel by means of bolts provided with lock washers, which pass through the rim from the inside.

For the small sizes when space does not permit of these bolts, the pole laminations are punched with dove-tails for fixing into the rotor centre. These dove-tails are held in place by two taper wedges.

The pole stampings are held together by heavy rivets passing through cast steel flanged end plates, the flanges being formed so as to serve also as supports for the field winding.

All pole pieces are built to permit the use of a damping winding when required, as, for example, in connection with synchronous motors, single-phase machines, and generators driven by gas or oil engines and generally to facilitate parallel operation with other generators. The bars which pass through the pole face are efficiently connected by welded joints to the end rings.

Field Coils.—Whenever possible the field coils consist of copper strip wound on edge and carefully insulated from the pole limb. This form of winding is specially recommended owing to the excellent cooling of the windings and its great mechanical strength. It is advisable, therefore, to select a low voltage for excitation, so that a strip-on-edge winding can be used.

Slip-rings.—These are of gun-metal and are subjected to special heat treatment which makes for good wearing quality of the rings and brushes. The rings are shrunk on to a cast-iron bush insulated by a micanite sleeve. The complete bush with rings is pressed on to the shaft. The rods connecting the rings to the rotor windings are designed so that they can be replaced if necessary without removing the rings.

Brushes and Brush Gear.—The brush holders and brushes are liberal in size, and there are usually two brushes for each ring mounted in one holder.

The brushes used are of a special composition of copper and carbon, which gives low brush resistance, low contact resistance, and low coefficient of friction.

The bearing at the collector end is provided with a seating for supporting the brush spindles which carry the brush holders.

Shaft.—The shaft is designed on ample lines. It is of forged steel finished to size by grinding on the bearing surfaces. The rotor centre, which is pressed hydraulically on to the shaft, is held in place usually by one key sunk in the shaft, but where the drive renders it advisable, tangential keys are used.

Bearings.—The bearings are of the self-aligning sleeve type liberally designed. All bearings are split horizontally to facilitate inspection and removal.

Best quality white metal only is used for the lining. The bearings are of the self-oiling type with adequate oiling rings, the housing being made with a generous reservoir of oil provided with a definite system of oil circulation for the proper lubrication of the bearing and the cooling of the oil.

The housing is furnished with overflow, oil gauge, and drain plug.

Means are provided to prevent oil creeping along the shaft outside the bearing and so reaching the windings.

Balance.—Great importance is attached to smooth running, and the rotor is balanced both during manufacture and at final erection to ensure this feature.

Ventilation.—In these machines special attention has been given to providing a positive system of ventilation. Air is driven outwards by fan blades on the rotor and is directed on to the windings and core by the special formation of the shrouds protecting the overhanging portions of the stator winding.

Exciters.—Whenever conditions permit, direct-coupled exciters are used. In most cases the direct-coupled exciter has its armature overhung on an extension of the main shaft at the collector end, no outboard exciter bearing being used.

The exciter frame is mounted either on a stool fitted to the bedplate or sole-plate, or alternatively on a cast-iron bracket bolted to the bearing housing. In exceptional cases belt driven exciters are used, in which case the exciter has to be supplied with a sliding base, belt and the necessary pulleys both on the exciter and synchronous machine.

Induction Motors.

Induction motors may be classed as polyphase or single-phase induction motors. The action of a polyphase induction motor may be likened to that of a direct-current motor in which both the fields and the armature are capable of rotation. Supposing the fields of such a motor to be fully excited and rotate with the armature at rest and short-circuited, a current of any desired magnitude may be induced in the armature, since the generation of a current depends simply on the relative motion of the fields and the armature. The torque produced by the action of the fields on the induced current will tend to turn the armature, and if the fields be kept rotating at a uniform rate, the armature will speed up until the relative motion of the fields and the armature is sufficient to generate a current that exactly balances the load ; uniform speed has then been reached. The slip, or the difference between the speed of the armature and the speed of the fields, is generally stated in per cent. of the speed that would be reached if the armature were rotating at the same speed as the fields. This speed is spoken of as the speed of synchronism. In a polyphase induction motor the rotation of the field is produced by magnetising the fixed part, or stator, by two or more alternating currents in such a way that the resultant magnetic field rotates at a uniform speed. Generally three alternating currents are used differing in phase by 120°. One advantage of such a motor over the direct-current motor is found in the absence of a commutator, for the current in the armature, or, as it is called, the rotor, can be induced by short-circuiting its coils, the current from the line being led directly into the stator without any moving contacts.

In the single-phase induction motor there is an inductive action between the field and the armature, similar to that which takes place in a polyphase induction motor : the field, however, is not a simple rotating field, but may be regarded as two fields rotating in opposite directions. The result of this is that at starting the armature is subject to an equal pull in both directions—in other words, the motor will not start by itself. But when once the armature has been started in either direction, the torque in that direction increases while that in the opposite direction decreases. As a result, the motor works as an induction machine at a speed just below synchronism similarly to the polyphase motor. This type of induction motor therefore needs some special starting device.

In a polyphase system the ratio of the power component of the current to the total current, as measured by the power factor, depends mainly upon the width of the air-gap between the fixed and moving parts of the motor. Hence it is of great importance to reduce the clearance to the smallest limit consistent with safety. This necessitates very careful construction, especially for polyphase motors on railways. Experience shows that induction motors can be constructed to run well under all conditions.

Variation of Speed with Load.—In a normal polyphase motor the speed is nearly independent of the load. This is in marked contrast to the D.C. series motor, but shows a strong resemblance to the torque-speed characteristic of a normal shunt motor.

Maximum Load.—As the load increases the speed slightly decreases, until the maximum load is reached. If the load be increased beyond this the motor is brought to a standstill. In practice the working load should not exceed 50 to 60 per cent. of the maximum load.

Speed Regulation.—If resistance be placed in the circuit of the rotor so as to increase the total resistance, say, to double its value, the slip for equal torque will be double what it was with the original resistance. Thus with any load not greater than the maximum, any required speed can be obtained by merely altering the rotor resistance. This is a wasteful method of speed regulation, and various methods are in use for obtaining economical speed control. These include :—

(1) Changing the number of poles, with or without change in the number of phases.

(2) Cascade connection with one or more motors.

(3) Addition of variable-speed set.

Starting.—There is a certain rotor resistance corresponding to standstill with maximum torque. If the rotor resistance has this value at the moment when the motor is connected to the line, it will start with its maximum torque. If the resistance is suitably taken out of the circuit as the motor speeds up, the torque during starting can be maintained constant at any value not greater than the maximum. In other words, the torque, and therefore the acceleration, can be maintained practically up to full speed.

Windings.—There are two kinds of windings. In the first the rotor winding consists of copper bars, rather longer than the rotor core, which are all connected together at their ends. In the second the rotor has a winding arranged in such a manner as to allow of an outside resistance being introduced into the rotor at starting to supplement for the time being the resistance of the winding. The former is shortly described as a ' short-circuited ' or ' squirrel-cage ' rotor, the latter as a ' slip-ring ' rotor.

Comparison of Motors.—If the full voltage is applied to the motor at starting with the rotor short-circuited there will be, owing to the low resistance of the bars, a considerable rush of current at starting. In the motor with the slip-ring rotor the current at starting may be kept quite low by means of the supplementary resistance. When giving its full-load effort at starting, such a rotor with resistance in its circuit will take its normal full-load current. A short-circuited rotor will take several times this, but the current can be kept down by using a starting transformer or star-delta switch. These appliances feed the motor at reduced pressure until it begins to get up its speed, but they render motors with short-circuited rotors suitable only for moderate starting torques.

On account of the constructional simplicity of short-circuited rotors it is preferable, whenever possible, to use motors having these. Save as regards starting current, the short-circuited rotor is superior in every respect to the wound rotor. The momentary excess of current it takes at starting does no harm to a small motor, but its effect on the regulation of the supply system may be sometimes objectionable, a point which must be carefully considered.

Effect of Starting Motors.—In choosing motors it is necessary to distinguish between those intended to work on town supply mains where the greater part of the current is used for lighting, and those suitable to a scheme in which the bulk of the current is used for power, the lighting being but incidental. In the former case it is necessary that the working of motors should not interfere with the constancy of pressure on the lighting circuits; in the latter case an occasional jump in the lighting may be of no importance.

The effect of a sudden overdraft of current at a low power factor is disturbance to a greater or less extent of the whole supply system, and fluctuations in pressure such as would cause no inconvenience in the working of a power transmission plant would not be permitted on town lighting circuits. The magnitude of the disturbance depends primarily on the amount of the overdraft relatively to the capacity of the generating plant, and to the margin of current-carrying capacity in the supply network.

Choice of Motors.—It will be evident from the foregoing that the choice of the motor depends upon circumstances, and that neither class can be pronounced the better under all conditions.

Motors with short-circuited rotors take momentarily up to five times their full-load current, if at starting they have to give their full-load effort, or from one to one-and-a-quarter times their full-load current giving 25 to 30 per cent. of their full-load effort, and using a starting device. For connection to town mains it is usual, consequent on the possibility of disturbance to neighbouring lighting circuits which might arise from the starting, to limit this class of motor to 5 h.p. or so, when it has to start at full load effort, or to 10 h.p. when operated with a starting transformer.

In a power transmission scheme where there are no neighbours to consider and the lighting is subsidiary, the short-circuited class of rotor can be employed for large sizes, provided that at starting no individual motor takes a current great enough to prejudicially affect the working of the plant. Thus, in a 500 h.p. transmission, motors of 25 h.p. may be switched right on to the mains without the use of starting transformers, while if the starting effort required is only from 25 to 30 per cent. of the full load effort, motors of 50 h.p. provided with starting transformers are quite permissible.

The conditions under which motors with slip-ring rotors should be used are determined by elimination, that is to say, motors of this class are installed in all cases where it is not advisable to use the other. They have their place on town mains for sizes above 5 or 10 h.p., and in power transmission work, when they have to start at full load effort, and their sizes are comparatively large in proportion to the generating plant. Again, in all cases where motors have to start with overload effort, a slip-ring rotor should be used. Not only do motors of this class give at starting their full load effort with only full load current, but 50 or 100 per cent. over the full load effort can be obtained with a current proportionately increased. This control of the current at starting constitutes the advantage of motors with slip-ring rotors.

The curve in fig. 36 shows the power-factor at full-load of polyphase induction motors, as designed by Messrs. Crompton & Co., plotted as a function of the horse-power per revolution. Other things being equal, the maximum power-factor that can be obtained depends upon the number of poles with a given core diameter. For the same size of machine the larger the number of poles the lower will be the power-factor. It will be noticed from the curves that as the size of the machine increases the curves become very flat, and therefore after a certain point a very large increase in size will only increase the power-factor by a very small amount. For the smaller motors, however, the power-factor increases much more rapidly with the size. The horse-power ratings shown are for a normal temperature rise, and show the maximum power factor that can be reached in these conditions.

The standard windings of these motors are arranged to work on voltages of 110, 220, 440, and 500. They can, however, be wound for any other periodicity and for any higher voltage. The machines can be supplied for polyphase or single-phase circuits with either slip-ring or short-circuited rotors. They are manufactured in 19 standard sizes and are supplied in the same types, and are of the same substantial design and construction as the direct-current motors.

The machines are designed to give a high power-factor at all loads, and to withstand heavy overloads before stalling. When required to start against a load, it is advisable to use motors with slip-ring rotors and starting resistances. Motors with short-circuited rotors are capable of exerting their full-load torque when starting, but the sudden rush of current may be as high

CURVE SHOWING THE POWER FACTOR OF POLYPHASE INDUCTION MOTORS PLOTTED AS A FUNCTION OF THE H.P. PER REVOLUTION.

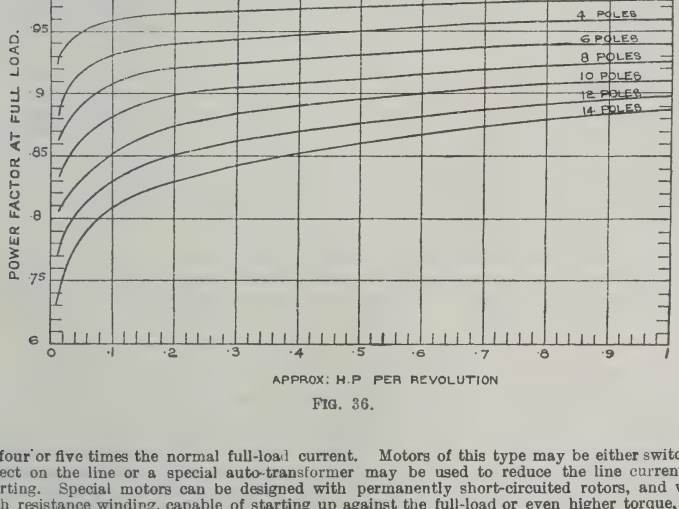

FIG. 36.

as four or five times the normal full-load current. Motors of this type may be either switched direct on the line or a special auto-transformer may be used to reduce the line current at starting. Special motors can be designed with permanently short-circuited rotors, and with high resistance winding, capable of starting up against the full-load or even higher torque, but such motors are usually required for special kinds of intermittent working, such as hydro-extractors.

SPECIFICATION FOR INDUCTION MOTORS.

(The English Electric Co. Ltd.)

The standard machine consists of stator frame with end shields, rotor, terminals, and complete internal connections. Unless otherwise stated in the quotation, the machine is supplied without pulley, coupling, sliding base, foundation bolts, or spanners.

These motors are usually supplied in the Protected or in the Enclosed-Ventilated type, but they are also made as Pipe-ventilated or Drip-proof Motors.

The *Protected type* motor is so designed that the internal rotating parts and live parts are protected mechanically from accidental or careless contact, a perforated metal cover being fitted to the cylindrical opening over the rotor fan.

The *Enclosed-ventilated type* is similar to the protected type, but a perforated metal cover is fitted over both cylindrical openings in the frame.

The stator frame is of cast iron. The stator core is built up of insulated stampings bedding directly on the stator frame. The coils are of the ' push-through ' type in the larger sizes and of the ' dropped-in ' type in the smaller sizes, the slots being nearly closed.

The rotor is built up of stampings with nearly closed slots.

In the case of squirrel-cage rotors the end rings are cast on to the rotor bars. The winding is specially designed to give a good starting torque.

In slip-ring rotors the ends of the windings are separated sufficiently to allow a free circulation of cool air.

A cast-iron terminal box is provided on the stator frame, and is fitted with a flange to take screwed conduit. Up to 650 volts, six terminals are provided, but for certain 210-volt motors the standard terminal box will take three terminals only. For pressures above 650 volts three porcelain-insulated terminals are provided.

A trifurcating box can be supplied to fit the above-mentioned terminal box. A trifurcating box can also be supplied for the rotor leads.

End shields are in the form of end plates bolted to facings on the stator frame, and form substantial supports for the bearings.

Ball or roller bearings, or in certain cases a combination of both, are used, and are of ample proportions. On the larger machines a ball-thrust bearing is fitted.

The bearings are enclosed in dust-proof housings.

This type of bearing has stood the test of lengthy experience in practical use, and is particularly advantageous in the case of induction motors, as there is no appreciable wear of bearings and consequently no change in the length of air gap after extended use. As the bearings will work equally well in any position, provided the shaft is horizontal, the motor may be fixed to wall or ceiling, without altering the position of bearings or end shields, as is necessary with ring-lubricated machines.

The slip rings are of phosphor bronze, and are arranged outside the end shield on an extension of the motor shaft. There is no earth connection to the slip rings.

The standard design permits of the addition of a short-circuiting and brush-lifting device, by which, through the movement of a hand wheel, the slip rings are short circuited and the brushes lifted out of contact with the rings, thus increasing the efficiency of the motor and reducing wear on both slip rings and brushes. With this device, a cover giving total enclosure to the slip rings is always supplied, and the brush holders are of the lever type.

If the short-circuiting and brush-lifting device is not provided, the slip rings are enclosed in a perforated metal cover and box-type brush holders are used.

The following accessories are supplied as extras, if required :—

Pulley, standard or otherwise, or half-coupling or flexible coupling.

Sliding base, with adjusting screws and four bolts for fixing the motor to the base.

Foundation bolts for fixing the sliding base to the foundations.

Spanners and spanner rack.

Cage-Rotor Induction Motor with High Starting Torque.

Although high-starting torque in cage-type induction motors can be obtained by means of high-resistance rotors, the consequent large rotor heating and reduced efficiency render such a construction unsuitable for many drives. Various designs have been evolved which impart to the robust cage-type motor a large starting torque without these drawbacks. Such motors may be started either by switching direct on to the mains or by means of a star-delta switch—a device usually preferred to the more costly and less simple auto-transformer starter. The various devices which have been developed for obtaining automatically a large inherent starting torque depend upon the effect of reactance, which is proportional to the rotor frequency or slip.

The common practice is to employ a double-cage rotor, consisting in its simplest form of two separate cage windings. The outer or starting cage has high resistance and low inductance; the inner or running cage has low resistance and—since it is sunk well into the rotor slots—high inductance. The large reactance of the inner cage at starting, due to the high frequency, keeps the current in this winding small; while the current in the high-resistance rotor cage produces a large starting torque. When running, the rotor frequency is low, and the main part of the current is carried by the low-resistance inner winding. The disadvantage of increased cost is partly offset by economies in control gear, and such a motor may cost less than a slip-ring type with its starter. The reduced power factor can be improved by suitable modifications in the design. In many drives, however, a slight sacrifice in efficiency and power factor is of small consequence compared with simplicity of control and robust construction.

Multiple-Speed Induction Motors.

The 'cascade' principle was originally applied to two motors mechanically coupled with their windings electrically connected in such a way as to make it possible to obtain two speeds. In the case of induction motors, the arrangement adopted was to connect the rotor slip-rings of motor No. 1 to the stator windings of motor No. 2, the torque of the combination being controlled by resistances placed in the circuit of the rotor of No. 2, slip-rings being used. If both machines had an equal number of poles, the 'cascade' connection gave effects equivalent to doubling the number of poles. Or if, for example, one was an eight-pole and one a four-pole motor, the speed for 'cascade' connection was that for a twelve-pole machine. Considerable use has been made of this system, notably on railways, the locomotives on the Valtellina line and for the Simplon tunnel being operated on this principle. The same effect may be secured by connecting the two rotors in series: the starting resistances may then be placed in the stator circuit and the use of slip-rings can be avoided.

In the Hunt 'Cascade' Induction Motor made by Sandycroft, Ltd., this principle has been developed so that the advantages secured hitherto only with two motors can be obtained in a single motor. In an ordinary induction motor, the stator acts on the rotor and there the inductive action stops. Starting torque and speed regulation can only be obtained by inserting resistances in the rotor winding. In the 'Cascade' motor, the rotor, by means of a supplementary magnetic field, reacts inductively upon the stator, to which the starting and speed regulating resistances are connected. The rotor in fact reflects back to the stator part of the energy received from it. This is accomplished by winding the rotor in such a way that it can, under the inductive action of the stator, simultaneously produce two magnetic fields of different numbers of poles; one of these reacts on the stator and generates in its winding induced currents. Each branch of the stator winding is divided into two parallel circuits which are tapped at suitable points. In the case of single-speed motors, or two-speed motors requiring starting or regulation with reduced rheostatic losses below two-thirds speed, these points are connected to resistances by which the torque and speed are controlled

Owing to the presence of two magnetic fields, one of which is at its maximum when the other is at its minimum, a very even turning movement is obtained at slow speeds, and a perfectly even pull with maximum torque can be obtained at as low as two revolutions per minute. This is a feature of importance with all kinds of winding engines. The slip of an induction motor depends upon the resistance of the windings in which the secondary currents circulate. In the 'Cascade' motor, these windings are in the stator and are of very low resistance, consequently the slip in these motors is very much less than that of ordinary induction motors, and the speed variation between full load and no load is only about 1·2 per cent. For constant speed work the absence of slip-rings is a matter of moment, especially in mining installations. These motors develop full-load starting torque with full-load current, and have a higher power factor than ordinary motors at low speeds where the tendency is for the power factor to become unfavourable.

The question of economical running at two or more speeds is one of great importance. The synchronous motor must run in step with its generator, and the induction motor runs at a speed very nearly that of synchronism. The speed of the former cannot be varied, the speed of the latter can only be varied by inserting resistances in the rotor at great loss of efficiency. A simple modification of the windings of the 'Cascade' motor, described above, enables two speeds to be obtained without rheostatic losses. Slip-rings are connected to a normal rotor winding in star mesh connection. When these rings are open circuited, the portion of the winding connected to the slip-rings is idle, the rotor reacts on the stator, as previously described, and the motor runs at 'Cascade' speed. When the slip-ring circuit is closed, the rotor winding becomes symmetrical, and produces only one number of poles; there is no reflex action on the stator and the motor runs as an ordinary induction motor. Thus, for example, in a twelve-pole 'Cascade' motor, running at 500 r.p.m., there are two fields, one of eight and one of four poles, the latter being the result of rotor reaction. When this is removed by current through the slip-rings, the effective number of poles is eight, and the motor runs at 750 r.p.m. without any resistance. If intermediate speeds are required, they may be obtained by the use of resistances in the usual manner.

A self-synchronising synchronous type of Hunt motor is now on the market and has many unique features. It resembles the Cascade Induction Motor, but has a modified form of stator winding. At synchronous speed the auxiliary field is stationary, and is excited by direct current supplied to the stator windings. These windings are connected to form two parallel-connected star windings, and the exciter is coupled to the neutral points. The direct current produces a field having half as many poles as the main field. The machine is started by resistances connected to the slip-rings, and when so connected the speed can be taken up to synchronous (Cascade) speed or even above it, so that all the usual difficulties of pulling-in are obviated. The motor will start and synchronise with loads of two to three times normal, and with a high starting-power factor and low current consumption. With motors designed for a leading power factor of 0·7, the starting current for full-load torque is of the order of 10 per cent. to 15 per cent. more than normal full-load current, and the starting-power factor is 88 per cent. to 93 per cent., depending upon the speed for which the machine is built. A remarkable feature possessed by this machine is its entire immunity from 'hunting' or 'phase-swinging.' Extensive tests have been made, but no trace of these troubles has ever been found.

The latest development of the Hunt machine is a self-paralleling generator. This motor closely resembles the synchronous motor, but, as slip-rings are not required, the rotor winding is of the low-voltage short-circuited type as used for the induction motor. These machines possess the same properties as the synchronous motor, and will run in parallel under conditions which would be impossible with generators of the usual type.

Other economical speed changes can be obtained in addition by Creedy's extension of the principle of the cascade motor, or by pole-changing, or by phase changing. A special application of the two-speed motor, apart from economical running at two speeds, is the avoidance of large starting peaks by two-speed starting in connection with winding and similar work, combined with a reduction in starting losses.

Induction-type Synchronous Motors.

The induction-type synchronous motor is a polyphase motor with a cylindrical rotor; it is started as an induction motor of the slip-ring type, and synchronises itself when direct current is switched on the rotor. It combines the good starting characteristics of the induction motor with the property of power-factor correction of the synchronous motor, and for this reason its

use is extending. It may with advantage be run at a leading power factor at all loads; the leading current increases somewhat as the load is reduced, and the speed is constant at all loads. A small D.C. exciter is mounted on the motor shaft. The stator is identical with that of the ordinary induction motor; the rotor may be wound three-phase or single-phase. Whilst starting, with a resistance in the rotor circuit, the machine exerts a large torque, and can be made to accelerate against more than double full-load torque. The maximum current during starting is about twice the full-load current, and persists for a very short period. The overload above which the motor falls out of step is 100 per cent. or less, depending on the power factor for which the machine is designed; on falling out of synchronism it will usually continue to run as an induction motor until the overload is reduced. In the operation of starting, the main notch is closed, and the rotor starting resistance is gradually cut out and short-circuited. The rotor circuit is then momentarily opened, and closed on the exciter; and the exciting current is adjusted to give the desired leading power-factor.

In some cases the power is supplied to the rotor, and the excitation to the stator.

The efficiency is slightly lower than that of a plain induction motor; the cost is 25 to 40 per cent. higher (including all accessories). The machine is most suitable for a continuous load of 100 h.p. or more.

AVERAGE EFFICIENCIES OF POLYPHASE INDUCTION MOTORS.

(*Meares.*)

Output, B.H.P.	1	5	10	20	50	100	150	200	300
Efficiency per cent.	80	85	86	88	89	90	91	92	93

Alternating-current Commutator Motors.

Alternating-current commutator motors are in most respects similar to ordinary direct-current motors, and may have either series or shunt characteristics. They operate under serious disadvantages, owing to the transformer e.m.f. induced in the coils short-circuited by the brushes, necessitating a low commutator voltage; but for certain purposes they are practically indispensable. For single-phase railroad traction the 'neutralised series' motor is used, the speed being controlled by a variable-ratio transformer. For smaller powers the single-phase 'repulsion' motor is very suitable, the speed being controlled by moving the brushes over a range from standstill to 30 per cent. above synchronism. Single-phase commutator motors with shunt characteristics are also satisfactory machines. The efficiency of single-phase shunt commutator motors is somewhat lower than that of direct-current motors, and the cost somewhat higher, but the weight is less.

Three-phase commutator motors are also made to work with a series or with a shunt characteristic, but have not come into extended use, except for special applications such as steel rolling-mill drives. Where variable speed is necessary, the multi-speed or the cascade induction motor can be considered as alternatives to A.C. commutator motors.

VARIABLE SPEED POLYPHASE COMMUTATOR MOTORS.

(*The British Thomson-Houston Co., Ltd.*)

This motor, known as the Schrage motor, has been developed by The British Thomson-Houston Co. for industrial applications requiring variable speed. While possessing the speed characteristic of a D.C. shunt-wound motor, it is suitable for operation on polyphase alternating current circuits.

The motors are provided with the following windings:—

(1) Primary winding located on the rotor and, by means of slip rings, connected to the supply leads.

(2) Secondary winding located on the stator.

(3) Regulating winding placed in the same slots on the rotor as the primary winding. The regulating winding is connected to a commutator and thence, by means of brushes, in series with the secondary winding on the stator.

For normal speed regulation, no external resistance is required in order to effect speed variation, and hence the motor operates with high efficiency at all speeds. Normal speed variation is obtained simply by turning the handwheel provided, which changes the position of the brushes on the commutator. The movement of the brushes can also be effected very conveniently from a distance either mechanically by means of wire rope and pulleys or by spindle and bevel gear wheels, or electrically by means of a small pilot motor coupled to the brush-shifting spindle and controlled by push buttons.

The polyphase shunt motor—unlike the D.C. variable-speed shunt-wound motor, where the maximum torque is developed at the lowest speed and decreases as the speed increases—exerts a constant torque throughout the whole speed range, *i.e.* the output is directly proportional to the speed.

The normal speed range of the standard motor is 3 : 1.

The motor operates at speeds above or below the synchronous speed and at any speed between the maximum and minimum values. When running near synchronous speed the motor operates exactly as an ordinary induction motor, the secondary winding being short-circuited through the brushes across one or more commutator segments. According to the amount that the two sets of brushes are displaced in one direction or the other, so the speed will vary either above or below synchronous speed. It is usual, therefore, to select a synchronous speed about midway between the maximum and the minimum speeds desired.

The difference between the no-load speed and the full-load speed for any brush setting is approximately 5 per cent. to 10 per cent. of the maximum speed of the motor, the exact percentage depending on the size of the motor. A creeping speed can be obtained by inserting a small resistance in each phase of the stator winding.

This motor is more stable than the ordinary induction motor when running at creeping speeds because it has normal operating speeds much below the synchronous speed.

Reversal of direction of rotation is effected by interchanging two of the line leads connected to the slip-rings.

Carbon Brushes.

*British Standard Specification for Parallel-sided Carbon Brushes for D.C. Commutator Machines. No. 96—1922.**

Definitions are given of centre line, brush dimensions, chamfer, and bevel, and these are exemplified by figs. 37 and 38, chamfer being the slope produced by removal of the four edges to prevent binding in holder box, and measured by taking one-half of the difference in side dimensions before and after chamfering (see Table II.). Flexibles to be of twisted copper strand, the

AE, BF, CG, DH are the edges.

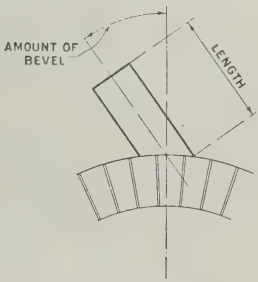

FIG. 38.

diameter of each individual wire not exceeding 0·0048 inch (0·12 mm.). One terminal only of the shoe type pressed on to the flexible shall be provided, the copper terminal shoe for all sizes being suitable for a No. 1 B.A. fixing screw (Table I.). Table III. refers to all classes of carbon and metal carbon brushes. Dimensions of compressed, unburnt graphite brushes increase with temperature. Sizes, when cold, must be stated by maker, and shall be less than values in Table III. at maker's discretion. When hot, dimensions must not exceed the values in Table III. Tolerance

* By permission of the British Engineering Standards Association.

permitted in actual dimensions stated by maker: length +0·060 inch, width +0·008 inch; thickness +0·006 inch to −0·000 inch in each case. The brush boxes shall be of the same nominal size as brushes with tolerances of width +0·008 to +0·001 inch, thickness +0·005 to +0·001 inch.

Electric Power Switchboards.

British Standard Specification No. 162—1928 deals with Electric Power Switchboards for indoor Installations up to and including 33,000 volts.

British Standard Switchgear.

Specifications for air-break switches and circuit breakers for pressures up to 660 volts are given in the *British Engineering Standards Association's Reports* 109—1923 and 110—1923. The specifications do not apply to switchgear for use in circuits containing high inductance. Lists of standard current ratings are given, and it is specified that the temperature rise on continuous full load shall not exceed 20° C. for switchgear rated below 100 amperes, or 30° C. for 100 amperes and upwards.

Distinction is made between: (1) A switch, being a mechanical device for non-automatically breaking a circuit carrying load-current; (2) An isolating switch for disconnecting a circuit only when carrying no load current; and (3) A circuit breaker, a mechanical device for breaking automatically a circuit under abnormal conditions such as that of short circuit.

Marble or slate slabs must be free from metallic veins, and, if of slate, must be treated all over with a damp-proof medium; the slabs are to be insulated from fixing bolts and the supporting framework. The sizes of round copper-back connections and their spacing are tabulated in the Reports. The test pressure to be applied to a switch or circuit breaker is 1,000 volts plus twice the rated pressure, with a minimum of 2,000 volts alternating.

In the case of circuit breakers, the temperature rise of coils is not to exceed 50° C. when the insulating material is impregnated cotton, silk, or paper, or enamelled wire, and 70° with materials such as asbestos, micanite, and built-up mica, and bare coils. Reverse-current devices must be capable of operating with 15 per cent. or less of the rated current; low-voltage releases must not operate unless the pressure falls to 65 per cent. or less of the rated pressure, but must operate before the pressure falls below 25 per cent. of the normal, at the rated frequency. A reverse-current circuit breaker must not be rendered inoperative if the pressure across the potential coil falls to (Class A) zero, (Class B) 50 per cent. of normal, and a reverse-current device must not operate with a forward current of any magnitude. Magnet-closing circuit breakers must operate between the limits 20 per cent. below and above normal pressure, and pressure-operated tripping coils must operate between the limits 50 per cent. below and 20 per cent. above normal pressure at 40° C.

When type tests have been made by a recognised authority, a millivolt drop test is to be accepted in lieu of a temperature test.

Specification 116—1929 gives the standard ratings, sizes, and marking, the temperature and voltage tests for oil-immersed switches and breakers for alternating current circuits. The temperature rise above the cooling air at any part must not exceed that measured at the hottest part of the oil, viz. 30° C. for ratings up to and including 2,000 amperes, 40° C. above 2,000 amperes; when the temperature of the cooling air exceeds 40°C the temperature rise must be such that the total temperature attained does not exceed 80° C. Temperature limits of coils and test voltages for switches as in Nos. 109 and 110; but, when operated from secondary of transformers the maximum testing voltage for coils to be 2,000, and for switches rated for 1,000 volts and upwards, 2,000 volts *plus* 2½ times the rated voltage. These conditions shall also be fulfilled after erection on site. Type tests specify that the circuit breaker shall interrupt its rated k.v.a. breaking capacity twice at a two-minute interval. A switch shall break twice in succession twice the rated current at rated voltage and after this carry its normal current without exceeding limits of temperature rise and then break twice the rated current a third time. A mechanical endurance test is to be carried out by operating 500 times with the main contacts carrying no current. Methods of calculating k.v.a. to be broken and notes on selection of oil circuit-breakers are given in appendices.

Specifications for totally enclosed air-break switches (No. 124—1923) and air-break circuit breakers (No. 130—1923) for circuits not exceeding 660 volts provide, in addition, for efficient earthing of containing case, arc shields and lining, and insulation of the interlocked handle. The insulation resistance must not be less than 10 megohms. No. 194—1926 specifies switchgear equipment for these circuits. No. 195—1929 specifies 33,000-volt, 3-phase switchgear.

Condition to be fulfilled by flame-proof air-break switches and circuit breakers (Nos. 126—1930 and 127—1930) require a test of flame-proofness by subjecting the apparatus to a single breaking test when filled and surrounded with the maximum explosive mixture of methane and air or the equivalent. Switches must then break a circuit carrying a current 50 per cent. in excess of normal at rated voltage on a non-inductive load; circuit breakers to operate under same conditions of current, voltage, and impedance as in service.

Flameproof enclosures for electrical apparatus and tests for flameproof enclosures are standardised in No. 229—1929. The performances required refer to conditions in the coal-mining industry.

Specification 158—1924 standardises bus-bar arrangements, connection diagrams, symbols and distinctive markings. No. 159—1925 gives sizes for bus-bars and connections constructed of bare copper and/or aluminium. Slate slabs for electrical purposes are standardised for tolerance on dimensions, shape, and flatness in No. 160—1923. Switchgear cells and cubicles

constructed of moulded stone, as regards concrete composition and preparation, strength tests on slabs and mouldings, design of cubicles, accuracy and finish are dealt with in No. 268—1926.

Specification No. 214—1929 deals with Distribution Boards up to 250 volts and 30 amperes per way.

Electric cut-outs for low pressure (Type O) are dealt with in Specification No. 88—1919.

In Specification No. 142—1927 of the British Engineering Standards Association, electrical protective relays are classified as to function and characterics. Temperature rise, limits of volt-ampere consumption and error for each type are laid down.

ELECTRO-MECHANICAL BRAKES.

Electro-mechanical brakes are used in connection with a variety of electrically driven machines, such as lifts, cranes, hoists, elevators, conveyors, rolling mills, paper reeling, slip-ways, presses, machine tools, etc., where either a quick 'stop' or adjustable gradual 'stop' is desired when the power is cut off either intentionally or unintentionally.

These brakes consist primarily of an electro magnet which operates the brake blocks through a system of levers or other medium. The magnet is so arranged that, when the current is applied, the magnet is energised and lifts the brake blocks from the drum. If for any reason the current is cut off the magnet is de-energised and the brake blocks are pressed against the drum, the requisite pressure being obtained by springs, weights, or a combination of each.

The brakes are quite automatic in action; thus, in the case of an electrically driven crane, as soon as the driver applies the current to the motor to raise the load the brake is automatically released, and when he switches off the current to stop the brake is immediately applied. Should for any reason the supply current fail, the brake automatically goes on and takes charge of the load.

It is desirable that an electro-mechanical brake should have the following features: compactness of design, robust construction, few and simple working parts, easy adjustment for brake blocks and pressure exerted for same. Coils should be liberally rated, well insulated, and protected from mechanical injury, and so placed that they are not likely to be damagee by oil exuding from the machine. The brake blocks should be readily renewable. If springs are used they should be of the compression pattern.

(*Elliston, Evans & Jackson, Ltd., London.*)

Motor Starters and Controllers.

'Starters' are devices for starting and accelerating a motor to normal speed, and comprise (*a*) Rheostatic starters (face-plate, drum, multiple switch, contactor, and liquid starters); (*b*) Compensation or auto-transformer starters for 2- or 3-phase motors; (*c*) Switch starters (star-delta connections for 3-phase starters, series-parallel connections for 2-phase machines).

'Controllers' (including shunt regulators) are used to regulate the speed of a motor, and may or may not be used for starting.

The following British Engineering Standards Association Specifications deal with starters:—

No. 117—1923. Drum starters for electric motors.

No. 118—1923. Drum controllers and resistances for use therewith, for electric motors (D.C. and A.C. slip-ring).

No. 123—1923. Face-plate controllers and resistances for use therewith, for electric motors (D.C. and A.C. slip-ring type).

No. 141—1923. Switch starters (star-delta and series-parallel) for electric motors (A.C. induction, without slip-rings, 2 to 40 h.p.).

No. 129—1923. Contactor controllers and resistances for use therewith, for electric motors (D.C. and A.C. slip-ring type) (excluding controllers for traction purposes).

No. 140—1923. Liquid starters for electric motors (D.C. and A.C. 2- and 3-phase induction with slip-rings).

No. 147—1923. Multiple switch starters for electric motors (D.C.).

No. 155—1923. Contactor starters for electric motors (D.C. and A.C. 2- and 3-phase induction with slip-rings).

No. 167—1923. Auto-transformer starters (hand-operated pattern) for electric motors (A.C. 2- and 3-phase induction without slip-rings).

No. 246—1927. Face-plate starters for electric motors (D.C.).

No. 247—1927. Face-plate rotor starters for electric motors (A.C. 2- and 3-phase induction with slip rings).

No. 280—1928. Field rheostats for electric generators, motors, synchronous converters and balancers.

AUTOMATIC CONTROL GEAR.

An automatic controller entirely eliminates the personal judgment of the operator in many cases, which is a distinct advantage where men accustomed to heavy work such as is met with in shipyards, steel mills and the like, are called upon to start up large machines. The controllers are now made suitable for practically any purpose, any horse-power, any supply, and for any particular design of motor requiring special starting apparatus.

The foolproof nature of automatic gear is not the only or the principal argument in its favour as compared with hand-operated controllers under frequent and heavy service.

An automatic controller is one in which the current supply to the motor is regulated by means of one or more switch units, each unit being operated by an electro-magnet; the operation of the magnet is controlled by an auxiliary switch, which therefore only has to deal with very small magnet-currents. This auxiliary switch can be put at any distance from the motor in the most convenient place, whereas the main automatic controller can be installed beside the motor, thus effecting the greatest economy in cable connections.

The original face-plate type of starter, which is still the standard type for moderate size motors starting up only a few times per day, has had to give place to the drum type controller for frequently operated motors as on cranes. This type of controller has been greatly improved in its mechanical and electrical construction, but its design has such inherent limitations when it has to deal with the large currents now employed that excessive wear of the contacts is produced. This necessitates constant attention to the wearing parts, and high maintenance charges. By inherent limitations is meant the fundamental fact that in order to carry larger currents the contact pressures must be increased, and such increase greatly increases the mechanical wear, so that in some cases the contacts may have to be renewed after a few weeks' operation. With an automatic controller of proper design, the wear is very much less, and does not increase with the size of the controller. Contacts operating under severe conditions will only require renewal about once or twice a year.

D.C. motors are controlled by a number of solenoid-operated switches or 'contactors' fitted with powerful magnetic blow-outs and arc shields; they are electrically interlocked so that they can only close in correct sequence, and so arranged that the motor cannot be started up except with all resistance in the armature circuit.

In some cases the time intervals between the closing of successive contactors depend upon the acceleration of the motor. This is generally determined by means of series relays fitted to each contactor except the last one. These relays are in the main motor circuit, and are adjusted so as to operate when the motor current drops to the value at which further acceleration is impossible. The operation of the relay closes the control circuit of the next contactor, which therefore closes, thereby cutting out a section of the resistance and speeding up the motor. This is repeated each time until the motor reaches full speed. It is thus evident that the motor current is kept within safe limits while the motor is accelerated to full speed in the minimum time, which means the minimum loss of power in the starting resistances.

The automatic control of any A.C. motor is now as reliable as with a D.C motor, for A.C. switches and contactors are manufactured for controlling motors of any horse-power on high or low tension supplies. A standard controller for a slip-ring motor consists of a stator switch or contactor and a number of D.P. rotor contactors complete with relays, the number depending on the h.p.

The stator switch coil is controlled by a small switch, accumulator switch or float switch, pressure regulator or other means, and on being energised closes the stator switch automatically, and the motor is connected to the mains with all the rotor resistance in circuit.

A time element controls the closing of the first D.P. rotor switch, which, on closing automatically, cuts out a section of the resistance in the three phases of the rotor circuit. As with the d.c. set, this is repeated until the motor is up to full speed with the leads to the rings short-circuited.

Pumps are arranged to stop and start according to the rise or fall of water in a tank by means of float gear and an automatic controller. The automatic control of air compressors is being universally adopted on account of the great convenience and economy effected in many cases, irrespective of the benefit of the elimination of skilled attendance.

Each plant requires individual investigation in order to ascertain the most economical method of control. On a D.C. or A.C. supply the compressor can be arranged to stop and start at maximum and minimum pressures only, or to stop and start at maximum and minimum pressures, the speed being reduced or increased between certain definite pressures, unloading at starting, or to run continuously, unloading only at maximum pressure, when the demand for air is great.

For certain duties, such as lifts, plate-edge planers or live rolls, operated by A.C. slip-ring motors, where a large initial starting torque is usual, the 'Eddystat' controller has many unique advantages. This controller is called an 'Eddystat' controller because it utilises the surplus power required when accelerating, to produce eddy current losses, just as the ordinary resistance type of controller uses up the surplus power in creating an ohmic loss in the resistances. The

controller has no moving parts, but requires a contactor for operating in the stator circuit, and when the duty is such that the motor runs continuously for a considerable period of time, it is preferable to have a double pole switch to short-circuit the 'Eddystat' controller.

The arrangement consists of three solid steel cores and insulated copper windings with tappings, which are connected across the sliprings, as shown in fig. 39. On starting the motor the rotor current is forced through the controller at line frequency, and the highest rotor volts, and produces the maximum eddy current loss. As the motor speeds up, the voltage and frequency decrease in proportion, and consequently the eddy current losses decrease automatically.

DIAGRAM OF CONNECTIONS OF 'EDDYSTAT' CONTROLLER.

Braking and Reversing.—This controller also acts as a very powerful electric brake, because if the stator circuit is reversed when the motor is at full speed, twice line frequency and twice standstill rotor voltage will be applied to the controller. For automatic reversing equipments, such as plate-edge planers or live rolls, this reduces the time of reversal, and increases the output. The maximum current when reversing in this manner is very little in excess of the current taken when starting up from standstill. The controller thus acts like a plugging resistance, but with the additional advantage that a single-speed master controller is sufficient. This eliminates the judgment of the operator, which is necessary when plugging with a three-point master controller. As the 'Eddystat' controller is always connected in the rotor circuit the motor is fully protected, a valuable feature absent in other forms of control.

Oil Immersed Type.—The 'Eddystat' controller is specially suitable for installation in fiery mines, explosives factories and chemical works, as, in addition to having no moving parts, it can be totally immersed in an oil tank, like a transformer.

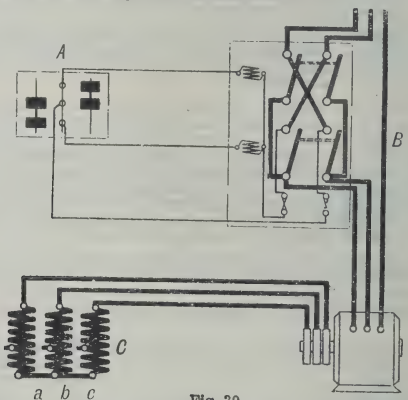

Fig. 39.

A—Master Controller. *B*—Reversing Contactors. *C*—'Eddystat' Controller.

NOTE.—An increase in the starting torque can be obtained by moving the star connection *a b c* up to the tappings immediately above.

A further increase is possible by connecting the coils in delta.

For the control of large cranes, whether the supply is direct or alternating current, the standard practice at the present time is to install contactor controllers on the crane with small master drum controller in the driver's cabin, in preference to the large drum controllers previously used.

Absolute control is afforded, and the manipulation is more efficient, with the added advantage that, due to interlocking, no damage can be caused to the gearing through carelessness. When lowering, the driver can vary the braking effect according to the load; in fact he has as efficient control as with a drum controller, but the apparatus being foolproof needs less care and attention, and frequent repairs are eliminated.

Automatic controllers are being installed in all up-to-date steel works and rolling mills, on charges, blast-furnace hoists, screw-down gear, live rolls, lifting tables, skids, and main rolls.

TRANSFORMERS.

TRANSFORMERS IN PARALLEL.

The simple distributing transformer usually has two high-voltage leads and four low-voltage leads coming out from its windings, as indicated in 1, fig. 40. It will be seen from fig. 2 that the two centre leads of the low-voltage coils are crossed inside the transformer before they are brought out through the case. This does not make any change in connecting the two sections in series on the outside of the transformer, as this is the same as connecting two batteries in series.

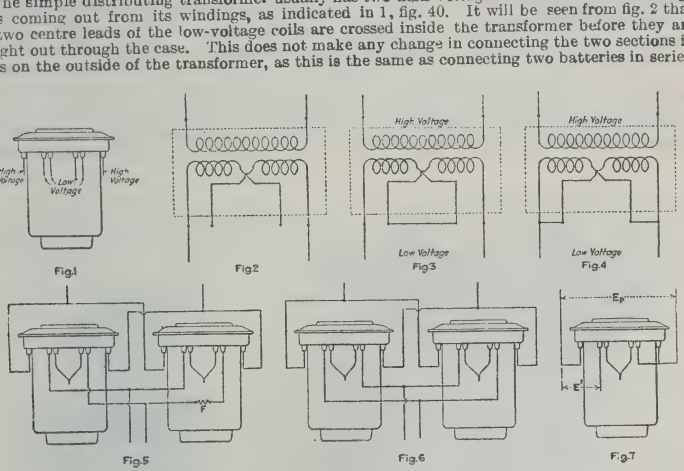

FIG. 40.

When the coils are connected in parallel, care must be exercised and adjacent leads connected together, as in fig. 4. Looking at the connections from the outside of the transformer, it would appear as though the two sections of the winding were short-circuited, but the diagram shows that the right-hand terminals of each section are connected together, also the left-hand terminals. This is just what is done in connecting batteries or other direct-current elements in parallel—like poles are connected.

Transformers to operate in parallel should be the same voltage, frequency, size, and possess the same characteristics, which means that they should be of the same make. In connecting transformers in parallel, it is only necessary to observe the same rules as used for connecting two or more pieces of direct-current apparatus in parallel; namely, connect like poles to like poles. The question now arises which are like terminals on two or more transformers. This is easily determined in most cases. After the transformers are arranged symmetrically, as in fig. 5, connect the right-hand terminals together and the left-hand terminals together and bring out a lead from each junction point, as indicated.

There is, however, a chance that one of the transformers may have its leads brought out in such a way as to cause a short-circuit when the transformers are connected as shown in the figure. To guard against this a piece of small fuse wire may be connected, as indicated at F. If the connections are correct, the fuse will not blow when the transformers are made alive without load, otherwise the fuse will blow. In case of a wrong connection it may be remedied by crossing either the high or low-voltage leads on one of the transformers, as indicated in fig. 6. A better way would be to test the transformers and find out which has wrong polarity and correct it.

The polarity may be tested as represented in fig. 7. Connect the high-voltage terminals to the line and with one terminal of the low-voltage coil to the high-voltage winding, as indicated in the figure. Measure the electromotive force at E*p* and E'. If it is greater at E' than at E*p*, the transformer has the correct polarity; if less, the polarity is wrong and either the high or the low-voltage leads must be crossed inside the transformer. The test may be made with 110 or 220-volt current.

THE ENGLISH ELECTRIC CO.'S. TRANSFORMERS.

In these transformers the windings are designed so that there is ample provision for the circulation of oil; this assures a very low temperature gradient between copper and oil, so that any danger of excessive heating is eliminated. Two patterns are manufactured, viz. the 'core' type

Self-cooled transformers can be built in sizes up to approximately 20,000 kVA. capacity, but in sizes above 4,000 KVA. a saving can usually be made by artificial cooling. Methods of artificial cooling of oil-immersed transformers include a water-cooling coil fitted inside the tank at the top; an outer sheet metal casing for cooling by air blast from motor driven fans; pumping the oil through a cooler of either the water or the air-blast type mounted outside the transformer.

Dry transformers up to about 150 kVA. single-phase and 200 kVA. three-phase are supplied protected by an expanded metal screen. Above this capacity, dry-type single-phase, air-blast transformers have been supplied to a limited extent for ratings from 300 to 1,500 kVA.

The increasing cost of erecting buildings has emphasised the advantages of installing transformers out of doors. This practice is being favoured for large power transformers in the layout of modern large generating stations and sub-stations, for which Metrovick transformers of the outdoor type have been installed for service up to 132,000 volts, and also is being adopted increasingly for power and lighting transformers in rural distribution systems.

A development that is finding increasing favour is a tapping switch mounted within the transformer and operated from outside the case. This switch enables voltage changes to be made quickly and without opening the tank, so that interruption is reduced to a minimum and even at the highest voltages perfect safety is ensured to the operator. Transformers have been supplied so arranged that tap changing can be effected without any interruption in the continuity of supply. Another convenient device for tap changing on distribution transformers is a set of sockets and adjustable plugs. This device enables transformers of a standard voltage to serve the requirements of a whole system, the voltage of individual transformers being adjusted, at the time of installation or subsequently, to compensate for voltage drop in the transmission lines.

Notes on Transformers.

To seal up holes in transformers or oil-switch cases where wires pass through, a mixture of sulphur and plaster of Paris may be used; a mixture containing equal quantities gives a material which sets very hard, and which is impervious to transformer oil. The sulphur should be melted in a ladle or pot and then an equal quantity of plaster of Paris mixed thoroughly into it. This mixture should be poured into place while hot.

Trouble is often experienced from oil being siphoned out of transformer cases on account of the braided insulation on the lead wires. When this takes place it is usually found that the insulation on the wires dips down into the oil. If the oil level is lowered below the terminal board inside the case and the insulation on the leads scraped off so that where the wire enters the surface of the oil its metallic surface only is exposed to possible contact with the oil, and the leads are properly sealed, there will be little trouble due to siphon action.

Mining type transformers are dealt with in B.E.S.A. Specification No. 355—1929.

Terminal Insulator Bushings.

Insulated terminals for transformers and switchgear require careful design for high-voltage working. The two principal types built are (*a*) oil-filled, and (*b*) condenser bushings. In each case it is the object of the construction to make the dielectric stresses or electric field densities sensibly uniform in radial distribution from the high-voltage conductor; and to avoid corona loss. This is effected in the oil-filled bushing by surrounding the conductor where it penetrates earthed metal by a long hollow porcelain cylindrical insulator, the space between the conductor (usually a hollow tube) and the porcelain cylinder being filled with transformer oil. Provision for expansion has to be made to accommodate excess oil due to heating. Condenser bushings are usually composed of bakelised paper and tinfoil wound directly on to the conductor, the tinfoil being arranged in concentric cylindrical layers, separated by bakelised paper, and forming a series of condensers of graded capacity. As far as possible the various capacities are made equal, resulting in a nominally uniform radial distribution of dielectric stress. Thus as the radius of a tinfoil condenser increases, its length is reduced. Condenser bushings are characterised by the 'stepping' of the lengths of successive tinfoil cylinders.

Static Balancers in Three-Phase Circuits.

In three-phase distribution circuits, the voltages commonly used for power purposes are often too high for lighting circuits; accordingly, where lighting is desired, it is necessary to introduce some means of obtaining a reduced voltage. A customary method of providing for this is to take advantage of the fact that by using a star connected generator or transformer having its secondary winding connected in star, it is possible to obtain between any one phase and the neutral point of either generator or transformer a reduced voltage. For example, in a circuit with 400 volts

between the phases, it is possible by taking out a connection from the star point, to obtain a voltage between this point and any one phase of $\frac{400}{\sqrt{3}} = 230$ volts only. To do this, however, the generator or transformer has to be star connected in such a manner that a cable can be brought out from the star point, and this cable must be led to the point where lighting is required. Apart from the cost of this cable, which for any distance is considerable, any out-of-balance lighting would cause unbalanced voltages due to the resistance of this cable and thus would affect the

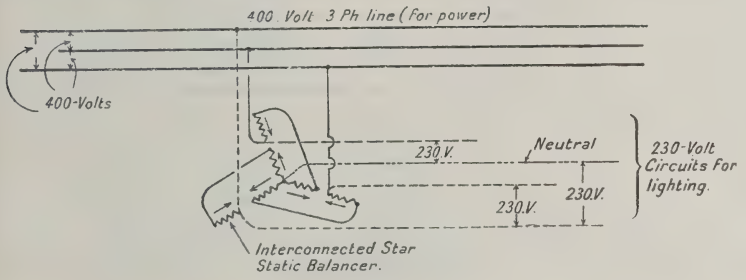

FIG. 42.

lighting detrimentally. Alternatively to the above arrangement, it is possible, by using static balancers, to save the cost of the cable referred to, and also to minimise very largely the out-of-balance effects.

The Metrovick static balancer, which is shown diagrammatically in fig. 42, consists of a three-phase auto-transformer having a lead brought out from the neutral point of the windings, and the three phases so inter-connected, that current flowing through the neutral passes equally through them.

Static balancers for ordinary industrial conditions are quite small, and of correspondingly low cost. On a 100-KVA. circuit, with a maximum out-of-balance current not exceeding 25 per cent. of the full-load current in the outers, a balancer would be similar in size to a 5-KVA. transformer, and under these conditions, the out-of-balance of the phase voltage would correspond to one-third the percentage voltage drop of such a 5-KVA. transformer. In cases where the voltage required for lighting is not exactly but only approximately the line voltage divided by $\sqrt{3}$ a combined balance and auto-transformer may be used to advantage.

The advantages gained by using static balancers are: (1) The balancer may be placed at any point on the system where lighting is required and the length of neutral wire greatly reduced. (2) The drop in the neutral wire is much reduced, so that better voltage balancing is obtained between the different phases. (3) The current is more equally distributed between the line wires. (4) A standard polyphase wattmeter can be used instead of a special four-wire wattmeter. (5) It is possible to supply a four-wire circuit from a transformer group connected in star-star or star-delta, thereby saving in the cost of the main transformers.

Induction Regulators and Booster Transformers.

(The English Electric Company, Ltd.)

The principal applications of induction regulators and booster transformers are:

1. The regulation of feeder voltage under all conditions of load.

2. The control of the reactive current in ring mains and in interconnector cables linking power areas where it is desirable that the station voltages shall be variable independently of each other.

3. The control of the alternating voltage applied to the slip-rings of synchronous converters in order to obtain voltage control on the direct current side.

Booster Transformers.

The apparatus consists of a potential and a series or current transformer. The primary winding of the potential transformer is connected across the mains and the secondary provided with a number of tappings which are brought out to a regulating switch. The series transformer has its secondary winding in series with the line and its primary excited from the variable secondary of the potential transformer, as shown in fig. 43. When the reversing arm of the regulating switch

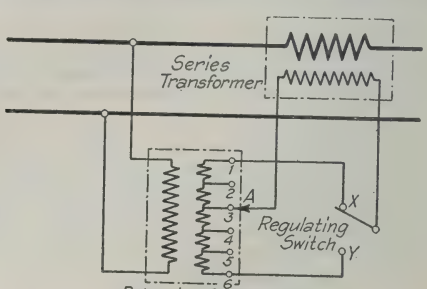

Fig. 43.

is on contact X, and the tapping contact A is on stud No. 1, the primary winding of the series transformer is short-circuited and the secondary of the potential transformer is open-circuited. The voltage of the feeder therefore is unaffected and the potential transformer takes only a magnetising current. As contact A is moved successively to studs 2, 3, etc., a voltage will be induced in the secondary winding of the series transformer and the outgoing line voltage increased. The voltage boost is thus a maximum on stud No. 6. If the operation be commenced with the reversing arm on control Y, then the tapping contact A on stud No. 6 gives normal mean voltage, and movement to successive studs Nos. 5, 4, etc., will induce in the series transformer a voltage opposing the line voltage; while on stud No. 1, the outgoing feeder voltage will be a minimum. To ensure continuity of circuit, the English Electric Co.'s booster transformer has a main circuit breaker and a pilot circuit breaker with renewable contacts which take all the arcing, the pilot breaker completing a circuit through a choke coil or buffer reactance. A 3-phase booster transformer consists of three separate identical units coupled together for simultaneous operation by hand, or motor operated from remote control, or by means of contactors. Where the supply voltage does not exceed 3,000 it is possible to omit the series transformer and to use the tapped secondary winding of the potential transformer directly in series with the line.

Induction Regulators.

Induction regulators provide a means of gradual change in the feeder voltage without the interposition of switches. They consist of two elements, one fixed and the other movable at will through 90 degs. for the 4-pole design and 180 degs. for the 2-pole. In double-range regulators the movements are through 180 and 360 degs. for 4- and 2-pole types respectively. The construction is similar to that of an induction motor, but usually with a vertical shaft. The rotor shaft projects through the tank cover and has keyed to it a worm quadrant which engages through reduction gearing with a handwheel or motor.

With single-phase regulators, the magnetic flux produced by the movable primary winding is pulsating and the voltage induced in the stationary secondary winding, connected in series with the line, is proportional to the amount of this flux linked with it. The movable primary carries a short-circuited compensating winding which is electrically and mechanically at right angles to the primary winding. As the regulator approaches the neutral position the reactance of the series winding is neutralised by this short-circuited coil.

In three-phase induction regulators the magnetic field rotates and the secondary windings are linked by a constant value of flux irrespective of the angular position. The secondary voltage is therefore constant and is added to or subtracted from the feeder voltage by varying its phase angle relatively to the feeder voltage. This is shown in fig. 44, in which OA is the line voltage, OB is the secondary voltage per phase, and AB the resultant feeder voltage. The regulated voltage AB and the unregulated voltage OA are only in phase with one another at the maximum and minimum

positions of the regulator. In ring mains or in an interconnector cable linking generating systems, phase displacement would cause circulating currents to flow. To correct this displacement it is necessary to resort to (1) the twin induction regulator, where each unit is half the total kVA. rating required, or (2) a bank of single-phase regulators.

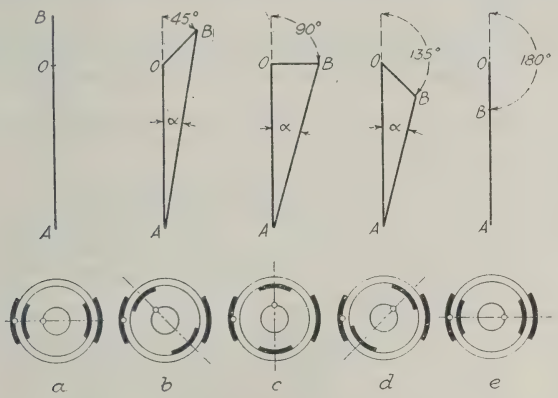

FIG. 44.

The English Electric Co.'s induction regulators are designed for air cooling and for oil self cooling for upwards of 1,000 kVA. in one unit. Very large sizes are designed for forced oil circulation. There is a growing tendency to accommodate induction regulators with the transformers and switchgear of outdoor substations. The operating gear is then enclosed in a weatherproof cover and the control panel, with its sensitive relays, mounted in an air-tight metal cabinet.

Power Factor Improvement.

With the continual growth of alternating current distribution, the necessity of improving the power factor resulting from an industrial load has become more and more apparent, as a low power factor, by reducing the working capacity of the generating plant and mains and lowering the efficiency of the system, adds to both the fixed and the running charges, besides unfavourably influencing the voltage regulation of the network. In fig. 45 curves are given for commercial induction motors at 500 and 1,000 r.p.m., showing the effect of output and speed on the power factor at various loads.

The power factor can be raised by three methods:—(1) Static condensers; (2) Synchronous condensers; (3) Phase adjusters.

(1) Static condensers afford one of the simplest and most efficient solutions of the problem, as they require no attendance and involve very little loss of energy. In the *General Electric Review* of August 1918, W. B. Taylor gives a diagram, fig. 46 (page 2309), by means of which the capacity of the static condenser required to neutralise more or less completely the wattless component of the power can be determined. The use of the diagram is best explained by an example. An a.c. feeder carries a current of 500 amperes at 500 volts, and the power factor is 0·6; required the capacity necessary to raise the power factor to 0·9. Taking on the 0·6 p.f. line the point corresponding to 250 kVA., it will be found that the wattless kVA. (ordinate) is 200 and the energy kW. (abscissa) 150. The 150-kW. ordinate cuts the 0·9 p.f. line at a height corresponding to 73 wattless kVA. Subtracting 73 from 200 gives 127 kVA. as the required condenser capacity. Similarly 88 kVA. would raise the power factor to 0·8 and 47 kVA. would raise it to 0·7.

The effect of added capacity is greatest when the power factor is lowest; owing to the relatively large capacity required to bring the power factor up to unity, it is not commercially advisable to attempt to raise it much above 0·9. The condensers should be fixed near the load, in order to improve the power factor in the mains as well as at the generator. The condensers should be disconnected at times of light load, if the leading current they can then take be not required in other parts of the system. High voltage and high frequency are favourable to the use of static condensers; they are made for pressures up to 750 volts by the *British Insulated Cables, Ltd.*, and for higher pressures they are connected in series. In the case of low pressures such as 400 volts, it may be found economical to install transformers to raise the

voltage at the terminals of the condensers, thus reducing the capacity required. Another method is to insert a suitable amount of inductance in series with the condensers, whereby the pressure across the latter is increased. To protect the condensers, the control switches should be fitted with overload trips, and to prevent accidents due to the stored-up charge, provision should be made for discharging the condensers through resistances when they are switched off. The efficiency of condensers exceeds 99·5 per cent.

(2) Synchronous condensers are simply synchronous a.c. motors, over-excited so as to take a leading current, in which condition they act like static condensers. The motor may be run without load, but in this case the method is costly, and it is preferable to use a loaded motor. A rotary converter can be employed for the same purpose. The necessary capacity to produce

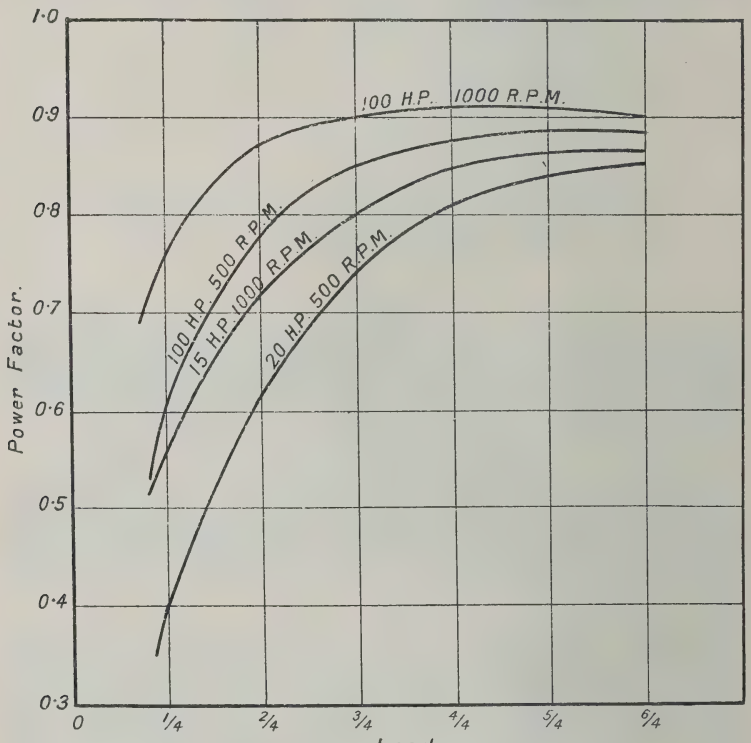

FIG. 45.

a given improvement in the power factor of the system is determined in the same way as that of static condensers, using fig. 46; the greater the mechanical load on the motor, the less will be its condenser effect, the rule being that the square of the kVA. capacity of the machine is equal to the sum of the squares of the kW. load and of the wattless kVA., so that the motor is used to the best advantage when the wattless output = the power output = 0·71 of the kVA. rating of the motor. The synchronous motor is usually started up as an induction motor with the aid of an auxiliary squirrel-cage winding embedded in the poles of the field system, or by means of an induction motor coupled to the same shaft, the field being unexcited until full speed is attained; direct-current excitation must be provided, either by a direct-coupled exciter or by an external source.

(3) The phase adjuster is a special machine, resembling a commutator induction motor, which is coupled to the slip-rings of an induction motor whose power factor needs correction, and is mechanically driven, either from the shaft of the main motor or by a small separate motor, the power taken being only that required to overcome friction and windage, and being fully compensated by reduced losses in the main motor. The function of the phase adjuster is to supply the magnetising current for the motor, thus raising the power factor to unity, or even passing that

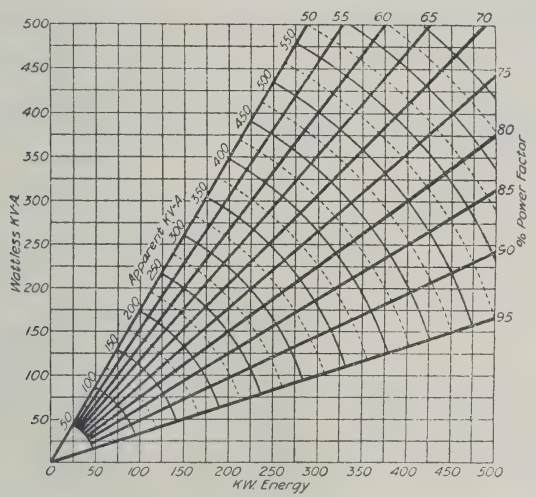

FIG. 46.

point and supplying current to the system to compensate for low power factor in other machines. An oscillatory type of phase adjuster is also made. A great advantage of this method is that the power factor of the individual motor is improved, so that a smaller motor can be used, with reduced losses. Advantages common to all methods are that the losses in the generators and cables are reduced, and the load factor of the plant is raised so that fewer generators need be run, and considerable economy of fuel as well as of capital outlay can be effected.

SIZES OF ENAMELLED COPPER WIRE FOR ELECTRICAL INSTRUMENTS.

A 'tentative' British Standard Specification No. 156—1922, has been issued, giving the dimensions and resistances of enamelled copper wire for instruments and apparatus. The sizes of the bare wires correspond with those given in Specification No. 128—1929. Tests are prescribed as follows:—

Mechanical.—The enamel must not be easily removed from the wire with the thumbnail. Below 0·0084 in. diameter, a 10-in. sample shall be extensible to 11 ins. without cracking the enamel; above that diameter, a sample shall be wound round a mandrel not more than four times the diameter of the bare wire without cracking the enamel.

Chemical.—The enamel shall not be dissolved when immersed for one hour in absolute alcohol or dilute sulphuric acid (sp. gr. 1·25); and the samples shall pass the mechanical tests after immersion as above.

Baking.—After baking at 266° F. for one hour the samples shall pass the mechanical tests.

Electrical.—Test samples twisted together shall withstand an arc test at a pressure varying from 150 volts (R.M.S.) up to 0·0032 in. to 1200 volts above 0·029 in. diameter. A sample passed through a mercury bath at a p.d. of 6 volts d.c. shall not make more than forty contacts in 50 yards.

The thickness of the coating prescribed ranges from $\frac{1}{4}$ mil on the smallest wires to $\frac{1}{2}$ mil at 6 mils diameter, 1 mil at 28 mils diameter, and 1·1 at 48 mils, but wide limits of variation are permitted. Tables of minimum and maximum dimensions are given.

Electric Measuring Instruments.

Ammeters and Voltmeters.—The types available are (1) Moving-coil, permanent-magnet; (2) Moving-iron; (3) Hot-wire; (4) Dynamometer; (5) Induction type; (6) Electrostatic voltmeters.

The following British Engineering Standards Association Specifications deal with electric measuring instruments:—

No. 81—1927. Instrument transformers.

No. 89—1929. Indicating ammeters, voltmeters, watt-meters, frequency and power factor meters.

No. 90—1929. Graphic (Recording or Chart-Recording) ammeters, voltmeters, and watt-meters.

Limits of Error in Ammeters, Voltmeters, and Wattmeters.

B.E.S.A. Specification No. 89—1929 classifies ammeters, voltmeters, and wattmeters into grades of sub-standard, first-grade and second-grade accuracy. The permissible limits of error are tabulated below:—

Table I.

Sub-standard Ammeters, Voltmeters, and Wattmeters.

Instrument.	Limit of Error over the Effective Range expressed as a percentage of the Maximum Scale Value.		
	Permanent-Magnet Moving-Coil Type.	Dynamometer Type.	Other Types.
Voltmeter, single-range, self-contained or with external resistance	0·2	0·3 *	0·5 *
Voltmeter, multi-range, self-contained or with external resistance	0·3	0·4	0·6 *
Voltmeter, for use with voltage transformer	—	0·3	0·5
Ammeter, single-range, self-contained	0·5	0·5	0·5
Ammeter, single-range, for use with separate shunt or transformer	0·3	0·5	0·5

	Single Element for D.C. or Single-Phase or Three-Phase Balanced Load.	Double Element for Polyphase Unbalanced Load.
Special dynamometer wattmeter, as described in Clause 30	0·25	—
Dynamometer wattmeter with single self-contained current-range, and single voltage-range, self-contained or with external resistance	0·5 †	1·0 †
Dynamometer wattmeter, but with single current-range and multi-voltage-range	0·6 †	1·2 †
Dynamometer wattmeter, but with double current-range by series-parallel connection and single voltage-range	0·5 †	1·0 †
Dynamometer wattmeter, but with double current-range by series-parallel connection and multi-voltage range	0·6 †	1·2 †

* For voltmeters with rated voltage exceeding 75 volts.

† Provided that the rated voltage be not less than 75 volts, and the rated current not more than 10 amps., nor less than 1 amp.

TABLE II.

FIRST- AND SECOND-GRADE AMMETERS, VOLTMETERS, AND WATTMETERS.

Instrument.	Limit of Error.			
	From the Maximum of the Effective Range to Half the Maximum Scale Value expressed as a Percentage of the INDICATION.		From Half the Maximum Scale Value to the Lower Limit of the Effective Range expressed as a Percentage of the MAXIMUM SCALE VALUE.	
	First Grade.	Second Grade.	First Grade.	Second Grade.
Voltmeter, single-range, self-contained or with external resistance	1·0	2·0	0·5	1·0
Voltmeter, multi-range, self-contained or with external resistance, permanent-magnet moving-coil type	1·2	2·4	0·6	1·2
Voltmeter, multi-range, of other types	1·5 *	3·0 *	0·75 *	1·5 *
Voltmeter, for use with voltage transformer	1·0	2·0	0·5	1·0
Ammeter, single-range, permanent-magnet moving-coil type, for use with shunt	1·0	2·0	0·5	1·0
Dynamometer ammeter, self-contained, for A.C. 5 or 10 amperes				
Ammeter, single-range, self-contained, or for use with transformer	2·0	4·0	1·0	2·0
Wattmeter, with single self-contained current range, and single voltage-range, self-contained, or with external resistance	2·5	5·0	1·25	2·5
Wattmeter, but with single current-range and multi-voltage range	3·0	6·0	1·5	3·0
Wattmeter, but with double current-range by series-parallel connection, and single-voltage range	2·5	5·0	1·25	2·5
Wattmeter, but with double-current range by series-parallel connection, and multi-voltage range	3·0	6·0	1·5	3·0

To determine the variation in the indication of a wattmeter for use with a 3-phase unbalanced load, the error is found with a balanced load and then with one current coil interrupted, but the same instrument-reading. The difference, expressed as a percentage of the maximum scale value, shall not exceed 0·5 per cent. in a sub-standard instrument, 2 per cent. in a first-grade, and 4 per cent. in a second-grade instrument.

* Provided that the rated voltage of the lowest range is not less than 100 volts, and the ratio of the highest to the lowest range not more than 5 to 1.

Variations due to Temperature.—The standard temperature is 20° C. The percentage variation in the indication of an instrument due to a change of 1° C. in the temperature of the surrounding air shall not exceed :—

Instrument.	Sub-standard.	First Grade.	Second Grade.
Voltmeter . .	0·05	0·1	0·2
Ammeter . .	0·10	0·2	0·4
Wattmeter . .	0·075	0·15	0·3

Variations due to Power Factor.—The variation in the indication of a wattmeter, for a change in the power factor of the load from unity to 0·5 shall not exceed 0·5, 1·0, and 3·0 per cent. of the reading in sub-standard, first-grade and second-grade wattmeters.

Limits of Error in Frequency and Power-Factor Meters.—The errors in a frequency meter shall not exceed 1 per cent. of the mean of the frequencies shown on the scale, nor a change of voltage of 10 per cent. produce more than 1 per cent. change.

The limit of error in a power-factor meter tested from 0·5 to 1·0 power factor at any current not less than one-fifth of the maximum, and at the rated voltage, shall be 2° of angle ; and a voltage change of 10 per cent. from rated value shall not cause a change in the indication of more than ½° of angle.

Weston Standard Ammeters and Voltmeters.

Direct Current.

In these instruments, although the scales are remarkably uniform, no particular 'law' of deflections is assumed, as must be done when printed or engraved scales are used. A skeleton of each scale is laid out by actual comparison with an accurate standard, and the lines afterwards are inked in. Finally, the work is checked by comparison with the same standard. No multiplying constant is necessary (except with high-range voltmeters), as simple inspection of the position of the pointer on the scale gives the value in amperes or volts. Time in making readings is therefore saved, and errors of calculation are avoided. The scales of all direct-current instruments have practically uniform divisions from zero to the top mark. The range is thus greater than is common, while the uniform size of the scale divisions permits of their visual subdivision with uniform accuracy. The pointer comes to rest at once, although absolutely no friction can be detected, thus reducing the time required for readings, and preventing unnecessary wear of the moving parts.

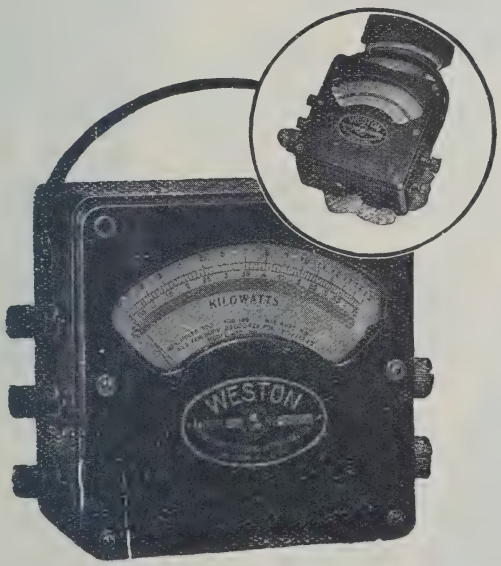
There is no 'magnetic lag,' giving rise to different deflections with the same current or potential, as in instruments having iron in the moving parts. The 'temperature correction' is negligible, being for all voltmeters having a range above 15 volts, not greater than ¼ per cent. for a range of 35° F. above, or 35° below, 70°, and for the ammeter, less than 1 per cent. for the same range of temperature. The instruments of the 'Direct Current' type may be kept in circuit any length of time, as the heating effect, except in the higher ranges, is so small as to be inappreciable. In the voltmeters provided with a 'calibrating' coil, changes in scale-value resulting from accidental injury are easily checked ; this is a very valuable feature, as all instruments are subject to occasional accidents and to rough usage, which may prove injurious. The user of these instruments can at any time roughly check their scale-values by applying a single cell of some constant form to the terminals of the calibrating coil.

Alternating and Direct Current.

These instruments can be used in measuring the current or voltage of both alternating and direct-current circuits with equal accuracy, being of the electrodynamometer type. Owing to the principle of operation, they cannot be made with a uniform scale throughout, but the upper two-thirds of the scale is practically uniform. To prevent errors from parallax, mirror scale-plates and knife-edge pointers are provided. The entire movable and field coil system is mounted in a double closed iron shield, which effectually protects it from external magnetic fields and electrostatic influences. Damping is accomplished by means of an air damper, which is very effective.

WESTON

ELECTRICAL INSTRUMENT CO. LTD.



SMALL TYPE PORTABLE A.C. INSTRUMENTS.

These new instruments are supplied as Wattmeters, Voltmeters, Ammeters and Mil-ammeters.

They are guaranteed accurate to ½% on D.C. Circuits or A.C. Circuits of any commercial frequency.

The scale length is 3·8″ and a set of four instruments, including our new Model 461 Current Transformer may be conveniently carried in a small suit case.

F. 2313

In voltmeters it is necessary for great accuracy to have the current taken by the instrument as small as practicable; the Weston Model 341 voltmeter is designed with this object in view, and the current required is much less than is usual in this type of instrument. For ordinary measurements no corrections are necessary for temperature or for frequencies up to 133 cycles per second, nor is it necessary to take reverse readings on direct-current circuits. When great accuracy is required, however, such corrections can be made. The instruments may be left in circuit continuously. In general, they are guaranteed to have an accuracy of ½ of one per cent. of full-scale value on the working portion of the scale.

Similar characteristics are found in the portable wattmeters made by the company.

All ammeters are really milli-voltmeters, as they merely measure the drop of potential across a constant resistance. This constant resistance is termed a shunt. The potential drop is directly proportional to the current passing through the shunt, and if the shunt is correctly designed, the instrument can therefore be graduated in amperes. The resistance of these shunts is very low: for a Weston switchboard ammeter of 100 amperes the resistance of the shunt is approximately 0·0005 ohm. The shunt must not be strained when fixing to the bus bars, for straining might affect the resistance and so alter the reading of the instrument. For this reason shunts are usually securely fastened to a base of hard wood. Low-range ammeters up to about 200 amperes can have the shunt contained within the instrument case. The resistance of the instruments does not exceed about 2 ohms, and about 25 to 30 milli-amperes is required for full-scale deflection.

Voltmeters which are placed directly across the circuit must be high-resistance instruments. These only require about 10 or 15 milli-amperes for full-scale deflection. For special testing work Weston voltmeters can be obtained which have a resistance of 2,500 ohms per volt, and only require 0·0004 ampere for full-scale deflection. It is important to have a high-resistance voltmeter for testing the E.M.F. of dry batteries, etc.

Owing to the temperature coefficient of copper being high, all copper in the instrument should be reduced as much as possible to eliminate temperature errors. The moving system should be as light as possible to reduce the wear upon the pivots, which should work in good jewels. The air gap must be small to ensure the permanence of the magnet, which must be specially aged and carefully made. In Weston instruments the air gap is approximately 0·04 in. Any number of different range shunts may be used with moving coil ammeters, so that accurate readings may be taken over a wide range.

More current is required to operate moving iron instruments than is necessary for moving coil instruments. For this reason moving iron voltmeters are not suitable for testing dry cells. The resistance per volt of moving iron instruments is about 12 to 20 ohms, against 60 to 100 or higher for moving coil instruments. The pointers of moving iron instruments always move in one direction, irrespective of the direction of flow of the current, and cannot therefore be made with centre zero. They will not have such uniform scales as moving coil instruments, the scale being contracted at one end, and in some instruments at both ends.

In reading instruments, the eye, the pointer, and the mark on the scale should be in a line at right angles to the plane in which the pointer moves, in order to avoid errors due to parallax. In edgewise instruments this line of vision must pass through the centre of the arc swept out by the pointer; one eye must be closed. In multi-range instruments each range should be a simple multiple of the other ranges; and the figures upon the scale of the instrument should preferably indicate the number of scale divisions. An instrument having a range of 150 or multiples thereof should be calibrated to have 150 divisions, figured 0–150. There is less liability of error in reading direct in scale divisions, and afterwards multiplying by a correct constant, than in mentally calculating the value of a fraction of a scale division, especially if there is a rapidly fluctuating load.

The accuracy of an instrument is best expressed as a percentage of the maximum load the instrument is intended to measure. For instance, an instrument having a range of 500 volts with an accuracy of $\frac{1}{10}$ per cent. should be correct at every point upon the scale to within half a volt. If the instrument has 100 scale divisions, this corresponds to $\frac{1}{10}$ of a scale division, which could be accurately read upon a portable instrument with a knife-edge pointer working over a mirror to eliminate errors due to parallax. If, however, the accuracy is taken as a percentage of the actual reading, when reading this instrument at 100 volts the error would not have to exceed 0·1 volt, which would correspond to $\frac{1}{50}$ of a scale division, and would not be readable by the naked eye. If the instrument is supplied with an additional range to read 0–100, an accuracy of $\frac{1}{10}$ per cent. upon this range would represent 0·1 volt, and would correspond to $\frac{1}{10}$ of a scale division.

The Synchroscope

Apart from special methods only applicable to polyphase machines, two devices are in general use for synchronising alternators, (*a*) the synchronising lamp or voltmeter, and (*b*) the rotating field synchroscope. The former is more simple, but suffers from the defect of being insensitive as regards the exact moment of switching in, which should be when the machines are in exact coincidence of phase. Machines may be as much as 16° out of phase before the synchronising voltmeter shows 1 per cent. of variation from its maximum reading, so that a little error of judgment may result in a considerable shock on switching in. A further objection is that although the rapidity of fluctuation of the lamp or voltmeter reading indicates the difference between the frequencies of the machines, there is nothing to show which of the two machines is the faster, and considerable time may thus be wasted. In order to make the lamp method of real service, therefore, it is necessary to combine it with some device for indicating exact coincidence of phase and also whether the incoming machine is fast or slow; and this is what has been done in the Weston Synchroscope.

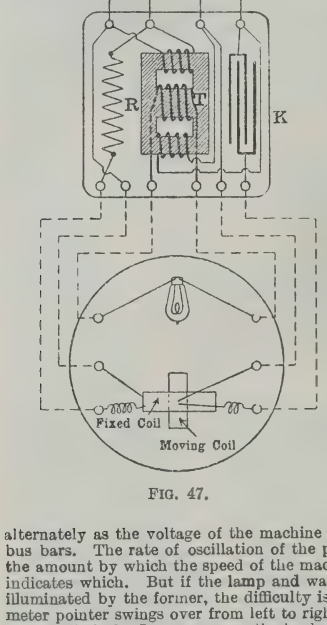

FIG. 47.

If an ordinary dynamometer wattmeter has both its fixed and moving coils wound with fine wire, and two alternating voltages are applied to the terminals of these coils, it will show very accurately when these two voltages are in exact *quadrature*, as the wattmeter will indicate zero in this case, and deflect to right or left if the phase difference is greater or less than 90. By connecting a condenser in series with one of the coils, and introducing a small amount of inductance into the other, it is easy to arrange that the wattmeter indicates zero when the two voltages are in phase instead of in quadrature, and this can be checked by connecting the two circuits to the same supply. Under these circumstances, if one circuit is connected to the bus bars and the other to the incoming machine it is only necessary to see that the synchronising lamp is bright and the wattmeter pointer at zero to be able to throw in without any shock.

But this only indicates when the machines are in exact synchronism, and not whether the incoming machine is too slow or too fast. If the speed of the incoming machine is low or high, the lamp will flicker in the ordinary manner and the wattmeter will also deflect to right and left alternately as the voltage of the machine alternately lags and leads with respect to that of the bus bars. The rate of oscillation of the pointer, like the rate of fluctuation of the light, shows the amount by which the speed of the machine is high or low, although neither of them by itself indicates which. But if the lamp and wattmeter are combined, so that the dial of the latter is illuminated by the former, the difficulty is at once solved. For if the machine is fast the wattmeter pointer swings over from left to right while the lamp is bright, while when it swings back the lamp is dark. In consequence the back swing is not seen, and instead of the pointer appearing to oscillate it appears to rise with the dawn of light at the left-hand side of the scale, to swing across in full light and to disappear on the right of the dial with the extinction of the light, almost exactly like the rising and setting of the sun, and as if it were steadily revolving in one direction. When the machine is slow, the lamp is bright as the pointer swings from right to left, and the direction of rotation is therefore apparently reversed. As far as its practical application is concerned, the instrument resembles in every way the rotating field synchroscopes (except that the fluctuation of the light is visible), and the arrangement is extremely simple, and free from any loose contacts.

The actual indicating instrument is almost identical in construction with the switch-board wattmeter, the only differences being that the dial carries a bold central mark with two arrows indicating 'Fast' and 'Slow,' and that the synchronising lamp is inserted behind it. This lamp can be easily withdrawn and replaced. An auxiliary box contains an ordinary synchronising transformer, T, for the lamp, and a non-inductive resistance, R, and a condenser, K, for connecting in series with the two wattmeter coils respectively. A small inductive coil for adjusting the exact quadrature is included in the instrument case. Fig. 47 is a diagram of the connections of the instrument and box, which will be readily understood from the principle of the instrument.

METERS

In all commercial motor meters there is necessarily a certain amount of friction, which as time goes on tends to increase more or less according to the design, and to cause the meter to slow down. This defect manifests itself particularly at low loads, and is the more serious as the majority of meters are worked at points very low down on their load curves. For long periods the working point is frequently at or below one-tenth full load capacity, and in many instances, particularly where metal filament lamps are used, the working load is liable to be between one-twentieth and one-fiftieth the full load capacity of the meter for many consecutive hours daily.

Pointer type clocks should have light machine cut gears, and should run with an exceedingly small amount of friction, which, being constant, is easily compensated for. This fact constitutes an important advantage in favour of clocks of this type.

Roller cyclometer clocks have more friction than the pointer type, and moreover possess the defect that as the friction is a varying quantity it cannot be compensated for. A meter may have to move round one counter only, or again it may have to move up to five counters at one time.

Jumping figure cyclometer clocks are a modification of the roller type, having the friction load more evenly distributed through the use of a falling weight device. This weight is wound up slowly by the meter. It is released at the proper time, and in falling carries round the additional counters which it is necessary to move.

This partial equalisation of friction makes cyclometer clocks which have springing figures better than the roller type, although not so good as the pointer type clocks, where the friction is a constant quantity. An important feature of springing figures in comparison with roller type counters is that with the former no halving of figures takes place.

Manufacturers are generally willing to guarantee the accuracy of their meters, so that a.c. meters can be obtained which are capable of easy adjustment within plus or minus 2 per cent. from 50 per cent. overload down to one-fiftieth of full load.

The voltage drop in the main coils should be as low as possible. The drop varies with the size of the meter, being greatest in the smaller sizes and diminishing as the ampere capacity increases, due to the fact that in meters of large capacity fewer turns are required to create a similar torque. The loss in the shunt circuit should also be small, but should not be reduced at the expense of the torque, as in meters where the torque is reduced in consequence of the current in the shunt circuit being very low, the retarding effect of friction becomes great, affecting the accuracy of the meter under low load conditions. Moreover, with low torque more compensation will be required to balance the friction, and under such conditions trouble from 'creeping' through vibration, due to street traffic or other external causes, will be much more liable to occur.

A record should be kept of the life of every meter on the system of any supply undertaking. As meters are received from the makers they should be checked against a standard which should be certified from time to time by some recognised authority such as the National Physical Laboratory. This check should be made at various loads, say 125 per cent., $\frac{3}{4}$, $\frac{1}{2}$, $\frac{1}{4}$, $\frac{1}{10}$, $\frac{1}{20}$ and $\frac{1}{50}$ full load, at unity power factor, and at half load 50 per cent. power factor, and the results obtained should be plotted on a card; a note of any subsequent attention required by the meter should be added to its record, and at the end of recognised intervals—say every two or three years—each meter should be brought in for overhaul and tested carefully before breaking any seals. The result obtained should be added to the record, thus affording a means of continuously studying the behaviour of every meter.

The following tests, arranged in order of their relative importance, are easily made:—

(1) Accuracy at varying currents from 2 per cent. to 150 per cent. load with voltage frequency and power factor constant. (2) Accuracy at varying voltage with constant current and frequency. (3) Accuracy at varying power factor with voltage, frequency, and current constant. (4) Accuracy at varying frequency with constant load and voltage.

British Standard Specification for Electricity Meters.

(*No.* 37—1930.) (*Abstract.*)

Two grades of accuracy—'sub-standard' and 'commercial'—are classified. The following provisions apply to both unless otherwise stated.

The construction of the meter shall be mechanically sound and suitable for its purpose and shall be such as to give reasonable assurance of permanence in all mechanical, electrical, and magnetic adjustments, and shall not be seriously affected by external magnetic fields.

The parts of the meter within the case shall be carried on a substantial stiff framework forming, if desired, part of the case. The framework shall not be liable to distortion by changes of temperature, presence of moisture, or other cause. They shall be completely enclosed in a substantial dust-tight metal case, the front and sides of which may be glazed. The case shall be of sufficient strength to afford adequate protection to the working parts against mechanical injury with reasonable usage, and capable of being sealed in such a manner that access to the working parts and the electric or magnetic adjustments of the meter can only be obtained by breaking the

seals. Care shall be taken to ensure that the mechanism as well as the interior of the case is free from dust or other extraneous matter immediately prior to sealing. Provision to be made for earthing any accessible metal part when case is closed.

One or more substantially glazed dust-tight windows shall be provided in the front of the case in such a manner as to give a clear view of the register, and also of those working parts the observation of which is necessary for rapid testing of the meter. It shall be impossible to remove the glass without breaking the seals of the case or breaking the glass itself. The case, etc., to be protected by an efficient coating of paint or suitable material.

The terminals of the meter itself shall be insulated with non-hygroscopic material and, unless of the switchboard type, shall be enclosed by a separate cover suitable for sealing, or contained in an external compartment of the case.

All meters of sizes above 100 amperes shall be provided with soldering sockets, except where provision is made for coupling with strip or bar connections. The left-hand terminal seen from the front shall be the positive in D.C. meters, and be connected to the incoming main in A.C. meters (or to transformer secondary of same polarity).

The pressure circuit shall be connected to the supply side of the main circuit, and a disconnecting device shall be provided in the terminal compartment, to enable the pressure circuit to be entirely disconnected from the main circuit, in order that it may be supplied with current from a separate source for purposes of testing. The disconnecting device is not necessary where separate terminals are provided for the pressure circuit.

The meter, unless of the switchboard type having external connections, shall be provided with separate facilities enabling the purchaser to seal independently the terminal compartment and the meter case. Facilities may also be provided for independent sealing by the manufacturer.

Every meter, the accuracy of which is affected by small changes in level, shall be provided with means of ascertaining, without breaking the seals, that it is correctly levelled.

A diagram of connections to be attached to the meter.

The circuits of the meter shall be capable of carrying full load continuously without injury to any part of the meter, without any permanent change in its accuracy, and without the temperature of any accessible part of the case exceeding 10° C. above the temperature of the surrounding air, except when a shunt is employed in a separate compartment forming an integral part of the meter, when the temperature of any accessible part of the case of such compartment shall not exceed 30° C. above the temperature of the surrounding air.

Every external resistance shall be completely enclosed in a strong metal case.

Every external resistance shall be so constructed that when the marked pressure is applied to the meter and resistance combined and is maintained continuously, no injury shall be done to any part of the resistance, and the temperature of any accessible part of the case shall not exceed that of the surrounding atmosphere by more than 30° C. The full-load speed shall not exceed 100 r.p.m. for a D.C. and 50 r.p.m. for an A.C. meter.

The insulation resistance between all the electric circuits of the meter coupled together, and the containing case, or other metal not intended to be insulated when the meter is in use, shall be not less than 5 megohms.

The insulation resistance between the main circuit and the pressure circuit (if any) shall be not less than 2 megohms.

The insulating material between all the electric circuits and the containing case, or other metal not intended to be insulated when the meter is in use, shall withstand, for one minute, an alternating pressure equal to twice the pressure of the circuit for which the meter is intended, plus 1,000 volts for voltages above 660, and 2,000 volts (alternating) on meters for circuits up to 660 volts, and on all meters used with transformers.

The insulation resistance shall be measured with a pressure of not less than 200 volts nor more than 500 volts (direct), applied for a sufficient time for the reading of the insulation indicator to become practically steady.

The rate of loss of energy in the pressure circuit at marked pressure shall not exceed the values given in the following table :—

Meter (Commercial Grade).	Marked Pressures up to 250 volts.	Marked Pressures above 250 volts.
Direct current . . .	5 watts	2 watts per 100 volts
Alternating current . .	2 watts below 50 cycles 1·8 watt, 50 cycles or above	1 watt per 100 volts

The rate of loss of energy in the meter current circuit for all meters having a marked current not exceeding 50 amperes shall not exceed the following values; with the further restriction that the pressure drop shall not exceed 1 volt.

Marked Current.	D.C. Meters.	A.C. Meters.
	Watts.	Watts.
Up to and including 10 amperes . .	5	2
Above 10 amperes and up to 50 amperes .	5	3

If the marked current exceeds 100 amperes, the voltage-drop in the shunt and meter combined when carrying the marked current shall not exceed 0·25 volt.

When the meter has more than one element the above requirements shall apply to each element independently. This clause shall not apply to electrolytic and commutator ampere-hour D.C. meters.

The forward direction of rotation of the rotor, if any, shall be clearly indicated and shall be from left to right, viewed from the front.

The following shall be the standard sizes of meters:—2·5, 5, 10, 20, 40, 50, 100, 150, 200, 300, 400, 500, 600, 800, 1,000, 1,500, 2,000, 3,000, 4,000, and 5,000 amperes.

When a current equal to 0·5 per cent. of the marked current of the meter (or when this is less than one-twentieth of an ampere, then one-twentieth of an ampere) traverses its main circuit, the rotor shall start and continue running steadily, the pressure circuit, if any, being energised at the marked pressure to give a condition corresponding to unity power factor in the main circuit.

The error at the standard or marked temperature, voltage, and frequency shall not exceed the following values. These accuracies shall be obtained with shunt, transformers, or auxiliary apparatus connected.

A.C. METERS, COMMERCIAL GRADE.

Conditions of Test.		Limits of Error.	
Current expressed as a Percentage of the Marked Current.	Power Factor.	Meters without External Shunts or Transformers.	Meters with External Shunts or Transformers.
	Per Cent.	Plus or Minus. Per Cent.	Plus or Minus. Per Cent.
125 to 20 . . .	1·0 to 0·5	2·0	2·5
20 to 10 . . .	1·0	2·0	2·5
At 10	0·5	2·5	2·5
At 5	1·0	2·5	2·5

D.C. METERS, COMMERCIAL GRADE.

Size of Meter.	Conditions of Test.	Limits of Error.
		Per Cent.
Below 10 amperes .	125% to 10% of marked current	± 2·5
10 amperes and over .	125% to 10% of marked current	± 2·0
	At 5% of marked current	± 2·5

For sub-standard meters of all types the error shall not exceed ± 1·5 per cent. under any of the following conditions :—

Type.	Percentage of Marked Current.	Power Factor.
		Per Cent.
A.C.	100 to 20	1·0 to 0·5
A.C.	20 to 10	1·0
D.C.	100 to 10	—

In addition, the total change of error over the range of the above conditions shall not exceed 1·5 per cent.

If the meter has a pressure circuit, a variation of 5 per cent. in the case of D.C. meters and 10 per cent. in the case of A.C. meters, above or below the marked pressure at any load from full to one-tenth shall not cause a change in the rate of registration in respect of such variation of more than 1 per cent.

Except D.C. mercury type for marked currents of 10 amperes and less, the temperature coefficient shall not exceed 0·2 per cent. per degree C. ; for A.C. induction meters 0·1 per cent. per degree C. at unity power-factor and 0·15 per cent. at 0·5 lagging at the marked current and 50 frequency ; for mercury meters for 100 amperes and above, 0·1 per cent.

The change in rate of registration from the time the main marked current is switched on to the time at which the rate of registration becomes constant shall not exceed the following values ; the voltage having been continuously applied for not less than six hours and no current in excess of one quarter of the marked current passed through the main circuit during this period.

	Commercial Grade.	Sub-standard Grade.
	Per Cent.	Per Cent.
Induction watt-hr. meters :		
At unity power factor .	0·75	0·5
At 0·5 power factor (lag)	1·5	0·75
All other types . . .	2·0	1·0

A variation of ± 5 per cent. from the marked frequency shall not cause a greater variation than 0·5 and 1·5 per cent. at unity and 0·5 (lag) power factors respectively in commercial grade, and 0·25 and 0·5 per cent. in sub-standard meters.

The meter shall not be injured nor accuracy impaired by overloads for 30 minutes of :—100 per cent. for whole-current meters rated up to 50 amperes ; 50 per cent. for whole-current meters from 50 to 1,000 amperes ; also all meters with current transformers and shunts ; 25 per cent. for whole-current meters rated above 1,000 amperes ; with compound-filled transformers, 25 per cent. The meter shall also withstand the passage of 30 times the marked current for not longer than half a second, the rotor, if any, being free to rotate, and the pressure circuit energised at marked pressure. No test current need exceed 15,000 amperes.

The meter shall maintain all these specified accuracies for 1 year after calibration, and other requirements for 3 years.

The accuracy of a 3-wire D.C. meter shall not change more than 1 per cent. when no current flows in one circuit : a polyphase meter shall comply with specification on balanced and unbalanced loads.

The meter shall not be injured, and its accuracy shall not be permanently impaired, by the application of a pressure 25 per cent. above the marked pressure for a period of half an hour.

Every meter having a pressure circuit shall not register with its main circuit open when the pressure circuit alone is acting, either when marked pressure is applied or when this pressure is increased to 10 per cent. above the marked pressure.

Insulation Measuring Instruments.

(Evershed & Vignoles, Ltd.)

These instruments are very largely used for the measurement of the resistance of insulators and conductors; they embrace ranges from 1 microhm up to 10,000 megohms. All are direct reading in the strictest sense, and the ruling feature of each is to provide a means of measurement which shall be so simple that it can be used by any unskilled person, so rapid to use that a test shall occupy but a few seconds, and so portable that the instrument can be taken anywhere to do the work required.

The 'Megger' Testing Set consists of a moving-coil type ohmmeter combined in one box with a high-pressure generator driven by a folding crank handle. The general principles of the construction and the electrical connections of the set are shown in the following diagram.

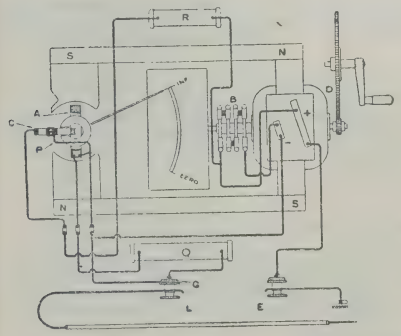

Fig. 48.—Megger Testing Set. Diagram of Connections.

A = current coil; P = pressure coil; C = compensating coil; N, S = magnets; Q, R = resistances; B = brush gear; D = driving gear; + − = generator terminals; G = guard plate; L = external 'line' terminal; E = external 'earth' terminal.

In external appearance the 'Megger' testing set is similar to the 'Bridge-Megger' testing instrument shown by fig. 49, but without the terminals at the end of the case. To carry out an insulation test on a system, connect the 'line' terminal to the circuit and the 'earth' terminal to a good earth. If testing between two wires, connect one wire to each terminal.

When the handle of the generator is turned at about 100 r.p.m. the rated voltage will be developed, and the value of the insulation resistance under test will be indicated directly by the pointer over the scale. The instruments are fitted with either variable or constant-pressure-generators; the constant-pressure type should always be used when testing the insulation of circuits having considerable electrostatic capacity, such as large house-wiring installations, supply and feeder cables, etc. The constant-pressure device consists of a centrifugal friction-clutch, which secures that when the handle is turned above the slipping speed, the speed of the generator, and consequently the terminal E.M.F., remains constant. All 'Megger' and 'Bridge-Megger' testing sets are provided with a system of guarded insulation to ensure that no internal or surface leakage can affect the readings. Any error in tests of high insulation due to leakage across the surface of the material under test can be eliminated by the use of a guard wire connected to the 'guard' terminal, which is provided on all high-range instruments.

The Bridge-Megger Testing Set, fig. 49, is a combined ohmmeter and generator of the usual 'Megger' type for insulation testing, but also arranged so that the ohmmeter can be converted into a Bridge Galvanometer by means of the change-over switch fitted. The current for the Bridge tests is provided by the generator (constant-pressure type), and a direct-reading

resistance box of special and convenient design is supplied as a standard of comparison. The whole combination forms the most rapid known means of measuring that range of resistances for which the Bridge method is adapted, and the value of the resistance is given plainly in a row of figures, which prevents errors. The series of ranges covers Bridge measurements from 0·01 ohm

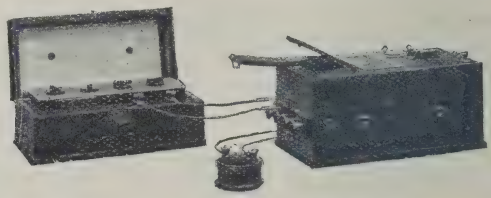

FIG. 49.—Bridge-Megger Testing Set in Use.

upwards, and insulation measurements up to 2,000 megohms. In addition to the measurement of insulation and conductor resistances, the set may be used for the localisation of faults on telephone and telegraph cables, or on electric light cables if their resistance falls within the limits of Bridge methods.

THE 'DUCTER' POTENTIAL OHMMETER TESTING SET provides for the measurement of resistances from 1 microhm up to 100 ohms by the direct deflection method. The current for this set is supplied by a separate battery, and a pair of duplex handspikes are used for making contact on the resistance under test. With these instruments the resistances of switch and fuse contacts, armature windings, rheostat coils, rail-bonds, sheathing and earth circuits in collieries, joints and the like, are easily and rapidly determined.

MEG INSULATION TESTER.

The most recent development in Evershed & Vignoles' resistance-measuring instruments, is the 'Meg' Insulation Tester (fig. 50), which was introduced in 1922. While the Megger and Bridge-Megger continue to be the standard instruments where the measuring instrument must be capable of dealing with a very long range of resistance values, it was felt that there was room

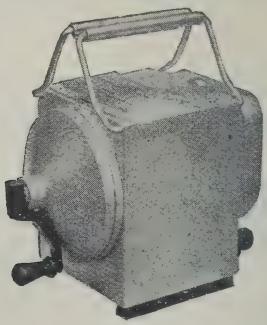

FIG. 50.

or a smaller, lighter, and less costly instrument of the Megger type. The 'Meg,' with its ranges up to 20, 50 or 100 megohms, is quite suitable for most classes of insulation testing, and is used very extensively for switchboard wiring, testing generator and motor coils, etc. Two models of the 'Meg' insulation tester are made for variable pressure and constant pressure, the latter having a speed-control device which ensures constant voltage, an important feature where the capacity of the insulation to be tested exceeds 0·5 microfarad, as, for instance, house wiring, insulation, etc.

ELECTRIC LAMPS.*

Metal Filament Lamps.

The gas-filled lamp, like the vacuum lamp, which it is rapidly replacing, has a filament of tungsten, the melting point of which is over 3,000° C.; this fact enables the filament to be operated at a higher temperature than any other metal, with the result that a high proportion of its total radiation is in the visible spectrum. While the melting point of tungsten is very high it oxidises readily at quite a low temperature (about 300° C.). When new it can be readily bent into any desired shape. It is this property which facilitates the manufacture of the filament, both in the ordinary up and down winding and also in the spiralised form.

In a tungsten lamp an increase in voltage produces an increase in resistance (in a carbon filament the resistance under such variation remains practically constant). Fig. 51 shows the relationship between watts and voltage of a modern Tungsten electric lamp, while the lumen characteristic is shown in fig. 52.

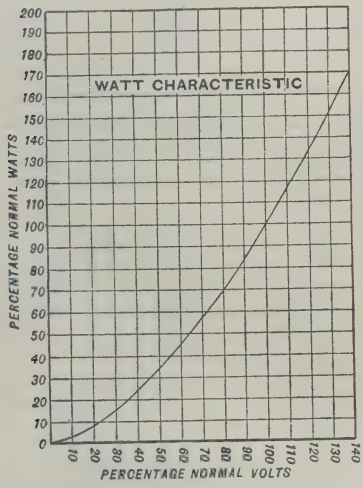

FIG. 51.

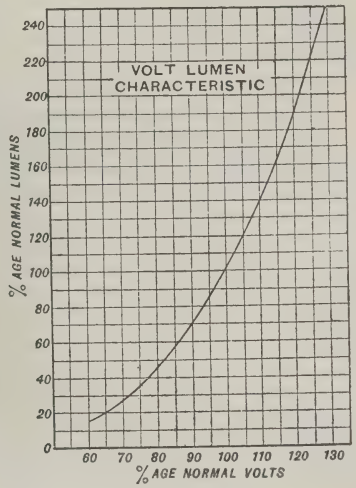

FIG. 52.

An increase in voltage produces an increase in temperature of the filament, so that a very great volume of light is obtained. An increase of 10 per cent. volts brings about an increase of 41 per cent. in light output, while a reduction of 10 per cent. reduces the light output by 32 per cent. For this reason under-running is to be greatly deprecated in view of the great loss of luminous energy. On alternating current of low frequency a flickering is obtained dependent upon the heat capacity of the filament itself, but the remedy in such cases is to eliminate the use of small lamps by installing a smaller number of larger units. This effect of flickering is less conspicuous in the tungsten lamp than in the carbon lamp because of the temperature coefficient. As far as possible it is recommended that where difficulties are experienced in this direction that lamps of not less than 100 watts be employed.

In the case of the gas-filled lamp the bulb temperature is considerable, while the lamp which is not gas-filled remains comparatively cool.

All lamps manufactured in this country by the members of the Electric Lamp Manufacturers Association are made in accordance with specifications which ensure that a uniform product is obtained of a standard quality.

MAZDA LAMPS.

(*The British Thomson-Houston Co., Ltd.*)

Mazda lamps, the filaments of which are made from pure-drawn tungsten wire, give a brilliant white light. They can be operated satisfactorily in any position, but in the larger sizes it is better to use the lamps set vertically. The lamps operate equally well on either continuous or alternating current circuits.

Mazda lamps, including both the vacuum and gas-filled types, have made it possible to design lighting units of suitable sizes for all lighting conditions, and of such high efficiency as to compete effectually with all other types of artificial illuminants. Users of electric light have a choice of sizes ranging from 5 watts to 1500 watts. Every size is adapted, as regards filament position and shape of bulb, for use in conjunction with specially designed glass or metal reflectors.

The gas-filled lamp is claimed to give, for the same current consumption, considerably more light than the previous best incandescent lamp. The recent development of 30 and 40 watt gas-filled lamps in standard supply voltages has brought the advantages of the gas-filled principle within reach of the ordinary householder.

The strength and durability of the drawn wire filament ensure satisfactory results from Mazda lamps under all conditions of service. They have successfully withstood the severe conditions of use aboard battleships during target practice.

* By permission of the British Engineering Standards Association.

† The Committee responsible for the preparation of this Schedule recommends the use of the 24-volt Lamp for Train Lighting.

The flexibility of the Mazda drawn tungsten wire has made possible the production of special forms of filaments which could not be produced with a brittle squirted tungsten wire used in previous lamp bulbs. Helical coil filaments, as used in Mazda headlight bulbs, are better in regard to focus than the types of filaments hitherto employed.

The intrinsic brilliancy of the lamp is stated to be eight times that of ordinary metal filament lamps.

The gas-filled lamp is now made in small sizes for headlight use. The master patents governing the manufacture of Mazda vacuum and gas-filled lamps are the property of the makers of Mazda lamps.

Siemens Lamps.

(Siemens & English Electric Lamp Co., Ltd.)

These lamps have drawn tungsten wire filaments, and the Standard Vacuum type operate at an efficiency of, approximately, 1·2 watts per c.p. The 'gas-filled' lamp represents the latest development in metal filament lamp manufacture, and the larger sizes attain an efficiency of, approximately, 0·5 watts per c.p. Both types of lamps are made in an extensive range of voltages and candle-powers.

Siemens Standard Type Lamps.—These are made in voltages from 20 to 260, and in wattages from 5 to 60, and cover the lamps in general demand for ordinary electric lighting schemes of average intensity.

Siemens Traction Type Lamps.—This type of lamp has been introduced to meet the requirements experienced in situations where lamps are subjected to severe shock and vibration, and is now largely used on the leading tramway systems and tube railways. A totally new arrangement of the filament is employed, which ensures maximum strength and adequate support. The complete length of filament is spiralised and carried in a series of loops on a special spider in the usual Siemens manner. The distance between the top and bottom supports is considerably reduced, which ensures maximum strength, while neighbouring lengths of filament are more widely separated, thus obviating short-circuiting of adjacent lengths of filament, which sometimes occurs in the ordinary type of lamp subjected to severe vibration. The filament has no sharp bends, and will not 'sag,' so that the lamp may be used in any position. The vertical candle-power of the lamp is increased, and the light emitted is uniform in all directions other than towards the cap end. It is claimed for this design that these additional advantages have been obtained without loss of efficiency in operation.

Siemens Gas-filled Lamps.—The gas-filled lamp was originally introduced in high candle-power types only, but the range has been increased, with the result that these lamps are now obtainable for standard lighting voltages from, approximately, 30 to 1,500 watts. Owing to their high efficiency, these lamps became known to the public as 'Half Watt' type lamps. It is, however, an essential condition to their production that they should be gasfilled in order to obtain a satisfactory life at the efficiency mentioned. The leading manufacturers are therefore stamping the word 'gasfilled' on the bulbs of these lamps, so that the consumer may be protected should he be offered lamps which, though resembling genuine high-efficiency lamps, are not gas-filled.

The range of Siemens gas-filled lamps now includes automobile head-light lamps, from 4 to 14 volts, from 8 to 48 watts; Siemens gas-filled lamps for railway lighting, 25 volts, can be obtained from 15 to 100 watts. The 50- to 60-volt gas-filled lamps are supplied from 15 to 500 watts; 100- to 130-volt from 30 to 1,500 watts; and the high voltage gas-filled lamps, 200- to 260-volts, from 40 to 1,500 watts. These high candle-power lamps are being employed in large numbers for general lighting in stores, workshops, factories, offices, shops, etc., and for street lighting; they produce illumination without flicker, and require no attention after installation, save occasional cleaning.

Siemens Automobile and Battery Type Lamps.—In addition to the range of gas-filled automobile head-light lamps mentioned above, Siemens Battery Lamps are made for automobile lighting, sign lighting, omnibus and yacht lighting; while there is also a variety of types suitable for use in miners' hand and rescue lamps. The voltages of these vary from 2 to 14, and the wattages from, approximately, 1 to 36 watts.

Osram (G.E.C.) Lamps.

(The General Electric Co., Ltd.)

The Osram (G.E.C.) lamps have filaments drawn from tungsten; they have also pipless bulbs, which greatly improves their appearance and renders them less liable to be broken, both in transit and in use.

In addition to the low c.p. sizes of Osram lamps, a new tungsten lamp has been introduced in which a gas-filled bulb is used in place of vacuum; the efficiency of these lamps approximates to ½ watt per candle, as compared with vacuum lamps which consume about 1 watt per candle. The Osram gas-filled lamp is known as the 'Atmos' type lamp, and is made from 30 to 3,000 candle-power. The high candle-power lamps are largely used in the place of arc lamps.

The Osram standard or 1-watt lamp is made in sizes from 4 to 400 c.p., and, in addition standard types have been supplemented by special types for different purposes, such as with concentrated filaments for projection and focusing work; with 'Axial' type filaments for downward illumination, such as over desks, etc.; and for use from low voltage batteries, such as miners' and general portable hand-lamps and automobiles (including motor-buses). The Osram (G.E.C.) lamp 'Atmos' type is also made for automobile headlights.

A modification of the gas-filled lamp is the 'White Osram,' which is a standard clear Osram lamp, the bulb of which is coated with a film of unglazed porcelain. This coating has the effect of efficiently diffusing the light, and eliminating all glare from the intensely bright filament. White Osram lamps should be used in all positions where the lamp itself is visible.

For industrial lighting, bowl sprayed White Osrams—that is, lamps having only the lower part of the bulb coated—when used with top reflectors, such as G.E.C. enamelled steel reflectors, are specially recommended.

A further development of the White Osram is the 'Colour Sprayed Osram' lamp, which is produced in six standard colours—red, orange, yellow, green, blue, and flame tint. Colour sprayed lamps are the most convenient means of obtaining colour light for both indoor and outdoor decorations, such as dances, concerts, restaurants, seaside promenades, etc.

In addition to the Osram lamps for ordinary lighting, they are made for a wide variety of special purposes, such as the 'Daylight' lamp for colour matching, projection lamps, ship type lamps, candle type lamps, striplite lamps, automobile type lamps, miners' lamps, etc.

The lamps are an entirely British product, every component part, including the brass caps, being produced within the G.E.C. organisation.

The Osglim Discharge Lamp.

(Osram G.E.C. Lamp Works.)

Whereas discharge lamps usually require at least 2,000 volts, by filling the lamp with neon gas the discharge will start on about 200 volts. The current flows through the neon from one electrode to the other, the gas glowing round the cathode with a soft rosy light. By using a resistance inside the cap, the consumption of the lamp is reduced to 5 watts. The faint light from this lamp (known as the 'Osglim') makes it ideal as a night light, or wherever subdued illumination and low consumption are important. By making the cathode in the form of letters or figures, effective indicators or advertising signs are obtained. The lamp can also be made suitable for use in the photographic dark room.

Efficiency of Filament Lamps.

Type of Lamp.	Average Efficiency in Lumens per Watt.	Average Efficiency in Watts per Spherical Candle.
Carbon	3·3	4·1
Tantalum	6·0	2·1
Tungsten (Vacuum)	8·0	1·5
Tungsten (Gas-filled)	12·5	1·0

Intrinsic Brilliancy of Lamp Filaments.

The candle power per square inch of the filament of carbon 3·1 w.p.c., tantalum 2 w.p.c., and tungsten 1·25 w.p.c. lamps is 480, 625, 750, and 1,000 respectively, while the gas-filled lamp is 5,000.

Quality of Light.

The light of tungsten lamps more closely approaches daylight than that of other illuminants. It naturally follows that tungsten lamps cause colours to retain more nearly their true values than any other artificial light source.

Attachment of Flexible Cords to Sockets.

The majority of short circuits occurring in pendant sockets and the attachment-plug caps of portable electrical appliances, according to the Underwriters' Laboratories (America), are due to loose strands of the flexible cord, which become separated from the terminals when the binding screws or terminals are loosened. This loosening is frequently the result of the omission of a knot or its equivalent in the cord inside the cap of the socket or attachment plug, the strains due to pulling separable connections apart or dragging portables around by their cords being transmitted directly to the small binding-screw connections.

The so-called 'Underwriters' knot,' fig. 53, provides an easily-tied strained relief forming a rather flat knot, which will fit snugly in the recess provided for the purpose inside the cap of pendant sockets and attachment plugs.

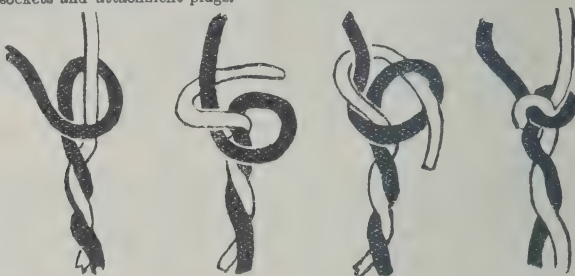

FIG. 53.

Arc Lamps.

In a D.C. arc lamp the top or positive carbon burns about 1½ inches per hour, and twice as fast as the bottom or negative carbon of the same diameter. A 1,000-candle-power lamp requires carbons about $\frac{9}{16}$ inch in diameter and consumes about 1,000 watts.

SIZES OF CARBONS.

Current of Lamp, in amperes .	4	5	6	7	8	9	10	12	14	15	20
Diam of Plain Carbons, in mm. .	7	7	8	8	9	9	10	11	12	12	13
Diam. of Cored Carbons, in mm. .	10	12	14	14	16	16	17	19	21	21	23

THE ANGOLD MAGAZINE FLAME ARC LAMP.

(The General Electric Co. Ltd.)

The Angold Magazine Flame Arc Lamp is arranged to burn carbons of comparatively short length (maximum 15 ins.) without copper coating or metal core ; twelve pairs of these carbons can be filled in the magazine at one time, and thereby, according to the type of lamp, 120 to 150 hours be obtained.

The carbons are so arranged that as soon as one pair is consumed the next pair comes into operation. The magazines can be filled up if only part of the trim has been consumed, so that at any time the full burning hours obtainable with a full magazine can be assured. The positive carbons cannot be put into the negative magazine, and when the last carbons are consumed, the feeding gear is automatically put out of action. Partly burnt carbons need not be removed. The interval of time during which the light is extinguished does not exceed two seconds.

The direct current lamp is manufactured for 8 or 10 amperes and can be supplied with self-contained equivalent resistance and automatic cut-out, or it can be supplied without these accessories. In the latter case, however, the lamps can only be used singly, on suitable voltage, or two in series on 100-120 volts. For longer series (or even for two lamps on higher voltage) equivalent resistances and automatic cut-outs have to be provided. If it is inconvenient to have these accessories self-contained they can be supplied in the suspension type, or if it is necessary to lower the lamp from contact gear a box type is recommended.

Both 8-ampere and 10-ampere lamps are designed for 9 mm. positive and 8 mm. negative carbons, 15 ins. long. Each trim of carbons consists of 12 pairs.

An alternating-current lamp of this make will burn in parallel singly on any voltage between 100 and 250 volts—25 cycles to 100 cycles. Each lamp is fitted with a self-contained transformer choker so that it can be connected directly to the mains.

THE STUDIO ARC LAMP.

(The General Electric Co., Ltd).

The G.E.C. Studio Arc Lamp is of the semi-enclosed type, and the high voltage long arc produced yields the highest possible actinic values.

It is equally suitable for portraiture and blue printing, as, owing to the purity of the light and to the absence of shadows, exceptionally good results are obtained.

It is supplied for use on A.C. or D.C. circuits.

To obtain the high voltage necessary the lamp is run singly on 220-250 volts. For average work a 16-ampere with these voltages is generally used.

ELECTRIC CLOCKS AND TIME SERVICE.

The Pul-syn-etic System.

The 'Pul-syn-etic' system, designed by *Gent & Co., Ltd., Leicester*, is arranged to operate any number of impulse clocks, workmen's time recorders, turret clocks, etc., installed in any large building or institution and connected electrically in series. The hands of such dials are all caused to advance simultaneously at half-minute intervals by means of step-by-step impulse propulsion movements (fig. 54) (or where inaudible working is required, the Silent Triangle Movement fig. 55) which, taking the place of the ordinary spring, or weight, and train of wheels, are operated by electric currents sent out periodically by a MASTER PENDULUM

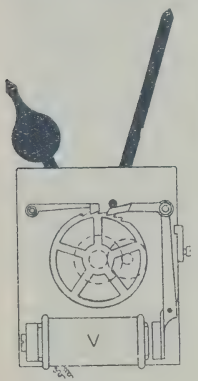

Fig. 54.

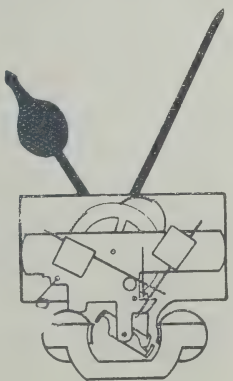

Fig. 55.

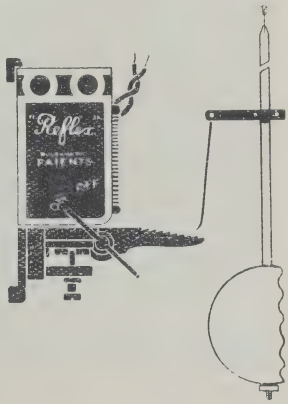

Fig. 56.

or TRANSMITTER. The latter (fig. 57) consists of a pendulum, which, by means of a pawl, causes a ratchet count wheel to revolve tooth by tooth—one tooth at every vibration. One of the teeth on the wheel is cut deeper than the others, so that a prolongation of the pawl is enabled to engage with and move aside a spring detent, which it misses during the passage of the other teeth. The detent, when moved aside, allows a weighted gravity lever to descend, and this through the medium of a friction roller carried thereon and an inclined plane fixed on the side of the pendulum, gives an impulse to the latter, imparting energy sufficient to enable the pendulum to swing during another revolution of the wheel—that is, for a period of half a minute. This gravity impulse is, of course, constant and invariable, so that other factors, such as temperature variation, etc., being suitably provided for, the time-keeping qualities of the pendulum are exceptionally good. The descent of the gravity lever is caused to close an electrical circuit, which fulfils a dual function: (*a*) energising an electro-magnet, which causes the restoration of the gravity lever to its potential position, and (*b*) sending an electrical impulse through the external circuit to operate the impulse movements. The duration of this contact is about 0·05 second; but, depending upon the total self-induction of the circuit, its duration is self-regulating, in that the contact is not broken until the self-induction has been overcome and all the dials operated.

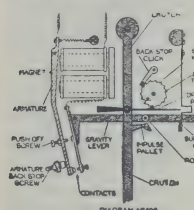

Fig. 57.

The system includes in series with the transmitter and the clocks a weak battery warning-bell which rings automatically every half minute should the battery run down and so endanger the safe working of the system. This warning is given before the actual breakdown point is reached, affording a safe margin of time in which to recharge or renew the battery. The 'Pul-syn-etic' system is noted for its low current consumption, and it is claimed that it takes the least current of any known Impulse system.

The system lends itself conveniently to the automatic operation of sound signals for the starting and ceasing of work, and also to the convenient operation of output and idle machine recorders. This class of recorder has proved itself useful in connection with textile machines and machines which should not be idle during working hours.

Workmen's Time Recorders are now controlled from the half-minute impulses of the system by means of the 'Pul-syn-etic Reflex' Pendulum Control (fig. 56). With this control the recorders remain independent units, and no mechanical alterations are made, but with the 'Reflex' fitting, as shown in fig. 56, attached to their pendulums, all recorders are compelled to keep in step with the transmitter.

Even if the electrical connections be removed the recorders continue to work under their own power as before, but uncontrolled. This 'Reflex' control is also applicable to the pendulums of existing large public clocks, under the name of Duflex Control, and its introduction is a marked advance in the science of the Unification of Time.

For large turret clocks, the accuracy of whose performance is subject to interference from variation in wind pressure or from accumulations of snow and ice on the hands, a special WAITING TRAIN movement is used, in which the hands are driven continuously by a special type of electric movement sufficiently powerful to overcome any such resistance ordinarily to be expected. The hands are caused to travel at a slightly faster rate than usual, to gain in fact about two seconds per half minute. Every half minute, however, the driving train disconnects itself from the hands, which then wait until the driving power is reconnected by means of the usual half-minute electric impulse current sent out by the transmitter driving the other impulse clocks in the building. The waiting period is practically unnoticeable—so that in very large turret clocks immunity from the usual weather interruptions is achieved, together with a greater degree of accuracy in timekeeping than in clocks operated in the usual manner. Efficient electric striking, or striking and chiming apparatus, can be supplied for bells of any size.

This WAITING TRAIN movement has been chosen for driving the hands of the large electric clock, in the towers of the offices of the Royal Liver Friendly Society at Liverpool. This has four 25-ft. dials, and the weight of a pair of hands is 5 cwt. The minute hands are 14 ft. long, 2 ft. 6 ins. wide at the greatest width, and 9 ins. thick where attached to the spindle. The combined weight of each pair of hands, spindles, and internal counter-weights, is a trifle over half a ton. The area of the hands exposed to snow and wind is very great, nevertheless the type of mechanism employed has shown itself able to withstand the disturbing effect of several severe storms since its erection in 1911. The size of the Liver Clock has now been exceeded by the new 'Singer Clock' in the tower of the works of the Singer Mfg. Co., Ltd., Clydebank, which clock has four 26-ft. dials, all driven by a single 'Waiting-Train' movement.

For ship use special clocks are provided, the Impulse Transmitter being fitted with an automatic arrangement, which enables the whole of the ship's clocks to be automatically advanced or automatically retarded, while sailing east or west. These 'Pul-syn-etic' marine clocks are installed in a large number of liners and ocean-going steamers.

LIGHTNING CONDUCTORS.

CODE OF RULES FOR THE ERECTION OF LIGHTNING CONDUCTORS.

(Lightning Rod Conference, 1882, *and Lightning Research Committee, Royal Institute of British Architects*, 1905.)

Two main lightning rods, one on each side, should be provided, extending from the top of each tower, spire, or high chimney stack by the most direct course to earth. Horizontal conductors should connect all the vertical rods (*a*) along the ridge, or any other suitable position on the roof; (*b*) at or near the ground line. The uppermost conductor should be fitted with aigrettes or points at intervals of 20 or 30 feet. Short vertical rods should be erected along minor pinnacles and connected with the uppermost horizontal conductor. All roof metals, such as finials, ridging rain-water and ventilating pipes, metal cowls, lead flashing, gutters, etc., should be connected to the horizontal conductors. All large masses of metal in the building should be connected to earth, either directly or by means of the lower horizontal conductor. Where roofs are partially or wholly metal lined they should be connected to earth by means of vertical rods at several points. Gas pipes should be kept as far away as possible from the positions occupied by lightning conductors, and as an additional protection the service mains to the gas meter should be metallically connected with house services leading from the meter.

Material for Rod.—Copper, weighing not less than 6 oz. per foot run, either in the form of tape or rope of stout wires, no individual wire being less than No. 12 S.W.G. Iron may be used but should not weigh less than 36 oz. per foot run. Subsidiary conductors for connecting metal ridging, etc., to earth may with advantage be of iron and of a smaller gauge, such as No. 4 S.W.G. galvanised iron.

Points.—The point of the terminal should not be sharper than a cone of which the height is equal to the radius of its base; but a foot lower down a copper ring should be screwed and soldered on to the upper terminal, in which ring should be fixed three or four sharp copper points, each about 6 ins. long. The number of conductors or points to be specified depends upon the size of the building, the material of which it is constructed, and the comparative heights of the several parts; no general rules can be given, but even ordinary chimney stacks, when exposed, should be protected by short terminals connected to the nearest rod, as accidents often occur owing to the good conducting power of the heated air and soot in a chimney.

Fixing.—Rods should preferably be taken down the side of the building which is most exposed to rain. They should be held firmly by holdfasts of the same metal as the conductors (not by insulators), but not so tightly as to prevent free expansion and contraction due to changes of temperature. They should not be bent abruptly round sharp corners; the vertical rods should be carried at a certain distance from the wall to prevent dirt accumulating, and to avoid the necessity of running them round projecting masonry or brickwork. In some cases it may be necessary to carry a rod through a string-course or other projecting stonework to avoid curvature, in which case the hole should be large enough to give ample clearance to the conductor, but it is better to run outside, keeping the rod away from the structure by means of holdfasts as mentioned above.

Joints.—Joints in series of conductors should be as few as possible. As a rule they should only be necessary where the vertical and horizontal conductors are connected, and the main conductors themselves should always be continuous, without artificial joints. Connections between vertical and horizontal conductors should always be in places readily accessible for inspection. Every joint, besides being well cleaned, screwed, scarfed, or riveted, should be thoroughly soldered, and should be protected from the action of the air, especially in cities.

Painting.—Iron rods, whether galvanised or not, should be painted; copper rods may be painted or not, according to architectural requirements.

Protection.—Copper rods to the height of 10 ft. above the ground should be protected from injury and theft by being enclosed in an iron pipe reaching some distance into the ground.

Earth Connections.—It is essential that the lower extremity of the conductor be buried in permanently damp soil; hence proximity to rain-water pipes and to drains is desirable. It is a very good plan to make the conductor bifurcate close below the surface of the ground, and adopt two of the following methods for securing the escape of the lightning to earth: a strip of copper tape may be led from the bottom of the rod to the nearest gas or water *main*—not merely to a lead pipe—and be soldered to it; or a tape may be soldered to a sheet of copper 3 ft. sq. and $\frac{1}{16}$ in. thick, buried in permanently wet earth, and surrounded by coke, charcoal, or pulverised arc-lamp carbons (coke, however, is likely to set up corrosive action on the earth-plate), or many yards of the tape may be laid in a trench filled with coke, well rammed. Where iron is used for the rod, a galvanised iron earth-plate should be employed. A tubular earth connection driven into moist ground makes an effective earth, especially if it is connected to a rain-water pipe. (See also 'Earth Connections,' *below*.)

Masses of Metal.—As far as practicable the conductor should be connected to all extensive masses of metal, such as ornamental ironwork, hot-water pipes, etc., both external and internal; but it should be kept away from all soft metal pipes, and from internal gas-pipes of every kind. Church bells and turret clocks should be connected with the conductor. In the case of a long line of metal ridging, each end of the ridging should be directly connected to earth by a rod. Where the ridge is non-metallic, a horizontal conductor should be run at a short distance above the ridge and be connected to earth.

Factory Chimneys.—These should have a copper band round the top, and stout sharp copper points, each about 1 ft. long, at intervals of one or two feet all round the circumference. The rods should be connected with all bands and metallic masses in or near the chimney. As an alternative, the rods above the band may be curved into an arch provided with three or four points. Two lightning rods should be carried down from the band to earth.

Collieries.—Undoubted evidence exists of the explosion of firedamp in coal mines through sparks from atmospheric electricity being led in to the mine by the wire ropes of the shaft and the iron rails in the galleries; hence the head-gear of all shafts should be protected by proper lightning conductors.

Inspection.—Before giving his final certificate the architect should have the conductor carefully examined and tested by a qualified person, as injury to it often occurs up to the latest period of the works from accidental causes, and often from the carelessness of the workmen.

Earth Connections.

In making earth connections for electrical circuits, lightning rods, etc., it is desirable to provide several paths to earth, as far apart as possible. Connection should be made with the stratum of permanently moist earth nearest the surface of the ground, rather than to deeper layers or even to the water in a deep well. The best earth connection is a water pipe. For most purposes galvanised iron pipes, about 1 in. in diameter, give satisfactory results; in a series of experiments such pipes, driven into stony clay soil, gave the following average results per pipe:—

1 ft. deep	149 ohms	4 ft. deep	50 ohms.
2 ft. „	88 „	6 ft. „	36 „
3 ft. „	64 „	8 ft. „	29 „

Generally, if moist earth is reached, pipes need not be driven deeper than 10 ft. The resistance of two earth-pipes in series, driven 10 ft. deep, becomes practically constant at any distance apart from 10 ft. upwards. Earth-pipes connected in parallel should be at least one foot apart. They need not be larger than 2 ins. in diameter.

If earth-plates are used it is better to bury two small plates 20 ft. apart, connected by a stout wire, than one large plate. They should be on edge, with the soil well rammed on both sides. In shallow soil over rock, long narrow strips of metal buried in trenches should be used. Patented devices offer no special advantages. Two plates in parallel, each 2 ft. by 4 ft., 6 ft. deep, 5 ft.

apart in stony clay soil had a joint resistance of 16 ohms. A strip of galvanised iron 1·5 ins. wide and 20 ft. long, in a trench 12 ins. deep, had a resistance of 17·7 ohms. The resistance of a water pipe is usually less than 1 ohm, averaging $\frac{1}{4}$ ohm. The addition of salt to the soil round the earth connection greatly reduces the resistance; so does the packing of coke or charcoal round the plate, but both these devices hasten the corrosion of the plate. As a high potential gradient may exist on the surface near the earth connection, unless it is of the buried type, the earth-pipe and connecting lead should be guarded to prevent accidental contact with them. The joint between the lead and the earth-pipe or plate should be embedded in concrete for protection, and the earth-wire should be covered throughout its length. All earth connections should be inspected and tested at least once a year.

Phœnix Office Rules for Lightning Conductors.

The Phœnix Fire Office, in their rules for lightning conductors, point out that the only way to obtain absolute security against lightning is to enclose the building in a metal framework constituting the 'bird-cage' system of conductors. This can be accomplished generally by utilising the rain-water pipes and gutters as part of the system. The ordinary conductors must be fixed in addition, and the whole system effectively earthed. The material of the conductor should be of copper tape, measuring at least 1 inch by $\frac{1}{8}$ inch, or, if copper cable be adopted, it should not consist of less than seven strands, each $\frac{1}{4}$ inch diameter. Soft iron may be used in place of copper, and, except for chemical reasons and for permanence, the sectional area need not be greater than in the case of copper. Conductors should be kept a certain distance away from walls so as to prevent the accumulation of dirt, but they must not be insulated. If a copper plate is used for the earth connection it should not be less than 3 square feet in area and $\frac{1}{4}$ inch in thickness, and should be adopted only where it will always be in water or moist earth; otherwise connection should be made to the water mains, or the 'tubular' system should be employed. The number of connections depends on the ground area of the building, but there are few structures where less than two are necessary. The elevation rod of factory chimneys should be a circular band placed round the top of the shaft, with points fixed at an angle of 45°, and extending outwards, or an arch of metal, provided with points, may be fixed across the mouth of the chimney.

Domestic Uses of Electricity.

It is seldom that lighting is the only domestic service obtained when an electricity supply is available. Provided the cost of electricity is not exorbitant, certain valuable appliances are to be met with in most households, *e.g.* flat iron, vacuum cleaner, desk fan, toaster, coffee percolator, milk boiler, kettle, warming pan, hair dryer, bowl fire, etc., etc. Such services can be had at a very small running cost, since the amount of energy consumed is generally small. Where electric energy can be obtained at a low rate, *e.g.* at an overall charge of $\frac{3}{4}d.$ to $1\frac{1}{2}d.$ per unit, main domestic services such as heating, cooking, and hot-water supply are available at costs comparable with other methods, such as coal or gas. Even where the cost of electricity may be prohibitive for general use, it may be low enough for occasional use. In addition the advantages of cleanliness, convenience, comfort, labour-saving, etc., are valuable assets. Reliable appliances for all the above-mentioned services are now available, and when the capital costs of wiring and of apparatus are suitably reduced or embraced in hire-purchase systems, etc., a great expansion of domestic electrification can be looked for.

Data concerning heating, cooking, and hot-water supply in private households will now be given. In Table I figures are reproduced from p. 305, vol. 64, of the *Journal I.E.E.* These figures were given by Prof. A. H. Barker in the discussion of a paper on 'An All-Electric House,' by Prof. S. Parker Smith, and are intended to show how many heat units are needed per person per annum for the stated services:

Table I.—Net B.Th.U. used per Person per Annum.

Description.	Estimate for well-to-do Person.	Estimate for Artisan.	From Barker's Experiments for One Person Living Alone.	From Parker-Smith's All-Electric House.
Heating . .	3,000,000	1,000,000	4,500,000	3,400,000
Hot-water supply and laundry . .	8,000,000	2,000,000	2,100,000	4,150,000
Cooking . . .	400,000	180,000	800,000	474,000
Total .	11,400,000	3,180,000	7,400,000	8,024,000

In all domestic electrification, the Regulations of the I.E.E. concerning Electrical Equipment of Buildings should be observed—particularly as regards earthing in bathrooms and kitchens.

AN ALL-ELECTRIC HOUSE.

In Tables II.–IV. the consumption and costs in the 'All-Electric House' just referred to are given.

The differences between the totals in Tables II. and III. are due to meter errors.

TABLE II.—TOTAL CONSUMPTION IN UNITS RECORDED ON TWO-RATE MAIN METER.

Year of 52 Weeks.	1st.	2nd.	3rd.	4th.	5th.	Average p.a. In Units.	Average p.a. Percentage.
Day load	10,299	9,713	9,079	10,727	11,720	10,307	64
Night load	6,043	5,827	5,241	5,848	5,897	5,771	36
Total for year	16,342	15,540	14,320	16,575	17,617	16,078	100
House closed	19	10	13	8	7 days		

TABLE III.—ANALYSIS OF CONSUMPTION IN UNITS AS OBTAINED FROM SEPARATE METERS.

Year of 52 Weeks.	1st.	2nd.	3rd.	4th.	5th.	Average p.a. In Units.	Average p.a. Percentage.
Heating	5,954	6,636	6,585	7,781	8,265	7,044	42·0
Hot water { day	1,242	1,245	1,103	993	1,315	6,951	41·5
Hot water { night	6,043	5,827	5,241	5,848	5,897		
Cooking	2,777	1,858	1,706	1,963	2,037	2,068	12·5
Lighting	568	687	717	785	863	724	4·0
Total for year	16,584	16,253	15,352	17,370	18,377	16,787	100

TABLE IV.—TOTAL ANNUAL COST OF ENERGY (BASED ON FIGURES IN TABLE I.).

Year of 52 Weeks.	1st.	2nd.	3rd.	4th.	5th.	Average p.a. In Cost.	Average p.a. Percentage.
Day load at ½d. per unit	£ 21 s. 9 d. 2	£ 20 s. 4 d. 8	£ 18 s. 18 d. 3	£ 22 s. 7 d. 0	£ 24 s. 8 d. 4	£ 21 s. 9 d. 6	50
Night load at ¾d. per unit	9 8 10	9 2 1	8 3 9	9 2 9	9 4 3	9 0 4	21
Fixed charge	12 10 0	12 10 0	12 10 0	12 10 0	12 10 0	12 10 0	29
Total for Year	43 8 0	41 16 9	39 12 0	43 19 9	46 2 7	42 19 10	100

Comments on above Results.

1. For the third year, an extra of £9 0*s.* 3*d.* falls to be added for the general strike of 1926.

2. The increase in the fifth year is to be accounted for by the exceptionally severe winter of 1928–29. No discomfort was experienced, but fires had to be switched on for a longer period before the room was occupied. The longer time taken for cooking operations and heating water during this cold spell was pronounced.

3. The fact that the extremes fall within 10 per cent. of the mean justifies the conclusion that a definite measure of the annual consumption and cost has been obtained.

4. Experience soon showed that undue care in consumption was not necessary. Extravagance was, of course, avoided, but except during the general strike, no particular economy in heating water, &c., was practised, while occasional heating of bedrooms has greatly increased.

5. The number of regular occupants in the house varied from four to six, whence it can be concluded that for such small numbers it is meaningless to express consumption or cost in terms of 'per person per day.'

6. The average overall cost per unit over the five years worked out at 0·64*d.*, or under two-thirds of a penny.

7. The consumptions for heating and for hot water are almost identical; cooking is only one-eighth of the total, while lighting is negligible.

8. Over one-third of the total consumption was taken between 11 P.M. and 7 A.M.—a valuable asset to stations with a small night load.

An All-Electric Flat.

A three-apartment flat with bathroom and kitchen was converted from gas and coal to all-electric working. The consumptions and costs for two years are given in Table V.

TABLE V.—Total Annual Consumption and Cost of Energy.

Year of 52 Weeks.	1st.	2nd.	Average	
			In Kind.	In Per Cent.

Average cost per unit . . . . . 0·66*d.*

The Artisan's All-Electric Home.

Figures were published by Dr. S. Parker Smith in *The Electrician* (vol. 96, p. 346). Allowing for losses in the hot water and cooking appliances, the estimate for an artisan given in Table I. is increased to 3,750,000 B.Th.U. or 1100 kw. hours per person per annum, making 5,500 kw. hours per annum for a household of 5 persons. At an overall cost of 1*d.* per unit, this works out at slightly under £23 per annum—a rather high figure for some families. In many areas, however, the cost per unit averages ½*d.* to ¾*d.*, bringing the annual outlay down to a figure between £12 and £17, which is well within the reach of many artisans' families, and compares favourably with alternative methods.

For large kitchens in restaurants, works canteens, etc., various sizes and combinations of apparatus are made. The following data are taken from actual installations.

Class of Kitchen.	Total kilowatts.	Annual Consumption units.	No. of Meals per week.
Restaurant	247·6	146,500	9,518
Staff feeding	120·6	97·140	2,944
,, ,, ...	40·5	21·141	991
,, ,, ...	32·8	20,690	640

British Standard Specification No. 106—1920 gives particulars of electric cooking ranges or 5 and 10 persons respectively.

See also 'The Domestic Applications of Electricity,' by A. J. Milne, Grad. I.E.E. and R. H. Rawll, A.M.I.E.E. (*Journal of the Institution of Electrical Engineers*, No. 379, July 1928.)

Large Electric Baking Ovens.

Asbestos in block form is the most convenient insulating substance for baking ovens. Slag wool can be used for horizontal surfaces, but for vertical situations block or slab asbestos should be employed. Slag wool mat can be exposed to temperatures as high as 1350° F. without losing its fibrous structure.

The following table gives *mean* temperature, *i.e.* the average between the hot and cold faces of a slab of slag wool mat when equilibrium had been attained.

Mean temperature.	Thermal conductivity in B.Th.U. per sq. ft. per hour per 1 in. thickness for 1° F. difference.
° F.	
300	0·48
400	0·56
500	0·64
600	0·72
700	0·80
800	0·88
900	0·96

Resistor.

The following can be taken as desirable electrical, mechanical and thermal properties of a resistor suitable for baking ovens.

Specific resistance . .	105 microhms per cm.³	Specific heat . . .	0·106.
Temperature coefficient .	0·00012.	Specific gravity . .	8·35.
Tensile strength . .	59 tons per sq. in.	Coefficient of expansion .	0·000015.
Melting point . .	1375° C.		

The above is a pure nickel-chromium alloy containing 20 per cent of chromium with but the merest trace of iron as an impurity.

Heating elements should dissipate their full rated energy at normal temperature without reaching red heat.

Long life and efficiency are the essential conditions demanded of a heating element, and attention must be given, when inserting them in the oven, to good heat transmission, sound end-connections, easy accessibility and low current density per unit of surface.

Elements embedded in cement are protected against oxidation and have an advantage over exposed elements, particularly when temperatures of 650° C. to 700° C. are exceeded. This method has a marked influence on the life of the element.

Cost of Operation.

Taking an average from over 4,000 electric bakery installations varying from 300 to 14,000 loaves daily output, the average power consumption is 90 watts per pound of bread baked. A typical bakery with 2 baking ovens having a total connected load of 41 k.w. has a daily output of 4,000 lbs. of bread and a monthly consumption of 3,500 kw.h.

One bakery in which tests were made had a monthly production of 3,000 cakes and 24,000 loaves of bread. Both gas and electric equipment were used for comparison. An average saving of 5 to 6 ozs. per cake, or a total of 156½ lb., was made by the electric oven. The bread savings totalled 500 lbs. It was further found that the gas-baked cakes shrank 5 ozs. each more than the electrically baked cakes in a period of 5 hours after baking. In another instance a bakery claims a saving of ½ to ¾ oz. per pound of bread baked.

To assure maximum economy in operation the smallest possible oven should be installed that will turn out the required production in the longest number of hours during continuous operation. This will keep the maximum demand to a minimum. It is shown that a smaller oven operating over a longer period of hours can be operated much more economically than a larger oven operated over a shorter period. Assume 1½ to 3 hours to preheat the oven, according to size. After preheating it takes from 50 to 60 per cent. of the maximum load of the oven to bake the heaviest products. Assuming the oven to be efficiently insulated, considerable heat is retained long after the current has been switched off.

The following is an example of the estimated cost of operation :

Connected load	10·8 kw.
Baking surface	30 sq. ft.
Capacity (1 lb. loaves)	80
Hourly capacity (1 lb. loaves)	120
Capacity when operating for 7 hours (1 lb. loaves)	840
Power consumption during preheating (2 hours)	21·6 kw.h.
Operating to maximum capacity for 7 hours (10·8 × 7 × 50 per cent.)	37·8 kw.h.
Total power consumption	59·4 kw.h.
Cost of current at 0·75*d.* per kw.h.	3*s.* 8½*d.*
Monthly cost (26 days)	£4 16*s.* 5*d.*
Monthly output of bread	21,840 lbs.
Electric current cost per 100 lb. of bread	5·3*d.*

It can be accepted that a good oven has an hourly capacity of 1½ times its deck capacity for bread baking, and twice the deck capacity hourly for rolls and buns, the hourly pastry depending upon the variety.

Records have established that baking-oven installations consume, on an average, 150 kw.h. per month for each kw. of connected load.

The maximum operating demand averages 50 to 60 per cent. of the connected load on the equipment. In some cases installations are consuming 200 kw.h. per month for each kw. of connected load.

An analysis of existing representative installations is given below.

	kw.h. per month per kw. of connected load.
82 baking oven installations	101
13 baking oven installations	146
15 baking oven installations	184
A wholesale bakery	185
	616
Average kw.h. per month per kw. of connected load	154
Load factor	40 per cent.
Power factor	Unity

(*Ellerd-Styles, Journal of the Institution of Electrical Engineers, No.* 378, *June* 1928.

ELECTRICAL PRECIPITATION OF SMOKE AND DUST.

In recent years the Lodge system of precipitating dust particles or fumes in gases, such as the flue gases from metallurgical works, cement mills or boiler furnaces, has been greatly developed by the Research Corporation, U.S.A., under Cottrell's patents. The apparatus consists of iron pipes through which the gases are led, preferably downwards, with a steel or nichrome wire suspended in the axis of each tube ; the wires are charged to a pressure of 30,000 to 100,000 volts and the pipes are earthed. The electric charge is derived from a.c. transformers with mechanical rectifiers driven in synchronism with the alternating pressure so that the polarity of the wires is always negative. The process can be carried on without cooling the gases and requires little power, from 5 to 50 kilowatts being usually sufficient. Resistance should be inserted in the low-pressure circuit to limit the short-circuit current and to provide means of regulation, and reactance in the high-pressure circuit to prevent surging of the electric charge.

From 80 to 98 per cent. of the dust can be deposited; in some cases the introduction of steam is necessary. In the case of blast furnace and cement mill gases, large quantities of potash can be recovered, particularly if salt is added to the charges of the blast furnace. Particulars of some successful installations are given below:—

Nature of Process.	Number of Pipes.	Length and Diameter of Pipes.	Pressure volts.	Rate of Flow of Gases.	Remarks.
Copper converter	608	10 ft. × 5 in.	30,000	10 ft. per sec.	97·25 per cent. recovered.
Silver furnace .	Chamber 8 ft. × 6 ft. × 16 ft.		50,000	—	Electrodes 6 in. lead strip.
Cement mills .	800	15·5 ft. × 12 in.	70,000	3·5 ft. per sec.	Temp. 900° F. 20 tons per day.
Copper and lead smelting works	384	15 ft. × 12½ in.	60,000	10,000 cub. ft. per day	Plant increased to 1,312 pipes.
Detarring coal gas	—	—	40,000 to 80,000	30,000 cub. ft. per hour	Unrectified alternating current.

Careful tests should be made before deciding on the dimensions, etc., of the apparatus to be installed. Corrosive substances can be dealt with satisfactorily. At a certain cement factory the potash recovered is worth more than the cement. The kenotron is an efficient rectifier up to 250,000 volts. A similar process is used for separating oil from water.

ELECTRICITY IN AGRICULTURE.

The principal use of electricity in agriculture is to drive machines, in addition to lighting the farm buildings; it is also experimentally used for stimulating the growth of plants. Motors are used either to drive stationary machines indoors from counter-shafting, or, being mounted on wheeled trucks or stretchers, to drive portable machines out of doors, through belting. A farm load has an excellent diversity factor, and as it does not come on during the evening peak load it is very acceptable to a public supply system. Experience shows that for remunerative supply, at least 25 per cent. should be arable or dairy land. At Hereford the average revenue from farms is about 20*l.* each per annum. With an electric milker one person can milk six cows at once, using 20 watt-hours per cow. To churn 165 lb. of butter requires 1 kw.-hour. Cutting 1 ton of ensilage consumes 1·38 kw.-hours. Threshing corn requires 70 watt-hours per bushel of oats, 100 watt-hours per bushel of barley, 160 watt-hours per bushel of wheat. Grinding a bushel of oats takes 420 watt-hours. Elevating 1 ton of hay, 200 watt-hours. The most suitable type of machine is the three-phase induction motor, on account of its simplicity and safety from fire; fire risk is a most important consideration in connection with farm work.

Electric ploughing is a special application of electricity under exceptional conditions; it is usually effected with hauling gear mounted on trucks, which travel along the sides of the field, hauling the plough (with three to five shares) to and fro across the land. The tractive effort required for ploughing in light soil is 740–820 lb. per sq. ft. of section ploughed; in heavy soil 1,100–1,250 lb. For ploughing a furrow or furrows w ft. wide and d ft. deep, at v ft. per second, the horse-power required = $kwdv/550$, k being a constant as above, depending upon the soil. The speed v should not exceed 5 or 6 ft. per second. The motor should be capable of hauling double the normal load at times. Furrows up to 650 yds. long can be ploughed in this way. On a large farm the capital charges amount to 12*s.* per acre, wages to 2*s.*, energy at 1*d.* per unit to 2*s.* 6*d.* per acre for deep ploughing (12–14 ins. deep), total 16*s.* 6*d.* per acre. For ordinary ploughing the cost is 11*s.* 4*d.* per acre. The hauling gear can be used also for harrowing and rolling the land, and for driving other machinery. The motor for ploughing should be of 25–30 h.p. (*Delamarre.*)

A large-sized plough can work 27 acres per day against one acre with horses.

For stimulating plant growth, the silent discharge from fine bare wires suspended above the crops at a pressure of 50,000 volts or more, d.c., has been much used for experimental purposes. The Agricultural Discharge Co. suspends the wires 10/12 yds. apart, at a height of 16/18 ft., using one pole to 3 or 4 acres.

The Board of Agriculture reported in 1918 that experiments extending over six years showed an average increase of 22 per cent. in the yield of spring cereals; some tests gave over 30 per cent. increase. The cost of a 100-acre equipment is estimated at 4*l.* per acre.

In a paper by R. Borlase-Matthews (*Journal I.E.E.*, 1926, vol. 64, p. 801) recent advances are described and the results of much experimental work given. Details of the results obtained with electric ploughing, rotary tillers, and the reduction of plough friction by passing a current between the coulter and ploughshare are recorded. Crop treatment has resulted in the production of a better milling wheat and superior malting barley. The electrical method of preserving green fodder (silage) has been improved by the addition of tubular heaters. In this case, the load is kept constant during the whole time of treatment, energy consumption averaging 1½ kw. hours per cwt. of material. Central manuring plants are in use in which the contents of the manure tank are agitated by electrically-driven revolving arms or by circulation through centrifugal pumps. The liquid is pumped out to stands in the fields and distributed by a hose pipe. The mains used for manuring can be employed for irrigating. The consumption for combined watering and manuring is stated to be 90 units per acre. By illumination of live-stock sheds and poultry houses, half an hour per day per man is saved in the feeding of stock, and an increase of 15 to 43 per cent in egg production during winter months is obtained. Lighting and heating in connexion with beehives has resulted in an additional 17 lb. of honey per hive per annum.

Agricultural type motors have been developed on the Continent and machines suitable for the very severe conditions which obtain are available. Such a machine is totally enclosed and embodies moisture-proof vacuum impregnated windings and internal ventilation. Ball bearings should be used, simple over-load circuit breaker provided, while the starter should be enclosed in the motor frame. Since the motor should be capable of working in any position the cable connection should be made through a plug and socket. A 5-h.p. motor is the largest size required on most farms except for ploughing, 2 h.p. being a generally useful size. This entails the use of suitable farm machinery. Recent practice tends towards the use of permanently installed motors on individual lines. Belt drives should be avoided by the use of self-contained compound reduction gearing, a friction drive replacing gear-wheels for motors of less than 5 h.p. Conductors are generally run outside the buildings under roof-eaves of farm buildings. For interior wiring the use of tough rubber-protected cable is advisable.

Electrical Heating of Soil for Horticultural Purposes.

This consists in heating the soil electrically by means of buried lead-covered cables enclosing high-resistance wire circuits. The success attained has made the system a commercial one. In Norway alone there are about 200 nurseries which make use of this method. In Great Britain (1928) there are two installations, one at the Cheshunt Horticultural Research Station and the other on the farm of Mr. Borlase Matthews at East Grinstead.

It is not necessary to maintain a constant supply of energy, as at 75° F., the standard temperature, the soil retains its heat for a long period.

Much less labour is required when the soil is heated electrically, and the plants are as healthy and strong as when the best manure hotbed is employed. In Sweden the method has been tested on a large scale. The standard electric beds are 92 ft. long and the cables are enclosed in earthenware ducts to prevent them being damaged by the gardener's spade. Strawberries have been raised to maturity in two months by this means. Potatoes planted in April were ready for digging at the end of June, two months before the ordinary crop. The commercial results obtained have proved satisfactory.

TELEPHONY.

Telephonic Transmissions.

The actual frequencies in normal speech range from about 200 to 2,500 periods per second, the mean frequency is assumed to be 800 for all transmisson calculations. Electromagnetic waves travel along telephone cables with a velocity depending on the electrical characteristics of the cable—i.e. resistance, inductance, capacity, and leakance; hence there is a time-lag between the application of an e.m.f. at the end of a cable and the time when it affects a point some way along the cable. At a certain distance a complete period will have been lost; the length to this point is called the 'wave-length' of the cable (α).

The magnitude of the e.m.f. also suffers attenuation, owing to the loss of energy due to resistance and leakage, according to a logarithmic law, involving the 'attenuation constant' of the cable (β). These constants are found by the following formulæ:—

$$\alpha = \sqrt{\tfrac{1}{2}\left\{\sqrt{(R^2+\omega^2L^2)(G^2+\omega^2C^2)} - (RG-\omega^2LC)\right\}}$$

$$\beta = \sqrt{\tfrac{1}{2}\left\{\sqrt{(R^2+\omega^2L^2)(G^2+\omega^2C^2)} + (RG-\omega^2LC)\right\}}$$

per mile in each case, where,

R = resistance in ohms per mile;
L = inductance in henries per mile;
G = leakance in mhos per mile;
C = capacity in farads per mile;
ω = angular velocity in radians per second = $2\pi f$, where f is the frequency in periods per second.

These constants are of the greatest importance, as they measure the speaking qualities of the cable.

The relative attenuation of the different frequencies present in the voice—i.e. the 'distortion'—is measured by the rate of change of the attenuation constant β with frequency, and is designated by δ. Measurements are made at frequencies giving ω values of 3,000, 5,000, and 7,000 radians per second, and the distortion is given by the formula:

$$\delta = 25\,(\beta_{7000} - \beta_{3000})/\beta_{5000} \text{ per cent.}$$

Transmission can be improved by decreasing R and C and by increasing L; the two former methods are limited by the resulting increase in the weight and size of the cable. β would be independent of frequency, and the cable therefore distortionless, if R/L were equal to G/C; for an ordinary cable R/L is of the order of 5,000, and for gutta-percha G/C is about 120, so that inductance has to be added, to diminish both attenuation and distortion. This is done either by winding iron wire uniformly in a close helix along the length of the conductor, or by inserting inductance coils at intervals; in the latter case there should be at least nine coils per wave-length at 800 cycles per second.

Loading has been extensively adopted for land-lines, but is more necessary for cables, underground or submarine; for the former, coils are used, but for the latter, both methods are employed.

To provide a standard of comparison for different types of cable, the Post Office has adopted a 'standard cable' having the following characteristics (unloaded) per mile: Total resistance, R, 88 ohms; inductance, L, 1 millihenry; capacity, C, 0·054 microfarad; leakance, G, 1 micromho; G/C, 18·5; wave-length constant, α, 0·1119; wave-length, 56 miles; attenuation constant, β, 0·1062; distortion, 9·5 per cent.

The British Post Office standard for long-distance communication is that the audibility should not be worse than over 35 miles of standard cable. Allowing 10 miles for the local lines, the balance for the transmission line proper is 25 miles. Examples of the lengths of certain types of line giving this equivalent are given in the table, all being 150 lb. per mile.

	Loading.	R ohms	L μH	C μF	G, μ mhos	G/C	α	Wave-length, miles.	β	Standard Cable Equivt.	Length = 25 m.s.c.	Distortion.
Underground cable	nil	11·73	1·0	0·065	1	15·4	0·537	117	0·0356	0·335	74·5	5·5
Aerial wire	nil	11·73	3·76	0·0084	1	120	0·0292	215	0·0087	0·082	304	2·6
Submarine cable	nil	11·73	1·25	0·15	18	120	0·0851	74	0·0525	0·494	50·5	6·0
Submarine cable	coils, 80 m.H. per naut.	16·08	70	0·15	18	120	0·513	12·2	0·0179	0·169	148	11·6
Submarine cable	coils, 80 m.H. per naut.	16·08	70	0·15	3	20	0·513	12·2	0·0127	0·120	208	5·0
Submarine cable	Continuous, 3 layers 0·008 inch iron	13·21	21	0·18	3·6	20	0·308	20·4	0·0199	0·188	133	5·0

The equivalent length of standard cable is now being superseded, as a means of expressing the inefficiency of transmission lines, repeaters, etc., by the 'transmission unit' or 'T.O.' When the input power (P_i) to a system and the output power (P_o) are such as to make the expression $10 \log_{10} \frac{P_i}{P_o}$ unity, the system is said to possess 1 T.O. of inefficiency. It is equivalent to 1·088 miles of standard cable at 800 cycles per second.

The thermionic valve (p. 2343) is an almost ideal relay for telephonic transmission. For perfect action the impedance of the line must be the same in both directions and for all frequencies; for this purpose each side is balanced by an artificial line, enabling even cables to be relayed on to aerial lines, but in this connection continuously loaded cables are much more suitable than coil-loaded cables. A double-relay repeater gives an improvement equal to 15–25 miles of standard cable; with the aid of successive repeater stations, good speech is now possible between New York and San Francisco, a distance of about 3,000 miles.

(*A. Rosen, Journal I.E.E.*)

Loaded and Repeated Telephone Cable Circuits.

(*Standard Telephones & Cables, Ltd.*)

The introduction of the telephone repeater to the sphere of practical telephony has made it possible to give high-grade telephone transmission over very long distances, and also to reduce

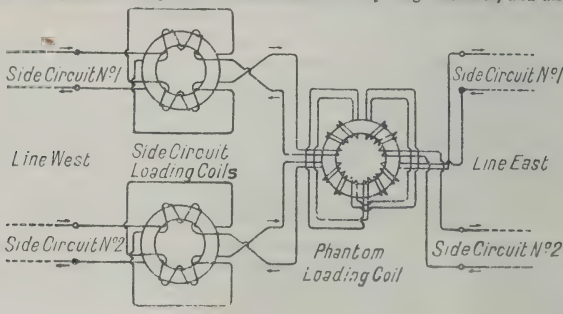

FIG. 58.

the cost and annual charges of many of the medium-length circuits found in the ordinary telephone plant. Telephone repeaters may be applied to improve the transmission of practically all circuits over which transmission is not normally satisfactory; but, when used in conjunction with carefully balanced and loaded telephone cable circuits, a system can be obtained which is as near the ideal as possible, both with regard to transmission qualities and to economical considerations.

Details of modern loading equipment and modern repeaters are briefly described under the following sub-headings.

LOADING.

The loading coils manufactured by *Standard Telephones & Cables, Ltd.* (formerly Western Electric Co., Ltd.), are designed to give the highest efficiency under all conditions of service. They have toroidal cores, which are constructed of a special magnetic material, rendering them immune from magnetisation troubles. The arrangement of the two side circuit coils and the phantom circuit coil, comprising a 'unit of loading,' is shown in fig. 58.

Loading coils can be designed to meet almost any inductance requirement. It has, however, been found convenient to establish certain standard types of coils, which cover the range of inductance required in most cases. These are, broadly speaking, classified (according to the amount of inductance) as 'extra light,' 'light,' 'medium,' and 'heavy' loading coils. The inductance of these coils covers a total range of from 25 to 250 millihenrys. When repeaters are used upon loaded lines it is necessary that the inductance of the coils be maintained within fine limits.

The coils, in suitable numbers, are contained in cast-iron cases, fig. 59, which are approximately of square cross-section, and which contain vertical spindles on which the loading coils are mounted, and are completely surrounded by insulating compound. The cases can contain up to and including 80 units of loading. In accordance with the latest practice, the coils are joined to the main cable through a single lead-covered stub cable.

FIG. 59.

Telephone Repeaters.

The three-electrode vacuum tube is the special feature of the modern telephone repeater as it is the special feature of modern radio-telephony and telegraphy. This vacuum tube is the most successful device for amplifying telephone currents that has yet been produced.

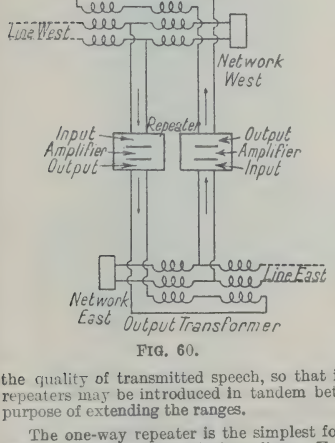

FIG. 60.

With the conducting and magnetic materials available to-day, the transmitted current on the best loaded line ultimately becomes attenuated beyond the value needed for commercial operation of the best telephone receiver. When this condition is reached the limit of improvement by loading alone has been obtained. This limit of distance is reached far short of the distances over which commercial telephony is desired, and other means for extending the range must be sought.

These are found in the telephone repeater, which is an amplifier or a device placed in the line at appropriate intervals for the purpose of adding new electrical energy to the circuit. In general, the current after passing the repeater is not better in wave form than the attenuated current which comes to it, and to this extent the repeater cannot serve one function of loading, which is to reduce the distortion. The modern telephone repeater functions so well, however, that the amplified current is to all intents and purposes an exact magnified image of the control current which it receives. In other words, it does not itself impair the quality of transmitted speech, so that if the line distortion is not too great a number of repeaters may be introduced in tandem between the transmitting and receiving stations for the purpose of extending the ranges.

The one-way repeater is the simplest form of repeater circuit. It is a device which can be connected between two telephone lines. Voice waves enter the input terminals from the transmitting ends of the circuit, and act upon circuit of the repeater in such a way as to set up an electromotive force in the output circuit which causes an output current to flow through the output impedance of the repeater to the receiving end.

Since it is essential that telephone lines should transmit equally well in both directions, it was found necessary to combine two of these one-way repeaters by special circuit arrangements, and the resulting apparatus is known as the two-way repeater (fig. 60). It will be seen that in addition to the two one-way repeaters there is additional apparatus supplied to prevent the flow of currents from the output circuit of each amplifier into the input circuit of the other. This consists of a three-winding transformer and a network, which are placed at each point where the circuits branch. Each network is made to balance its respective line, and consequently the output circuit of one amplifier and the input of the other have been effectively separated, while at the same time the inputs and outputs of the amplifiers have been left connected to the telephone circuits.

The two-way or 22-type repeater is usually used on circuits up to a length of 350 miles. Above this length the four-wire repeater is used in conjunction with a 4-wire circuit, which consists of two one-way transmission paths connected together at the ends by suitable transformers. The one-way paths may be either physical or phantom circuits. If these are physical circuits, the four-wire circuit really uses four conductors; while if the one-way paths are phantom circuits, the four-wire circuit has eight conductors. In principle the four-wire repeater consists of two one-way repeaters, each of which contains two vacuum tubes connected in tandem.

Telegraph and Telephone Lines.

Report No. 139—1921, of the British Engineering Standards Association, provides a specification for red fir poles. They should be felled when the sap is down, and contain the natural untrimmed butt of the tree. After seasoning, the poles should be impregnated with a minimum of 12 lbs. of creosote oil per cu. ft., the specific gravity of the oil being between 1·015 and 1·07 at 38° C. The properties of the oil are detailed in the Report, together with the methods of determining them, and the limiting dimensions of light, medium, and heavy poles, from 16 to 85 ft. long, are tabulated.

Report No. 134—1927 deals with iron and steel tubular poles.

Report No. 204—1924 gives terms and definitions used for telegraphs and telephones.

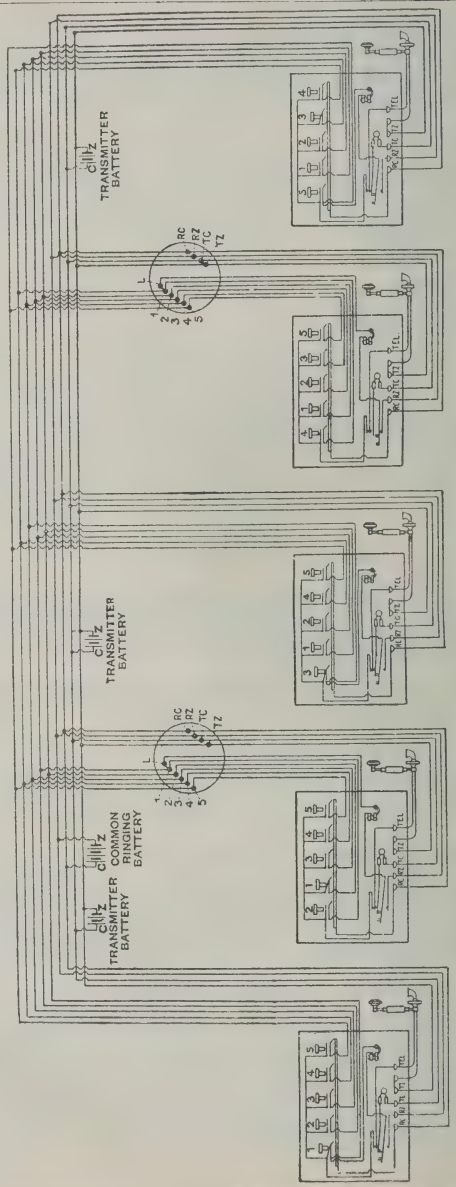

FIG. 61.—Wiring Diagram for G.E.C. Intercommunication Telephone System.

SPEAKING AND RINGING BATTERIES SHOULD NOT BE LESS THAN THREE CELLS EACH.)

Intercommunication Telephones.

(General Electric Co., Ltd.)

The circuit diagram of the G.E.C. Intercommunication Telephones is given in fig. 61, and a wall instrument (metal-cased, electro-magnetic type without induction coils) in fig. 62.

FIG. 62.—G.E.C. Wall Pattern Instrument.

This type of instrument has been specially designed by the G.E.C. with a view to strength and smooth and reliable working.

All working parts are easily removed should it be necessary at any time to make adjustments without disconnecting any of the internal wiring.

The push button line selector, line and instrument bar springs, together with the spring operated by the cradle switch, are all mounted on a steel frame by machine-cut screws, the frame being securely fixed on a stout hard wood base by means of metal bridge pieces at each end. Faults caused by warping woodwork or loose wood screws are thus obviated. The instrument possesses several unique points. It can be used either for a table or wall instrument, the cradle being of a design allowing the instrument to be fixed in either a horizontal or vertical position. This facilitates the keeping of stocks and ordering for export.

The instrument is made from one standard pattern, and can be readily extended from the minimum number of five lines to a maximum of twenty lines, by simply adding extra push buttons and springs, which are supplied at a reasonable price and in banks of five per set. These extra lines can be added without removing the instrument from its fixed position.

It is equipped with a hand combination, buzzer wound to 25 ohms, impedance coil and cradle switch, the cover being of black enamelled pressed steel.

To reduce inductive cross-talk, which is so noticeable with some types of intercommunication telephones, the G.E.C. have introduced the 'electro-magnetic' circuit in which no induction coil is used. Diagram fig. 69 shows a complete system with internal and external wiring. It will be noticed that more than one speaking battery of two cells is used, in order to keep the voltage constant on the common speaking battery leads. One battery only will suffice, providing all the instruments are within 50 or 60 feet of the battery. One ringing battery of three cells is usually sufficient to operate the calling signal. All lines are fitted with a black button with the exception of the home line, which is usually fitted with a red button.

With the electro-magnetic circuit the receiver, transmitter, and impedance coil are in series and connected across the speaking battery terminals marked T. C. and T. Z.

The receiver is constructed with a soft iron core for one pole, and the case as the other, and is only magnetised when the current is allowed to flow through the coil winding. The usual practice, of course, is to have permanent magnets, but if this type of receiver were used with the electro-magnetic circuit the permanent magnets would in time become depolarised unless care were taken to ensure the receiver and battery being so connected as to allow the current to flow in the right direction. To answer an incoming call the hand-combination must be removed from the cradle rest and the red button pressed down; it is automatically held in this position by a sliding bar which is drilled with the necessary number of holes to allow each of the plungers attached to the buttons to pass through, the bar being kept under tension by a spiral spring which forces the bar back and automatically holds the button down and at the same time brings the instrument spring in contact with the line spring and completes the line circuit. The bank of springs which are operated when the hand-combination is removed from the cradle rest automatically complete the speaking circuit.

To call out, the button corresponding to the tablet on which the name of the person required is written should be depressed; this movement temporarily connects the line spring on to the common ringing battery bar, allowing the current to pass along the line and operate the buzzer of the called instrument.

When the pressure is removed from the button the ringing circuit is disconnected and the line and instrument springs are brought into contact, this circuit being completed in the same manner as an incoming call. The button last pressed remains down, but is automatically replaced when another is depressed.

RADIO COMMUNICATION.

The services required include communication between ships and between ships and shore, long-distance telegraphy and telephony, broadcasting, direction-finding and radio beacons, and aeroplane communications.

Radio-Telegraphy.

Transmission systems may be classified as continuous-wave and spark systems. Continuous-wave systems comprise stations employing arc transmitters, high-frequency generators, or thermionic valves. In them a continuous wave of constant amplitude is produced. This wave requires less power and smaller aerials than the older spark systems.

Spark Transmitters.

In spark telegraphy a succession of groups of damped waves is radiated. Though still the most important from the point of view of the number of messages handled, these systems will eventually be superseded because of the disturbance caused to other radio-communications by the number of frequencies simultaneously radiated by spark transmitters. A typical spark transmitter is shown

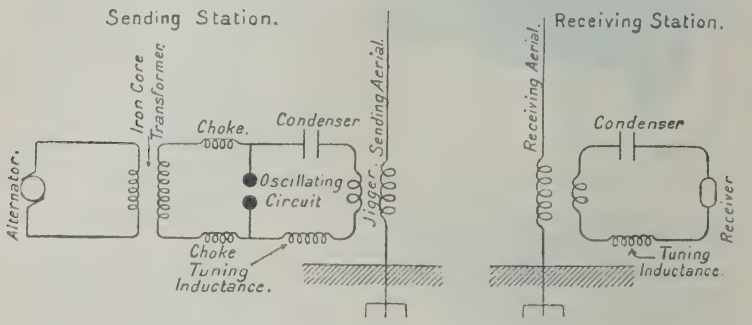

FIG. 63.

in fig. 67. The condenser is charged by the alternator through a step-up transformer. At every peak value of the voltage the spark gap breaks down, and the frequency with which successive sparks follow one another determines the pitch of the note heard in the receiver. This frequency depends on the speed and number of poles of the alternator, and may be from 100 to 1,000 per second. At every discharge of the gap a high-frequency wave-train is radiated by the aerial which is magnetically coupled to the oscillating circuit through an air-core transformer or 'jigger.' The frequency of this oscillating circuit is determined by the values of the condenser capacity and the tuning inductance. The aerial is tuned to this frequency. The corresponding wave-length is given by

$$\lambda \text{ (metres)} = 1885 \sqrt{\text{L (microhenries)} \times \text{C (microfarads)}}.$$

The heating of the spark gap causes difficulty at those higher note frequencies which are preferable for reception. By the use of a rotary spark in which projections carried by the alternator shaft come successfully opposite to a fixed insulated sphere, the discharge takes place only for a short time, and the automatic cooling prevents return of energy from the aerial. In the quenched spark system the discharge takes place between very short narrow gaps formed between thick parallel insulated metallic plates provided with radiating fins. The conducting spark is thus 'quenched' directly the voltage falls below the peak value. Spark systems are a source of great interference to neighbouring wave-lengths.

Reception of spark signals is by means of a telephone receiver connected in a receiving circuit tuned to the wave-length of the transmitter station.

Continuous-wave Transmitters.

Arc Transmitter.

The ' negative-resistance ' characteristic of the electric arc is employed to produce a continuous oscillation, the arc itself being connected in the aerial circuit which is tuned to the desired frequency by the loading inductance L in conjunction with the aerial capacity. In fig. 64 R is the stabilis-

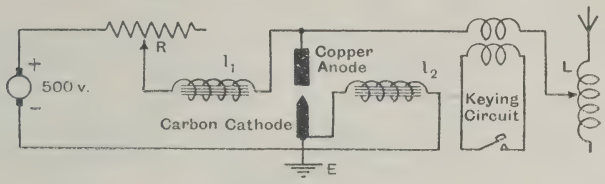

FIG. 64.

ing resistance and l_1 and l_2 are inductances which prevent the high-frequency currents passing through the alternator and also provide a powerful magnetic field across the arc to assist its extinction at each oscillation. The hollow copper anode is cooled by internal water circulation and the carbon cathode is slowly rotated. The arc is enclosed in an atmosphere of hydrogen or coal-gas. For signalling, the arc is not switched off, but ' marking ' and ' spacing ' waves are transmitted by the short-circuiting of a coil coupled to the aerial inductance. The system has the disadvantage that the apparatus is heavy and bulky, and a large number of intense harmonics are associated with the radiated wave.

' *High-frequency Alternators* ' for the direct generation of an oscillating voltage of comparatively low frequency for telegraph stations promise to have relatively little importance in the future, owing to the expense, complication, and restricted frequency range compared with valve transmitter stations.

Thermionic Valves.

In the three-electrode valve a filament heated by the passage of a current forms the cathode, the plate or anode being maintained at a potential positive relatively to the filament. A third electrode, the grid, is placed between the plate and filament. These electrodes are enclosed in a bulb exhausted to a pressure of about 0·00001 mm. of mercury or less. Electrons are emitted by the heated filament, and, owing to the high vacuum in the bulb, they are the only current carriers. The variation of the conductivity of the space between anode and cathode, therefore, is independent of the nature of any residual gas, and thus control of the anode current is effected by variation of the electron stream. This control is the function of the grid, while the amplification factor of a valve is determined by the relative dimensions and spacing of the electrodes.

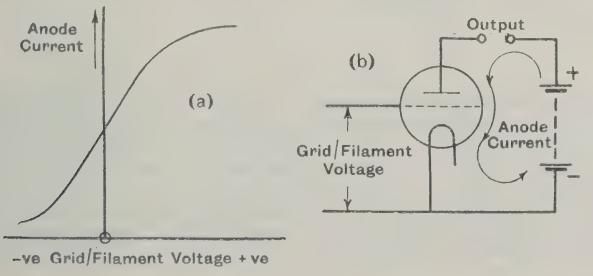

FIG. 65.

A typical valve characteristic curve and a diagram of valve circuits are shown in fig. 65 (*a*) and (*b*). An oscillating potential applied to the grid causes corresponding fluctuations in the anode current, which produce magnified fluctuations in the voltage across an output circuit connected between the anode and high-tension battery. The valve thus acts as an *amplifier*.

The valve may be used also as an *oscillator* by coupling the anode circuit inductively to that of the grid, as shown in fig. 66.

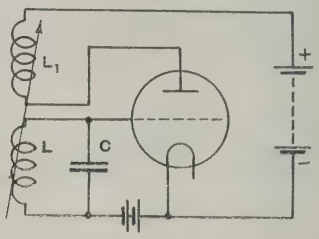

FIG. 66.

An increase in voltage across the tuned circuit LC applied to the grid causes an increase in the anode current in the coil L_1. This increase of current induces an e.m.f. in L, which can be arranged further to increase the grid voltage. At a value of the mutual inductance between L_1 and L greater than a critical value, determined by the valve characteristics and the resistance and inductance of the circuits, a condition of unstable equilibrium results, and the variation of grid voltage extends the whole length of the characteristic corresponding to the working plate voltage. The valve thus becomes a generator of oscillations, the necessary power being obtained from the high-voltage battery in the anode circuit.

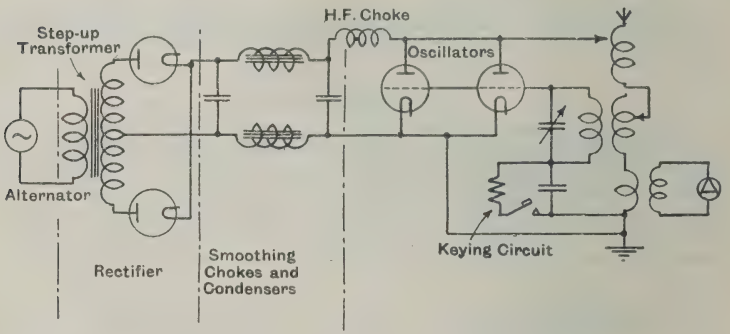

FIG. 67.

A typical *continuous-wave valve transmitter* is illustrated in fig. 67. Keying is effected by disconnecting the grids of the oscillating valves, the resulting negative potential acquired by the grids stopping the oscillation. The size of the valves employed is limited only by the rate of emission of heat from the anode. Silica valves are constructed up to about 12 kw. In larger sizes the containers are partly of metal, which form the anodes, and are water cooled. The input power to the valves may be obtained from special direct-current generators, or from the high-voltage side of step-up transformers through two-electrode rectifying valves. Frequency stabilisation may be effected by tuning-fork control, in which an amplified harmonic of the fork is applied to the grids of a bank of large power valves in parallel forming the output stage of the transmitter. For a description of a large modern valve station 'The Rugby Radio Station of the British Post Office,' by E. Shaughnessy (*Journ. I.E.E.*, vol. 64, pp. 683–713), should be consulted.

Radio Telephony.

Wireless telephony has become commercially possible by the introduction of the three-electrode thermionic valve. Valve oscillators provide a radiation of constant amplitude and frequency to

form a carrier wave upon which the low-frequency speech wave is superimposed. Fig 68 shows how the microphone M modifies the transmitted high-frequency wave. The speech wave of

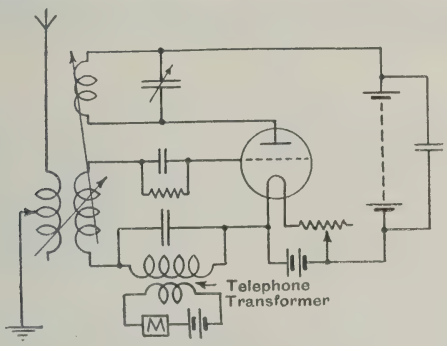

FIG. 68.

frequency f_n, superimposed on the carrier of frequency f, adds the two radio frequencies of $(f + f_n)$ and $(f - f_n)$ to the original wave. As f is increased, the smaller will become the percentage difference between $(f + f_n)$ and $(f - f_n)$. If f_n represents the highest note to be transmitted, the band of frequencies between $(f + f_n)$ and $(f - f_n)$, which are known as the upper and lower side-bands, must be allocated to one particular station to avoid interference with other stations. With high-power low-frequency (long-wave) stations this allocation is becoming difficult. From Rugby, the largest valve station in the world, in addition to world-wide telegraphic transmission on a wave-length of 18,740 metres, a successful trans-oceanic commercial telephone system is operated. Economy in the frequency band occupied and a certain degree of secrecy is obtained by filtering out one of the side-bands and radiating only the other. The necessary carrier frequency is inserted at the receiving station.

Broadcasting.—For the faithful reproduction at the receiving end of broadcast music, the band of frequencies must extend to about 10,000 cycles on either side of the carrier wave, whereas 2,000 cycles on either side suffices for commercial telephony. To avoid interference between the large number of broadcast stations working in Europe, international agreements now govern the allocation of the carrier frequencies of these stations and endeavour to ensure that these frequencies are maintained within very narrow limits. A modern broadcast receiver is shown in fig. 69, in

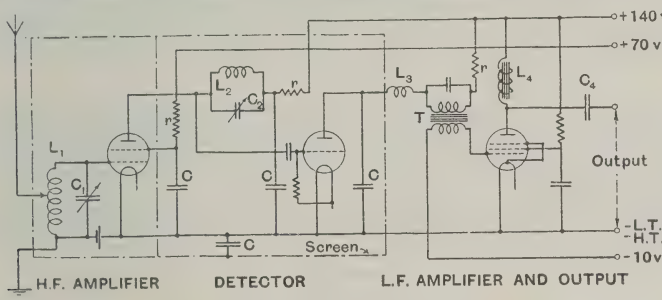

FIG. 69.

which L_1C_1 and L_2C_2 are tuned circuits, L_3 is an H.F. choke, T is an intervalve transformer, L_4C_4 are output filter circuits, and rC are anti-coupling filter circuits. The 4-electrode screened-grid valve amplifies the incoming signals, which are rectified in the second valve. The audio-frequency output from the second valve is amplified by the 5-electrode valve which provides for the operation of the loud-speaker. Screening and resistance-capacity filters are necessary, since

the H.F. valve has an amplification of about 100, and any trace of back coupling would lead to instability. These valves represent the latest advance. With 4- and 5-electrode valves employed in this fashion, no more than three valves are necessary for the reception of distant stations, distance being limited only by atmospherics and interference from other stations. Compared with the most suitable 3-electrode valve, the 5-electrode or pentode valve operates a loud-speaker with only one-tenth of the input A.C. grid voltage and one-half the anode voltage.

Directional Wireless.

The development of short-wave transmitters has recently culminated in their commercial application in the beam systems for trans-oceanic communication. In one system the waves are collected and concentrated in the required direction by an arrangement of reflectors. In another system the radiations from a number of transmitters interfere and nullify one another, except in the one wanted direction in which they reinforce one another. An aerial system designed for directional transmission is effective for receiving in the same direction. At the Bridgwater station in Somerset, aerials for receiving from Canada and from South Africa respectively are each supported from five masts, and the reflectors, consisting of vertical screens parallel to the line of oscillators, are tuned to the oscillator wave-length. Energy radiated in the direction of the reflectors is absorbed and retransmitted in the proper direction. Short-wave stations for long-distance communication are far less costly than long-wave stations, while directional transmission is less affected by atmospheric disturbances because of the short wave-lengths employed. Other important applications of the wireless beam are to surveying and direction-finding, which is of great assistance to navigation when approaching the coast during foggy weather. By the installation of directive receivers in land stations which are linked up by ordinary telephone, it is now possible to communicate its bearings to aircraft inside a radius of some 300 miles within about a minute of the pilot's inquiry.

Standard Specifications for Radio Work.

The British Engineering Standards Association have issued the following specifications:

No. 234—1925. Ebonite for Panels for Radio Reception Purposes.

No. 271—1926. Fixed Condensers for Radio Reception Purposes.

No. 289—1927. Plug-in Coils for Radio Reception Purposes.

The I.E.E. Rules covering radio apparatus connected to supply mains are dealt with on p. 2239.

INSULATING MATERIALS.

British Engineering Standards Specifications No. 231—1925, for Pressboard, and No. 216—1926, for Vulcanised Fibre for Electrical Purposes, refer to the composition, dimensions, tensile, shearing, tearing, and electrical strengths, freedom from conducting particles, and other physical properties. The methods of determination are specified. Specification No. 234—1925, for Ebonite for Panels for Radio Reception Purposes, in addition to the above information, gives standard values and tests relating to sulphur, acetone, and ash contents, the breaking strength, surface leakage, dielectric loss, and electric strength. Specification No. 157—1923, refers to Moulded Flat Top Insulating Bushes, and No. 316—1929 to Synthetic-resin Varnish-Paper Boards and Tubes.

DEXONITE.

This material (*Dexine Ltd., Stratford, London, E.*) possesses the properties of vulcanite and ebonite, but unlike the two latter it retains its normal degree of hardness under high temperature. It is easy to tool, screw, and tap, is not brittle, and is capable of being moulded into any shape or size. It has a high electrical resistance, and is non-corrosive and acid resisting. *Specific Gravity* at 60° F., 1·2765. *Tensile Strength:* Stress per sq. in. at maximum load 6,765 lbs., equivalent to 3·02 tons.

Articles made from Dexonite include insulating parts for electrical apparatus, medical requisites, binocular parts, etc. It is also supplied in sheet, rod, or tube form to any convenient sizes.

MACONITE.

See p. 2254.

WILLESDEN PAPER.

(*The Willesden Paper and Canvas Works, Ltd.*)

This material is largely used for electrical insulation, chiefly on the field magnets and armatures of continuous current dynamos, and is found by manufacturers to be of great value, as it is less

hygroscopic than other materials formerly employed. It can also be used with advantage instead of vulcanised fibre in many places such as small switches, washers on fuse and switch boards, and for telephone work, etc.

Resinous Insulating Materials.

(The Ioco Rubber and Waterproofing Company, Ltd.)

' Linapex Varnished Fabrics.'

Linapex Varnished Cloths are manufactured from carefully selected cambrics which are coated with a hardened film of a special oil varnish. They form one of the most extensively used insulating materials for the taping of field and transformer coils, etc., and for repair work generally. They are manufactured in thicknesses of 4–12 mils and supplied in the full width of 36 ins. or in tape form of any desired width, cut either on the straight or on the bias. A dielectric strength of 1,000 volts per mil is guaranteed.

Linapex Varnished Silk is a similar type of material, except that silk is employed as a base fabric instead of cotton. Such Varnished Silks have a higher dielectric strength than Varnished Cambrics, namely, about 1,400 volts per mil. These are also supplied in tape form, and are largely used for instrument work and where space is limited. All Linapex Varnished Cloths and Silks are oil and moisture resisting.

' Formapex Varnishes.'

These are solutions of the well-known brand of Phenol-Formaldehyde Synthetic Resin (Bakelite) employed mainly for impregnating paper, cloth, asbestos, etc., for the manufacture of Formapex Miocarta Tubes and Sheets, and also for impregnating coils, etc., affording a protective water-resisting coat of high dielectric properties. To apply, the coil is first dipped in the varnish, allowed to drain and air-dry, and is finally stoved in a moderate temperature.

' Formapex Boards and Tubes (Bakelite Type).'

These are manufactured from paper or cloth which has been treated with Formapex Phenol-Formaldehyde Synthetic Resin. In the case of sheets, the material is cut into plies, which are built up and placed in a heated hydraulic press and subjected to high pressure and temperature. For tubes, the treated paper is rolled on to a steel mandril between the heated rollers of a tube winding machine, and afterwards baked and varnished with a water- and oil-resisting varnish. Formapex Paper Boards and Tubes are characterised by their high dielectric strength and low water absorption value. Unlike Ebonite they do not soften with heat. They are readily machined and are used for insulators in all high-tension work. Formapex Condenser Bushings are used for transformers and switchgear. Formapex Cloth Boards are, on account of their remarkable mechanical strength and resistance to water, steam, oil, acids, etc., largely employed for mechanical purposes, such as silent gears, railway track insulators, etc.

Insulating Oils for Electrical Purposes.

British Standard Specification for Insulating Oils for Electrical Purposes.*

(No. 148—1927.) *(Abstract.)*

Classification and Temperature Limits.

Two classes of oil, Class A and Class B, are referred to in this Specification.

2. Class A oils, sometimes referred to as non-sludging oils, are suitable for use in transformers in which the working temperature of the oil, measured by a thermometer, exceeds 80° C. (176° F.).

They are also suitable for use in oil switches in which the temperature exceeds 70° C. (158° F.).

They may be used with advantage in all oil switches of above 500 amperes capacity having their main contacts under oil and operated for long periods near their rated current or in hot situations.

Class B oils are suitable for use in transformers in which the working temperature of the oil does not usually exceed 75° C. (167° F.).

They are also suitable for general use in oil switches not subjected to conditions requiring the use of Class A oils.

3. The oil of each class shall be a pure hydrocarbon (mineral) oil, clean and sufficiently free from moisture or other matter likely to injure its insulating properties, and shall satisfy the requirements of the specification.

* By permission of the British Engineering Standards Association.

4. The characteristics shall be within the limits shown in the following Schedule :—

Class of Oil.	Sludge (maximum).	Viscosity at 15·5° C. (60° F.) (maximum).	Electric Strength (minimum).	Flash Point (minimum).	Evaporation (maximum).	Cold Test (maximum).
	Per cent.	Redwood Secs.	Volts.		Per cent.	
A.0 A.10 A.30	0·1	200	30,000	145° C. (293° F.)	1·6	0° C. (32° F.) — 10° C. (14° F.) — 30° C. (— 22° F.)
B.0 B.10 B.30	0·8	200	30,000	145° C. (293° F.)	1·6	0° C. (32° F.) — 10° C. (14° F.) — 30° C. (— 22° F.)

6. The oil shall not contain any inorganic acid. The acid value per gramme of oil due to organic acids shall not exceed 0·2 mg. KOH.

7. The saponification value per gramme of oil shall not exceed 4 mg. KOH.

8. The oil shall not cause discoloration of copper.

B.E.S.A. Specification No. 358—1929 gives rules for measurement of voltage with sphere gaps.

Test for Moisture in Transformer Oil.

While a thorough test for the suitability of oil for transformers and oil switches can be made only with high-tension testing apparatus, very good indications of the presence of moisture have been obtained by Mr. J. K. Mackie, superintendent of the Connecticut Power Co., as follows :— A sample of the oil to be tested is drawn from the bottom of the transformer, oil switch, or storage tank. (Samples from the upper parts of the tank are not considered suitable for the test, as water is heavier than oil and usually collects at the bottom.) In the sample thus taken is placed powdered anhydrous copper sulphate. If moisture is present the copper sulphate will be dissolved, producing a blue colour that will diffuse through the oil if moisture is in suspension. Since enough copper sulphate is added to ensure a saturated solution, the intensity of the blue tint will be a measure of the amount of moisture present. As small percentages of moisture have a very deleterious effect on the dielectric strength of oil, however, the lightest shade of blue is sufficient indication that the oil should be dried by filtering. It may be pointed out that other substances giving a deeper tint than copper sulphate may be used, the only requirement being that they dissolve quickly in water but not in oil.

'No-Mag' Non-Magnetic Cast Iron.

This is a patented non-magnetic cast iron, which combines the non-magnetic property with a high electric resistance, thereby giving great freedom from hysteresis and eddy currents.

The efficiency of 'No-Mag' non-magnetic cast iron is shown as follows :—

Metal.	Magnetic Permeability.	Specific Resistance.
	Maximum.	Micro-ohms per cm. cube.
Ordinary cast iron . . .	330·00	95·0
'No-Mag'	1·03	140·0
Brass	1·00	7·5

The 'No-Mag' can be applied for the purposes of oil switch covers, bus bar clamps, brackets, cable boxes, transformer covers, separating pieces, sealing bells, etc. ; by using 'No-Mag' for end plates and shields for generators and motors the losses due to stray flux are reduced to a minimum, thus allowing economies in design.

Anchorage for Overhead Line Structures.

In the *Electrical World* Mr. A. W. Malone describes a cheap and effective method of making anchorages for overhead telegraphic or electric light line structures. A small hole is bored or drilled into the ground at a suitable angle, and an explosive is ignited at the bottom of it; the explosion makes a cavity, which eventually contains a ball of concrete, as shown in

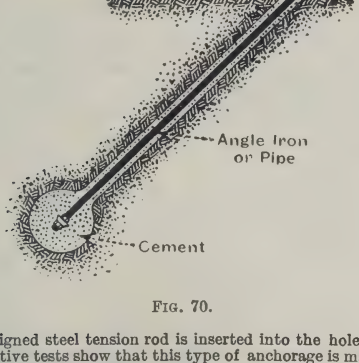

FIG. 70.

fig. 70. A specially designed steel tension rod is inserted into the hole, which is then filled up with concrete. Exhaustive tests show that this type of anchorage is many times as resistant to uprooting as the ordinary type, whilst it is far cheaper in labour, time, and material. A Malone anchor having a concrete 'bulb' 26 ins. in diameter, 9 ft. below the ground surface, offered a resistance of 56,000 lbs. after yielding 2 ins., whereas a grillage type of footing had a resistance of only 15,000 lbs.

This type of foundation has been adopted by the Central Electricity Board for some of the grid towers. The tower leg-stubs are fitted into position by means of a template and the cavities are filled in with concrete. The operation is simple, economical, and accurate.

X-Rays in Industry.

(C. Norman Kemp, B.Sc., F.R.S. (Edin.), A.I.C.)

The term 'opacity' has reference to a characteristic of certain substances in their reaction to ordinary light (λ about 8,000-3,900 Ångström units).

No substance known is totally opaque to X-rays, owing to their extremely small wave-length, although, of course, a sufficient thickness of a dense material may, in a given case, effect complete absorption, this being proportional to atomic weight and thickness.

From Planck's equation there may be derived the simple and useful relation that the product of the *maximum* tube voltage and the *minimum* resulting X-ray wave-length is a constant, the wave-lengths being expressed in Ångström units (Å.U.),
i.e.

$$\lambda_{min.} \cdot V_{max.} = 12{,}400,$$

whence

$\lambda_{min.}$ at 12,400 volts = 1.0 Å.U.; $\lambda_{min.}$ at 124,000 volts = 0·1 Å.U.

Within the range of wave-lengths from 1 to 0·1 Å.U. a vast amount of modern radiological work is done, commonly employed tube voltages being 45, 60, and 100 kv.

For work on metals, however, the last figure is often largely exceeded, values up to 500 kv. being used, and 1000 kv. having been proposed, if not actually attempted, with the object of reducing exposure times, and increasing the thicknesses which may be examined.

Industrial applications are based on the employment of X-radiations having a penetrating power (a function of λ) and an intensity related to the atomic weights (or numbers) of the constituent elements of the material under examination, so that, as indicated, very high tube voltages are necessary for the radiography of iron and steel products.

At present, definite information as to the homogeneity of such materials may readily be secured with commercially available equipment with an exposure of 30 minutes, this permitting of the detection of flaws in steel down to a sixteenth of an inch in size and up to three inches in thickness. Some of the practical uses of X-rays may be conveniently grouped as follows:—

1. Examination of natural objects or substances for information as to internal structure.

2. Examination of substances or objects from stage to stage in manufacturing processes with a view to more effective control, tending towards the elimination of waste, with consequent cheapening of production.

3. Examination of manufactured products or assembled articles for homogeneity or freedom from foreign matter in the one case, and correctness of assembly in the other.

4. General research in the foregoing and other directions whereby new applications and new methods of attacking existing problems are sought.

One of the most recent applications of radiological technique is the study of the internal structure, or, as it has been called, the ' mineral skeleton ' of coals, anthracites, cokes, etc., which may be visually studied, and also photographically recorded if required.

Particularly valuable in this connection is the use of stereoscopic radiography, whereby the interior of the specimens may be viewed in natural relief, and the ash-forming constituents examined as regards nature, quantity, and distribution.

The outstanding feature of X-ray methods lies in the provision of an easy, rapid, and non-destructive test of opaque materials, a field capable of almost unlimited extension as a result of continued research.

Electrical performance of transformers for X-ray purposes are dealt with in B.E.S.A. Specification No. 326—1928.

ADDENDA.

Cables for High Voltage. (See p. 2209.)

'H' and 'SL' Cables.—For medium and high voltages the use of the so-called ' H ' (Hochstädter) and ' SL ' (Self-Leaded) type cables has become general in the last few years. In the H-type each core has a thin metal-foil sheathing, while the SL construction provides a separate thin lead sheath for each core. This arrangement ensures a radial electric field (economising insulating materials) and obviates any discharge when the cores are inadvertently separated. The sheaths acquire earth potential by contact, so that the fillers carry no electric stress : they can therefore be made of cheaper material.

SO-Type Cables.—Cables of the ' SO ' type have been designed to improve the mechanical and thermal properties of high-voltage cables, the internal form being roughly triangular corresponding with the three conductors. The insulation of the conductors remains unchanged, but the filler area is much reduced, resulting in a shortening of the periphery and a reduction in the lead sheath and armouring.

Oil-Filled Cables.—Three-conductor cables, with paper insulation impregnated with highly viscous oil-resin compound, are satisfactory up to about 22 kV., but have given considerable trouble when used for higher voltages. This is due to the combined action of two processes : (1) fluid dielectrics experience mechanical forces tending to move them away from regions of high electric field density towards the sheathing ; (2) the viscosity of impregnating compounds decreases with rise in temperature.

These difficulties have been overcome in the oil-filled cable. Single-conductor cables are generally used, although SL-type 3-conductor designs are possible. The conductors are wound with graded paper, the impregnating medium being a low-viscosity mineral oil. The system is arranged so that the expansion of the oil due to temperature rise is accommodated by means of external reservoirs which return the oil to the cable under a small hydrostatic pressure when the temperature falls.

Oil-filled cables at 132 kV. are in operation between Kidbrooke and Deptford, Wimbledon and Battersea, in London, for connection to the national grid network.

Transformers. (See p. 2301.)

The out-door transformers on the 132 kV. system of the National 'Grid' System have standard capacities of 7,500, 10,000, 15,000, 20,000, 30,000, 45,000, 60,000 and 75,000 kVA. Those of 30,000 kVA. rating or less are of the 3-phase type, larger capacities consist of single-phase units. Natural cooling is used on the smaller sizes: the larger transformers have forced air-blast cooling when working above half full-load. The 132 kV. windings are star-connected with neutral point directly and permanently earthed: lower voltage windings are delta-connected. The voltage regulating equipment can be operated under load and provides for ratio variation of $\pm$ 10 per cent. in steps of not more than 1·43 per cent. Automatic interlocking ensures that all transformers in a sub-station must have the same transformation ratio before being paralleled.

All insulating materials are required to withstand oil temperatures of 95° C. continuously and 110° C. for short periods. The insulation is graded to withstand between turns for 3 seconds full-line voltage on 1 per cent. of the end turns, at each end of the phase windings, $\frac{1}{3}$ line voltage on 5 per cent. of the end turns, and $\frac{1}{4}$ line voltage on the remainder of the main winding. Tapped coils and 3 per cent. of the winding on each side can withstand $\frac{1}{3}$ line voltage between turns.

The terminal bushings must withstand when dry a test pressure of 300 kV. for 1 minute when mounted as in service, and no corona must appear below 1·4 times normal voltage. All bushings are mechanically interchangeable. Conservator tanks with calcium chloride breathers are fitted to exclude moisture from the oil. In addition to an alarm device which operates when a winding temperature of 100° C. (or other value) is reached, the circuit breaker is automatically tripped at a temperature of 10° C. above that at which the alarm is given. All ratings are in accordance with B.S.S. No. 171—1927, and oil is defined in B.S.S. No. 148—1927.

Electric Clocks and Time Service. (See p. 2327.)

In connection with frequency indication and control in central stations, the Warren self-starting hysteresis synchronous motor has been combined with a standard clock. The latter has one set of hands driven by the clock and another set by gearing from the motor. Any error is indicated by a differential mechanism. The standard clock keeps time to 1 second a day, and a difference of 0·005 per cent. in the mean frequency can be detected. A standard time service can, therefore, be given from central stations, the frequency of which is standardised, to synchronously-driven repeater clocks connected to the supply mains.

Other types of synchronously-driven clocks have also been brought into service.

Porcelain Insulators for Overhead Lines. (See p. 2225.)

For the national 132 kV. transmission scheme, insulators of the cap and pin type with ball and socket fittings have been selected. Each suspension string consists of 9 units and for tension insulators 10 units. The factor of safety is not less than $2\frac{1}{2}$ when the insulator is supporting its maximum working load (4,000 lbs. on suspension and 8,000 lbs. on tension insulators) with full normal voltage applied to it. The minimum flash-over voltage of a unit is 85 kV. dry and 60 kV. wet. The minimum puncture voltage is 145 kV. per unit. The complete strings with all fittings have minimum dry flash-over voltages of 395 kV. and 450 kV. for suspension and tension types respectively, and 385 kV. and 440 kV. wet flash-over voltages. Since the normal voltage to earth is 76 kV., this gives a nominal factor of safety of 5. Each chain of insulators has a guard ring at the conductor end and arcing horns at the earthed end with the object of equalising the voltage distribution over the units and preventing damage to clamps, conductors, and insulator when a flash-over occurs. Two insulator strings in parallel are used at tension points.

Electric Measuring Instruments. (See p. 2310.)

The most notable advance in recent years has been the introduction of nickel-iron alloy having a high permeability at low flux densities and very small hysteresis loss. Used in the cores of instrument transformers, current transformers have been constructed with a secondary burden of 12·5 VA., a ratio, constant to 1 part in 10,000 between 0·1 and 1·2 times the rated current, and a phase displacement of 0·75 minute. The very exacting limitations imposed by the Central Electricity Board for bar-type current transformers which include a maximum error of 1 per cent. between 5 and 125 per cent. of rated current with a change of ratio of only 0·3 per cent. have been met. Applied to soft-iron or moving-iron instruments it has permitted first-grade accuracy on a.c. or d.c. with angular scales of about 120° carried down to one-tenth of the maximum reading and almost uniformly divided down to about one-fifth. The instruments have very large overload capacities and are accurate on all frequencies from 25 to 500 cycles per second.

A recent introduction is the 'A.C. Test,' in which the movement of the iron takes place in the gap of a projecting laminated ring through which the current-carrying cable passes. No terminals are required, and by winding the cable the appropriate number of times through the ring, any desired range below that for which the instrument is scaled may be obtained. Ranges from 100 to 300 A. for a single conductor are available. A coil attachment enables the same instrument to be used in conjunction with current transformers, or as a voltmeter taking 75 mA. at 100 volts. The 90° scale reads to about one-tenth of the maximum, and first-grade accuracy is given between 25 and 50 cycles.

Moving-coil permanent magnet instruments are now adapted to the measurement of alternating current and voltage by the incorporation of thermo-junctions and copper-oxide rectifiers. The employment of vacuum thermo-couples has resulted in instruments being available for all ranges from 25 mA. to 10 A. and above, and for radio frequencies up to 108 cycles per second. For commercial sensitive a.c. instruments up to 10,000 cycles, the copper-oxide type has the advantages of a nearly linear law, a long range and low power consumption. On most ordinary wave-forms a 2 per cent. accuracy on frequencies from 20 to 6,000 cycles is claimed. In these instruments the rectifier, consisting of plates of copper with oxidised surfaces in contact with a soft metal such as lead made up into units, is contained in the instrument case. Recording instruments of this type are also available.

Photo-Electric Cells and their Uses.

Photo-electric cells include the following principal types: (*a*) *Photo-Conductive*, in which a change of ohmic resistance occurs on exposure to light. Selenium cells belong to this class. They are employed where the time lag is not a disadvantage. (*b*) *Photo-Voltaic*, in which certain metals, immersed in an electrolyte, develop an e.m.f. when illuminated. (*c*) *Photo-Electronic*, based on the emission of electrons from the surface of alkali electro-positive metals, such as sodium, potassium, rubidium, and caesium when exposed to light. The following notes refer to this type, which became of practical importance when the thermionic valve amplifier was developed, by permitting the small currents available from p.e. cells to be amplified to any desired magnitude. In its simplest form, the p.e. cell comprises a glass or quartz bulb, with an inner deposit of some photo-sensitive metal and a separate anode of wire. The wave-length or colour sensitivity of the cell depends upon the cathode metal and its base, *e.g.* potassium deposited on a base of the same metal has a maximum sensitivity in the violet and ultra-violet region, whereas potassium on a copper base has a maximum sensitivity in the orange-red range. There are many available coatings, including caesium, rubidium, barium, and various organic dyes.

Both vacuum and gas-filled cells are manufactured. The former has the higher output up to saturation, after which any increase in the cathode-anode voltage has no effect on the output. Gas-filled cells having a trace of argon are more sensitive on account of the increased emission due to the ionised gas. Their output is limited by glow discharge, consequently a protective resistance of some 10,000 ohms must be used in series with them.

(Contributed and Revised by Professor Percy A. Hillhouse, D.Sc., M.I.N.A., and James Thomson, M.I.N.A.)

DIMENSIONS OF SHIPS.

Moulded Dimensions.

LENGTH L = 'Length between Perpendiculars' = Length on load water-line measured from the fore side of the stem ('F.P.,' or 'Fore Perpendicular') to the aft side of the stern post ('A.P.,' or 'After Perpendicular'), or fore side of rudder stock if there is no stern post.

BREADTH B = 'Moulded Breadth' = Breadth measured over the widest part of the frame at the middle of the length L.

DEPTH D = 'Moulded Depth' = Depth measured from top of keel to top of deck beam at side at the middle of the length L. To avoid error the name of the deck to which the depth is measured should be stated.

Registered Dimensions.

LENGTH = Length from fore part of stem head to aft side of stern post, or fore side of rudder stock if there is no stern post.

BREADTH = Breadth measured over the outside of the shell plating at the widest part.

DEPTH = 'Depth of Hold' = Depth measured from top of ceiling to top of deck beam at the centre line of the vessel at the middle of the length. This depth is measured to the 'tonnage deck,' which is the 'second deck from below.'

Overall Dimensions.

LENGTH = 'Length Overall' = Length measured from the foremost point of the stem or figure-head (but excluding bowsprit if any) to the aft side of the taffrail, or cruiser stern.

BREADTH = 'Breadth Extreme' measured over the outside of the shell plating or belting or paddle sponsons, if any.

DEPTH = Depth from top of keel to top of deck amidships.

Drafts of a Ship.

The DRAFT d of a ship is the distance of the lowest point of the keel (or of the line of the keel produced) below the water line.

The MEAN DRAFT is half the sum of the drafts at the forward and after perpendiculars or at the stem and the stern post.

The MOULDED DRAFT δ is the distance of the top of the keel (or of the line of the top of keel produced) below the water line.

The LIGHT DRAFTS of a vessel are the drafts forward and aft when the vessel is floating complete, with water in boilers, but without crew, fuel, cargo, stores, water, or other loads.

The LOAD DRAFT of a vessel is the mean draft of the vessel when floating complete and ready for sea and with all fuel, cargo, passengers, crew, baggage, stores, spares, water, and other loads. The maximum load draft is determined by the freeboard tables of the Board of Trade; for passenger vessels the actual draft is limited to that determined by the spacing of the water-tight bulkheads, in accordance with the recommendations of the Convention for the Safety of Life at Sea. This draft is called 'The Bulkhead Draft.'

The FREEBOARD of a vessel is the height of the top of the wood deck at side at the middle of the length above the water line. The minimum freeboard allowable for any vessel entering or leaving a British port is fixed by law. It is assigned for each vessel by the Board of Trade or Classification Society, and must be marked upon each side of the vessel amidships by the 'Freeboard Disc' or 'Plimsoll Mark.'

The 'TRIM' or 'LEAD' of a vessel is the difference between the drafts forward and aft. It is said to be 'by the head' or 'by the stern' according as the draft forward or the draft aft is the greater. When the drafts forward and aft are equal, the vessel is said to be 'on even keel.' 'Change of Trim' is the arithmetical sum of the changes of draft forward and aft produced by the shifting of any weight.

Displacement.

The DISPLACEMENT of a vessel is the amount of water displaced by the underwater portions of her hull. It may be stated either by volume or by weight. The weight of the water displaced by a floating vessel is equal to the total weight of the vessel and her contents. If the vessel be floating in salt water, her displacement in tons, Δ, is equal to $\frac{1}{35}$ of her volume of displacement, ∇, in cubic feet. If in fresh water, $\Delta = \frac{\nabla}{35{\cdot}8}$.

The TONS PER INCH of a vessel at any draft is the number of tons weight which must be placed on board in order to increase the mean draft one inch.

$$\text{Tons per inch, in salt water} = \frac{\text{area of water plane}}{420} = \frac{A}{420},$$

$$\text{Tons per inch, in fresh water} = \frac{A}{430},$$

where A is the area of the water plane in square feet.

Coefficients of Displacement.

The BLOCK COEFFICIENT, or *Coefficient of Fineness*, C_b, is the ratio of the immersed volume of displacement to the volume of the circumscribing parallelepipedon.

$$\text{Block coefficient} = C_b = \frac{\nabla}{L\,B\,\delta} = \frac{35\,\Delta}{L\,B\,\delta} \text{ in salt water} = \frac{35{\cdot}8\,\Delta}{L\,B\,\delta} \text{ in fresh water},$$

where ∇ = Immersed volume of displacement in cubic feet,
Δ = Displacement in tons,
L = Length on load water-line, in feet,
B = Moulded breadth in feet,
δ = Moulded draft in feet.

Builders of cargo vessels usually estimate block coefficient with reference to length B.P., breadth over shell plating, and draft including flat plate keel.

The PRISMATIC COEFFICIENT, C_p, is the ratio of the immersed volume of displacement to the volume of the circumscribing cylinder having the same form of cross-section as the vessel below the water-line amidships.

$$\text{Prismatic coefficient} = C_p = \frac{\nabla}{La} = \frac{35\,\Delta \text{ or } 35{\cdot}8\,\Delta}{La},$$

where a is the immersed area of the midship section to outside of frame in square feet.

The MIDSHIP SECTION COEFFICIENT, C_m, is the ratio of the area of the midship section up to the water-line to the area of the circumscribing rectangle.

$$\left.\begin{matrix}\text{Midship section coefficient} \\ \text{or midship area coefficient}\end{matrix}\right\} = C_m = \frac{a}{B\,\delta}.$$

From the above values for the three coefficients it is easily seen that

$$C_o \times C_m = C_p.$$

Mr. W. H. Riddlesworth, M.Sc., gives the following approximate formulas connecting draft, displacement, and block coefficient:—

Let α = water plane area coefficient $= \frac{A}{LB}$.

β = block coefficient.
δ = moulded draft.
Δ = displacement in tons.

Then, approximately,

(1) The water plane area coefficient is equal to one-third plus two-thirds of the block coefficient,

i.e. $$\alpha = \tfrac{1}{3} + \tfrac{2}{3}\beta$$

(2) The change (c) in block coefficient per foot change in draft is equal to the complement of the block coefficient divided by three times the draft,

i.e. $$c = \frac{1-\beta}{3\delta}.$$

(3) The complement of the block coefficient varies inversely as the cube root of the draft,

i.e. $$1-\beta = \text{constant} \div \sqrt[3]{\delta},$$

the constant being determined for each ship from any one known draft δ_o and the corresponding block coefficient β_o; constant $= \sqrt[3]{\delta_o}(1-\beta_o)$.

The above three relations have been found to be both useful and reliable in practical work.

Curves of Displacement, etc.

As the draft of a vessel changes, the displacement, area of water plane, coefficients, etc., also vary, and it is customary to record these changes by means of curves whose vertical abscissæ represent draft, while the horizontal ordinates represent areas, displacements, coefficients, etc.

The ordinate of the curve of displacement at any draft is proportional to the area of the curve of water plane areas up to that draft.

Centre of Buoyancy.

The Centre of Buoyancy, B, at any draft, is the centre of gravity of the volume of displacement at that draft. The vertical position of the centre of buoyancy is the same as that of the centre of gravity of the curve of water plane areas, and its longitudinal position is the same as that of the centre of gravity of the prismatic curve. (See next page.)

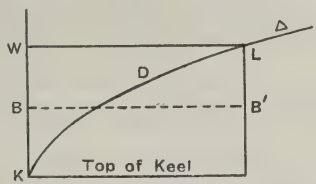

Fig. 1.

To find the height, K B, of the centre of buoyancy above the top of keel, draw the line BB′, across the displacement curve so that the area of the rectangle WB′ is equal to the area W L D K above the displacement curve.

Morrish's Rule.

Very approximately $KB = \frac{5}{6}\delta - \frac{V}{3A}$;

where K B = height of centre of buoyancy above top of keel, in feet;
δ = moulded draft, in feet;
V = displacement, in cubic feet;
A = area of the water plane, in square feet.

$\frac{V}{A}$ is called 'Rankine's Mean Draft.'

KB is approximately 0·55 of the draft.

Wetted Surface.

The WETTED SURFACE or IMMERSED SURFACE of a vessel is the total area of the surface of the shell plating, keel, bilge keels and rudder in contact with the water in which the vessel is afloat.

Approximately,

$$\left.\begin{aligned} S &= L(1{\cdot}7\,\delta + C_b B) && \text{(Mumford)} \\ S &= 3{\cdot}4\,\nabla^{\frac{2}{3}} + 0{\cdot}5\,L\nabla^{\frac{1}{3}} && \text{(Froude)} \\ S &= 15{\cdot}4\sqrt{L\nabla} && \text{(Taylor)} \end{aligned}\right\} + \text{surfaces of keel, bilge keels, and rudder.}$$

where L = length between perpendiculars, in feet;
δ = moulded draft, in feet;
C_b = block coefficient;
B = moulded breadth, in feet;
Δ = displacement, in tons; ∇ = displacement in cubic feet;
S = wetted surface, in square feet.

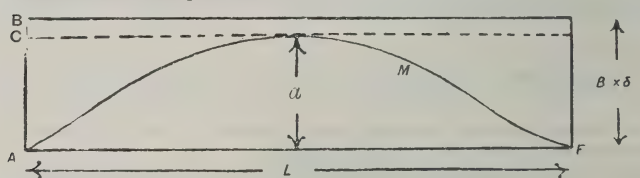

FIG. 2.

The PRISMATIC CURVE or CURVE OF AREAS for any draft is a curve whose horizontal base represents to scale the length of the vessel on load water-line, and whose ordinate at any point is proportional to the immersed area of the corresponding transverse section of the vessel. This curve shows the longitudinal distribution of the displacement, which has an important bearing upon the resistance.

Let A M F (fig. 2) be a prismatic curve, inscribed within a rectangle C F of height representing the area of the midship section, and surrounded by another rectangle B F of height representing the area of the rectangle circumscribing the midship section. Then

Area of prismatic curve is proportional to displacement.

$$\frac{\text{Area of prismatic curve}}{\text{Area of rectangle C F}} = \frac{\nabla}{L \times a} = \text{Prismatic coefficient.}$$

$$\frac{\text{Area of prismatic curve}}{\text{Area of rectangle B F}} = \frac{\nabla}{L \times B \times \delta} = \text{Block coefficient.}$$

$$\frac{\text{Height of rectangle C F}}{\text{Height of rectangle B F}} = \frac{a}{B \times \delta} = \text{Midship section coefficient.}$$

Centre of Flotation.

The CENTRE OF FLOTATION is the centre of gravity of the water plane. The two waterlines defining any small change of trim or heel intersect at the centre of flotation.

Transverse Metacentre.

If a vessel be slightly inclined to one side the centre of buoyancy, B, will move slightly from the middle line towards that side, say to B′, and the vertical line through B′ representing the upward pressure of the water will cut the inclined middle line at the point M called the 'Transverse metacentre.'

$$BM = \frac{I}{\nabla}.$$

where,

BM is the height of the transverse metacentre above the centre of buoyancy,
I is the transverse moment of inertia of the water-plane about its middle line,
and ∇ is the volume of displacement.

BM is approximately equal to ·075 to ·085 × breadth^2 ÷ draft, at load draft.

The METACENTRIC HEIGHT, GM or m, in any condition of loading is the vertical distance between the transverse metacentre, M, and the centre of gravity, G, of the whole vessel and her contents. If, in the upright condition, G lies above M the vessel is unstable and will not remain upright; if G lies below M, the vessel is stable and will return to the upright position if slightly inclined and set free. GM is a measure of the vessel's 'Initial Stability.'

The value of GM can be obtained either by separate calculation of the heights of G and M or by an inclining experiment.

Inclining Experiment.

In carrying out an 'Inclining Experiment' on a vessel, to determine the height, KG, of the centre of gravity, the following procedure should be observed :—

Have the vessel free from wind, tide, current, transverse mooring ropes, gangways, and particularly from loose water or other weights liable to move when the vessel is inclined. Have no men on board except those engaged on the experiment. Read the drafts carefully at each end from a small boat. Move any known weight w (enough to produce an inclination of about 2°) transversely across the deck through a total distance, a, and observe the corresponding deflection d, of a simple pendulum of length l, suspended anywhere on board. Several shifts of the weights are usually made to each side of the ship and the mean value of d taken. From the draft readings and the curves of displacement and transverse metacentres we can obtain the value of Δ, and of KM.

Then GM as inclined $= \dfrac{w\,a\,l}{\Delta\,d}$, w and Δ being in tons, GM and a in feet, and l and d in inches,

and KG as inclined = KM − GM.

These results apply only to the vessel in the inclining condition. To obtain the metacentric height for any other condition it is necessary to make suitable corrections for the different amounts and positions of the various items of loading and for the new values of Δ and KM.

It is usual to estimate the value of GM for the following conditions :—

Light Condition.—Ship and machinery complete, boilers and condensers full, but no fuel, cargo, passengers, crew, baggage, stores, spares, fresh or salt water, or reserve feed-water on board.

Docking Condition.

Load Condition.—Fully loaded condition; ship and machinery complete, boilers and condensers full, and with all fuel, passengers, crew, baggage, stores, spares, fresh and salt water, reserve feed-water, and holds filled with homogeneous cargo of such density as to bring the vessel to her load draft.

Spent Condition.—Same as full load condition, but with all fuel, water, and stores consumed.

Ballasted Condition.—Same as spent condition, but with water-ballast tanks filled.

Any other special conditions likely to arise in practice.

Rolling Period of a Vessel.

In Smooth Water.

K = Radius of gyration of the vessel and all weights on board, about a longitudinal axis passing through her centre of gravity.

m = Metacentric height;

2 T = Time of double roll, say from port to starboard and back again, in seconds;

g = Force of gravity = 32·2.

then

$$\mathrm{T} = \pi\sqrt{\frac{\mathrm{K}^2}{g\,m}} = \cdot 554\frac{\mathrm{K}}{\sqrt{m}},$$ neglecting water and air resistances.

The period 2T of a double roll varies from about 3 to 30 seconds; in large Atlantic liners it is about 20 seconds.

Stability.

The Initial Stability of a vessel is the measure of the tendency of the vessel to return to the upright if she is forcibly inclined to a small angle, θ, of not more than about 10°.

Initial Stability or Righting Moment at the inclination $\theta = \mathrm{RM}_\theta = \Delta\,m\,\theta$ foot-tons.

where,

Δ = displacement in tons;

m = metacentric height in feet;

θ = angle of heel in circular measure

= inclination in degrees ÷ 57·3.

CURVE OF STABILITY.—When a vessel is inclined to any angle θ (fig. 3), the centre of buoyancy moves to one side (B to B'). The upward force of buoyancy, Δ, now acts through B', while the weight acts downwards through G, the centre of gravity. These two forces form the righting couple, whose arm is GZ (the righting arm) and whose moment is W.GZ

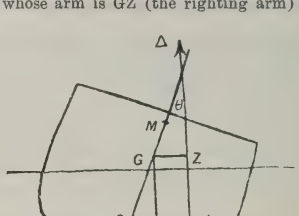

FIG. 3.

(the righting moment). When θ is small, B'Z passes through M, as already stated, and $GZ = m\theta$; at larger angles GZ must be separately calculated, and it is customary to obtain its value at each 10° of inclination and to connect the series of righting arms by a curve which is called the curve of stability (fig. 4).

OR is called the 'Range of Stability,' H the 'Maximum Righting Arm,' occurring at some

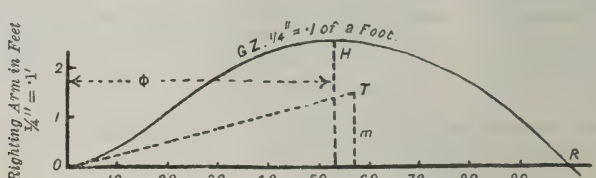

FIG. 4.

angle ϕ, while the initial slope of the curve is measured by the metacentric height, m, set up at 57·3° ($\theta = 1$), as shown in the figure, where OT is tangent to the curve at the origin O. (The scales marked are those to which the curves are usually drawn, but of course do not apply to the reduced figure.) The area of the curve of stability up to any angle is proportional to the work which must be done (by wind or other external forces) in order to incline the vessel to that angle. The work so done is called 'Dynamical Stability.'

Longitudinal Metacentre.

If a vessel be slightly inclined about a transverse horizontal axis, the centre of buoyancy will move longitudinally, and the point in which the vertical line through the new centre of buoyancy cuts that through the centre of buoyancy corresponding to even keel is called the 'longitudinal metacentre.'

The height of the longitudinal metacentre above the centre of buoyancy = LBM = $\frac{I}{V}$, where I is the moment of inertia of the waterplane about a transverse axis through its centre of gravity, and V is the volume of displacement.

The LONGITUDINAL METACENTRIC HEIGHT, LGM, is the height of the longitudinal metacentre above the centre of gravity = LBM − BG = M.

The longitudinal GM is used in calculating changes of trim. If any weight, w, be moved longitudinally through a distance, a, the 'moment to change trim' is wa.

The 'moment to change trim one inch' or 'inch trim moment' $= {}''M = \frac{\Delta M}{12L} \doteq \frac{I}{420L}$

Approximately, $''M = \frac{30\,t^2}{B}$

where, $''M$ = inch trim moment, in foot tons.
Δ = displacement, in tons.
L = length between draft marks, in feet.
t = tons per inch.
B = moulded breadth, in feet.
I = longitudinal moment of inertia of water plane.

The *change of trim* in inches due to any moment $w\,a$ is $\frac{w\,a}{''M}$. Of this total change of trim half is usually added to the draft at the end towards which the weight w was moved, and half deducted from the draft at the other end.

If instead of merely moving a weight already on board, we desire to find the alteration of drafts due to placing a new weight on board, first imagine the weight to be placed at the centre of flotation F. This will increase the drafts both forward and aft equally by an amount $\frac{w}{t}$. Then imagine the weight moved longitudinally to its assigned position and calculate the change of trim. Then combine these changes of drafts with the additional immersions $\frac{w}{t}$ and so find the total changes of draft forward and aft.

Curves connecting the mean draft with the position of the centre of flotation, the tons per inch, and the inch trim moment should be prepared to facilitate such calculations.

For large additions of weight the above method is not accurate, and it is necessary to prepare a complete list of all the items making up the displacement, together with their moments forward or aft of midships. Then

$\frac{\text{Total moment}}{\text{Total weight}} = \text{G}\,\boxtimes$ or $\boxtimes\,\text{G}$ = distance of centre of gravity aft or forward of midships.

From a curve connecting draft with the distance of the centre of buoyancy for even keel from midships, we can find the value of B $\boxtimes$ or $\boxtimes$ B, and hence the value of GB or BG, that is the longitudinal distance of the centre of gravity aft of or forward of the centre of buoyancy. The moment to change trim is then $\Delta \times$GB, and the change of trim $\frac{\Delta . \text{GB}}{''M}$.

RALSTON'S STABILITY AND TRIM INDICATOR.

This useful piece of apparatus determines the metacentric height and trim of a vessel by mechanical means instead of by calculation. It consists of a capacity profile of the vessel

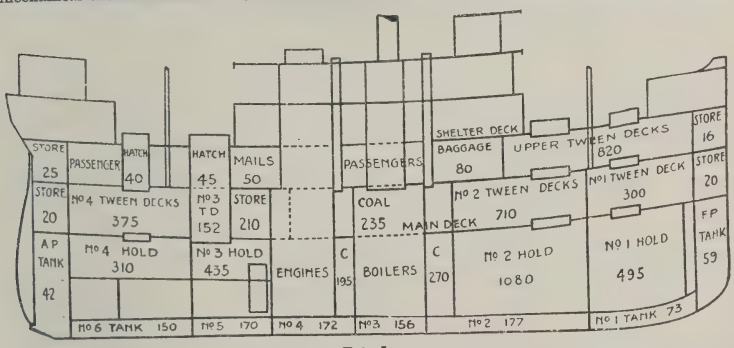

FIG. 5.

(fig. 5), the vertical scale of which, for convenience, is made greater than the longitudinal scale. This profile is engraved on a steel plate or table upon which are mounted two balance weights

* $\doteq$ is the symbol for 'approximately equal.'

FIG. 6.

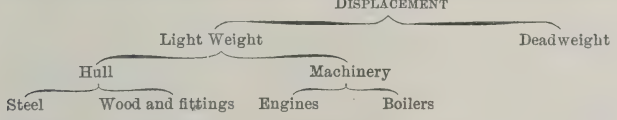
or sliders, one for stability and the other for trim. These are moved by rack and pinion over vertical and horizontal scales of 'index numbers,' engraved on the edges of the plate. The combined weight of table and sliders is made proportional to the light weight of the ship and in the zero position of the sliders the common centre of gravity corresponds in position to that of the ship in the light condition. The weights of cargo, fuel, stores, water, etc., are represented by a series of small brass weights which are placed in position on the capacity profile so as to represent any condition of loading for which it is desired to know the metacentric height and trim.

A separate diagram (fig. 6) gives mean draft and deadweight together with a series of G.M. and trim curves distinguished by index numbers corresponding to those over which the sliders move. The G.M. and trim scale movable over this diagram can be set to any draft and deadweight by means of racks and pinions. In use the table is supported firstly upon a longitudinal axis passing through the light C.G. and the vertical slider moved until balance is obtained and the 'index number' noted. The G.M. scale is then set to the correct deadweight and draft and the metacentric height read at the curve having the same index number. The table is then transferred to a vertical axis passing through the light C.G. and a similar process repeated to obtain the trim.

The instrument is simple, ingenious, and accurate; it takes into account all the features of the vessel's form and weight-distribution, obviates a considerable amount of calculation, and is being extensively adopted in the mercantile marine.

Weights.

The total weight or displacement of a merchant vessel may be subdivided as follows:



The *Weight of Steel* includes:—

Steel and iron plates and bars of all kinds.
Structural forgings and castings, whether of steel or of bronze.
Pillars.
Steel masts.

The *Weight of Wood and Fittings* includes:—

Carpenter work.	Deck machinery and piping.	Cement.
Joiner work.	Electric lighting installation.	Insulation.
Plumber work.	Refrigerating machinery.	Rigging and sails.
Wood masts and spars.	Heating installation.	Canvas covers and awnings.
Upholstery.	Ventilation.	Sheet iron work.
Boats.	Galley outfit.	Fixed ballast.
Smithwork.	Paint.	Deck Coverings. Etc.

The *Weight of Engines* includes:—

Main propelling engines.	Sanitary and fresh-water pumps.	Piping in engine-room and tunnel.
Shafting and propellers.	Floors, ladders, and gratings in engine spaces.	Water in condensers and piping.
Condensers and circulating pumps.	Feed water.	Tools, etc.
Air-pumps and bilge-pumps.	Oil in forced lubrication system and drain tank.	Blowers, silencers.
Electric generators.		Air bottles.

The *Weight of Boilers* includes:—

Main boilers and donkey boiler.	Piping in boiler rooms.	Floor-plates, ladders, and gratings in boiler-rooms.
Uptakes and funnels.	Feed-pumps.	Tools.
Fans and fan engines.	Fuel pumps.	Etc.
	Hot water in boilers.	

Deadweight includes:—

Spare gear.	Reserve feed water.	Stores and provisions.
Crew and effects.	Water ballast.	Bedding and napery.
Passengers and baggage.	Bilge water.	Cutlery and crockery.
Coal in bunkers and on firebars.	Cooling water.	Glass and silverware.
Fresh water for ship's use.	Mails and cargo.	Weights added by the owner.
Salt water for ship's use.	Oil fuel in tanks and pipes.	Etc.

Hull weight may be estimated either in detail or as a whole. Detail calculation requires that complete plans of the vessel are available, together with reference lists giving weight-rates or actual weights of all varieties of fittings. An accurate record of the finished total weights of the various items of the outfit of previous completed vessels is of great value in this connection.

For preliminary work, where a rapid estimate of the weights is required, the method of coefficients is largely relied on. In this method the whole weight of the hull, or of certain sectional portions thereof, is compared with some arbitrary parameter or parameters of simple form, depending upon the principal dimensions of the vessel or of her sectional parts. For each vessel completed an accurate record of these weights is filed, and the values of the 'Coefficients of Weight' $\left(= \frac{\text{weight}}{\text{parameter}} \right)$ worked out. Then for any proposed new vessel the weight of the hull, or of any of its parts, is found approximately by multiplying the proper parameter by a suitable coefficient chosen from among those of similar finished vessels.

The most commonly used parameter is the *Cubic Number*, which is the product of the Length, Breadth, and Depth, divided by 100.

$$\text{Cubic number} = N = L\,B\,D \div 100.$$

where L = Length between perpendiculars, in feet,

B = Breadth moulded, in feet,

D = Depth moulded, in feet, taken to the highest deck to which the shell plating extends continuously or almost continuously throughout the whole length of the vessel;

then,

$$\text{Weight of Hull, } H = N \times \text{Coefficient of Weight of Hull}$$
$$= N \times C_h$$

Similarly,

$$\text{Weight of Steel, } S = N \times C_s$$

$$\text{Weight of Wood and Fittings, } W = N \times Cw.$$

The weights of deck machinery, refrigerating machinery, insulation, etc., may either be included in the wood and fittings coefficient or separately estimated.

The following table gives average values of these coefficients :—

Type of Vessel.	C_s	Cw.	Ch.
Torpedo Boat Destroyer	·27	·10	·37
Cruiser	·34	·12	·46
Battleship	·33	·12	·45
River Paddle Steamer.	·20	·10	·30
Channel Steamer	·25	·13	·38
Coasting Steamer	·32	·20	·52
Cargo Tramp	·35	·12	·47
Intermediate Liner	·42	·17	·59
Fast Mail Liner	·40	·16	·56
Oil Tanker	·38	·06	·44

Other parameters sometimes used for estimating the weight of wood and fittings are

$$(L \times B) \text{ and } L\,(B + D)$$

Weight of Machinery.

In making preliminary estimates, the weight of machinery can be taken as proportional to the horse-power, the number of horse-power per ton of total machinery weight being recorded for all vessels completed and tried. A more accurate method is to record separately the weight of engines and the weight of boilers per horse-power, and to employ these rates when estimating the weights of proposed machinery of similar type. The weight of reciprocating engines may be taken as proportional to the product of the square of the diameter and the square root of the stroke of the high-pressure cylinder. For cylindrical boilers a suitable weight parameter is the product of boiler volume and square root of working pressure. For the greatest accuracy the weights of both engines and boilers must be made up in detail from the drawings and the detailed weight records of previous jobs.

Deadweight.

The total deadweight may either be specified by the owner or must be made up in detail from the particulars of the service to be performed.

Spare Gear.—Make up the weight in detail from the specified list of spares or allow a total approximate amount by reference to the actual weights carried by similar steamers. The amount may vary from about two tons in river paddle steamers and fast Channel steamers to about 120 tons in an Atlantic liner.

Crew and Effects.—Allow about one ton per ten men.

Passengers.—Allow one ton for every fifteen persons in ordinary cases and for every twenty persons in excursion crowds including women and children.

Baggage.—For the hand baggage of excursion passengers allow about one ton for every 250 persons. For long voyages allow about three tons for every ten persons.

Fuel in Bunkers = horse-power at sea, including that of auxiliaries × pounds of fuel consumed per horse-power per hour ÷ 2240 × distance between fuelling stations farthest apart ÷ service speed, + coal for galleys etc. + allowance for use in port + a margin of 10 to 20 per cent. for emergencies.

For rates of coal consumption see tables on pages 2375, 2392.

Coal on Bars.—Allow about 35 lbs. per square foot of grate area.

Fresh Water.—Allow about one ton per day for every 25 first or second-class passengers and about one ton per day for every 75 third-class or steerage passengers and crew.

Salt Water.—For sanitary purposes a tank containing from ½ ton to 5 tons according to the extent of the sanitary accommodation.

Reserve Feed Water.—Allow about 4 tons per 1,000 H.P. per 24 hours for short voyages and about half as much in vessels where distilling apparatus is carried.

Provisions.—Allow about one ton per day for every 75 first- and second-class passengers and about one ton per day for every 250 third-class or steerage passengers and crew.

Water Ballast.—As may be required for purposes of immersion, stability or trim during the voyage. Say one-half of weight of consumables.

Bilge Water.—Is more or less inevitable, but should not amount to much if proper care in pumping is continually taken. Allow about one-fifth of the vessel's 'tons per inch.'

Mails, cargo, and stores.—As required by owners.

Bedding and napery
Cutlery and crockery } Together about one ton for every 15 persons on board.
Glass and silverware

Resistance of Ships.

The total resistance to the ahead motion of a ship is made up of four parts :—

1. 'Skin-friction resistance,' or 'skin resistance.'
2. 'Wave-making resistance,' or 'wave resistance.'
3. 'Eddy-making resistance,' or 'eddy resistance.'
4. Air resistance.

2 and 3 are usually considered together under the name 'residuary resistance,' or 'wave resistance' merely, since eddy resistance should be very small. An allowance of 10 per cent. is usually added to the resistance of the 'naked' hull to account for the resistances of bossings, bilge-keels, rudder and other appendages, and air resistance.

HORSE-POWER.

The horse-power required to overcome any of these resistances is proportional to the resistance multiplied by the speed, and is called the 'effective horse-power.' It is from about ·45 to ·57 of the corresponding indicated or shaft horse-power developed within the vessel, the remainder of the power developed being absorbed by engine and shaft friction and losses in the propeller.

The ratio of effective horse-power to indicated or shaft horse-power is called the 'propulsive efficiency,' or 'propulsive coefficient.'

$$e = \frac{\text{E.H.P.}}{\text{I.H.P.}} \text{ or } \frac{\text{E.H.P.}}{\text{S.H.P.}}$$
$$= \text{from } \cdot 45 \text{ to } \cdot 57.$$

Skin Effective Horse-Power.

Skin E.H.P. is directly calculable :—

$$\text{Skin E.H.P.} = \text{E}_s = \frac{\text{S}}{100} \times \text{F}_{10} \times \left(\frac{\text{K}}{10}\right)^{2 \cdot 83}.$$

where,

S = wetted surface in square feet.
F_{10} = Skin E.H.P. per 100 square feet at 10 knots.
K = speed in knots.

The following table gives the values of F_{10} and of $\left(\frac{\text{K}}{10}\right)^{2 \cdot 83}$ for various lengths and speeds :—

L.	F_{10}.	L.	F_{10}.	K.	$\left(\frac{\text{K}}{10}\right)^{2 \cdot 83}$	K.	$\left(\frac{\text{K}}{10}\right)^{2 \cdot 83}$
50	1·999	450	1·832	10	1·00	18	5·28
100	1·918	500	1·826	11	1·31	19	6·15
150	1·888	600	1·816	12	1·68	20	7·11
200	1·873	700	1·807	13	2·10	25	13·37
250	1·863	800	1·798	14	2·59	30	22·40
300	1·854	900	1·790	15	3·15	35	34·65
350	1·846	1000	1·782	16	3·78	40	50·56
400	1·839			17	4·49		

From these figures curves may be drawn upon squared paper from which intermediate readings can be obtained.

Wave Effective Horse-Power.

The wave effective horse-power is not directly calculable, although several empirical formulæ and curves of coefficients have been published.

Taylor gives :—

$$\text{Wave E.H.P.} = \text{E}_w = \text{B}_\bullet \frac{\Delta^{\frac{2}{3}}}{\text{L}} \times \cdot 0030707 \, \text{K}^5.$$

Where $\text{B}_\bullet$ = from ·35 to ·55, according to the degree of fullness of the vessel and her ratio of length to breadth.

The most accurate method of estimating E_w is by using the results of model experiments or of actually tried vessels, and Froude's 'Law of Comparison.' The Law of Comparison may be stated thus :—If two vessels of exactly similar form, but of different size, are run at speeds proportional to the square roots of their lengths, then their wave effective horse-powers will be proportional to the products of their displacements by their speeds. If, then, we are designing a vessel n times as long as a model or similar smaller ship whose speeds and corresponding wave E.H.Ps. we know, the following ratios which various elements of the design bear to corresponding elements of the prototype may be used :—

Linear dimensions	n	Speeds	$\sqrt{n}$
Surfaces	n^2	Wave resistances	n^3
Displacements	n^3	Wave E.H.Ps.	$n^3 \sqrt{n} = n^{3 \cdot 5}$

Speeds related as above are called 'Corresponding Speeds,' and the ratio $\frac{\text{K}}{\sqrt{\text{L}}}$ of speed to square-root of length is called the 'Speed-Length Ratio.'

Model experiments give us the total E.H.P. at any speed. From this the wave E.H.P. can be obtained by separately calculating the skin E.H.P., as above described, and deducting it from the total. The wave E.H.P. for the full-size ship will be $n^{3\frac{1}{2}}$ times that of the model, and the skin E.H.P. for the full-size ship can be separately calculated. The sum of these two results gives the

total E.H.P. for the full-size ship. It is then finally necessary to assume a suitable value for e, the propulsive coefficient, and calculate the I.H.P. or S.H.P. by dividing the total E.H.P. by e. If we are designing from the trial results of a similar completed vessel, the procedure is slightly different :—

I.H.P. or S.H.P. of Type Ship $\times\ e$ = E.H.P. of Type Ship

$\frac{S}{100} \times F_{10} \times \left(\frac{K}{10}\right)^{2\cdot83}$ = Skin E.H.P. of Type Ship } at K knots.

Difference = Wave E.H.P. of Type Ship

Multiply by $n^{3\frac{1}{2}}$

and so obtain Wave E.H.P. for Design

$\frac{S'}{100} \times F'_{10} \times \left(\frac{K'}{10}\right)^{2\cdot83}$ = Skin E.H.P. for Design } at $\sqrt{n}$ K knots.

Sum = Total E.H.P. for Design

Divide by e

To obtain I.H.P. or S.H.P. for Design

where,

S = wetted surface of type ship, in square feet,
$S' = n^2 S$ = " design "
K = speed of type ship, in knots,
$K' = \sqrt{n}\,K$ = corresponding speed of design, in knots,
F_{10} = skin E.H.P. per 100 square feet at 10 knots for type ship,
F'_{10} = " " " for design.

D. W. Taylor's book, 'The Speed and Power of Ships,' which contains a series of curves based on model experiments and covering a large range of proportions of dimensions and speeds, will be found to give very accurate estimates of effective horse-power.

For fast, fine vessels, the paper 'On some Results of Model Experiments,' by R. E. Froude, published in the 'Transactions of the Institution of Naval Architects for 1904,' may be advantageously consulted. Many other experimental results have now been published both in Great Britain and America.

Admiralty Coefficients.

The 'Admiralty Coefficient of Performance' $= \frac{\Delta^{\frac{2}{3}} K^3}{P} = C$

where,

Δ = displacement, in tons,
K = speed, in knots,
P = I.H.P. or S.H.P.

Conversely $P = \frac{\Delta^{\frac{2}{3}} K^3}{C}$, so that if C is known or can be correctly assumed, P can readily be calculated. In similar ships at 'corresponding speeds' $\Delta^{\frac{2}{3}} K^3$ varies as $(n^3)^{\frac{2}{3}} (\sqrt{n})^3$, that is, as $n^{3\frac{1}{2}}$. Hence, if P were also to vary as $n^{3\frac{1}{2}}$, the values of C would remain the same. And also, if for any given vessel P varied as K^3, C would be the same for all speeds. For these reasons C is sometimes called the 'Admiralty Constant,' but as the above relations are theoretical assumptions only, and C is found to vary from speed to speed and from ship to ship, it is better to use the term 'Admiralty Coefficient.'

Although wave-making power follows the law of comparison, and therefore varies as $n^{3\frac{1}{2}}$, skin-friction power does not obey the same law and only increases at the lesser rate

$$n^2 \frac{F'}{F} (\sqrt{n})^{2\cdot88} = \frac{F'}{F} n^{3\cdot415}$$

And hence larger ships have relatively less power and larger values of C than smaller vessels. In the case of large vessels, also, a lesser proportion of power is lost in overcoming internal friction and eddy-making, and a further increase of C is the result.

In spite of its known defects, the 'Admiralty Coefficient' is largely used for estimating horse-power, the assumed value being based upon that for a similar, or nearly similar, completed vessel at 'corresponding' speed, and suitable allowances made for variations in size and proportions,

If the prismatic coefficient of the type ship differs from that of the proposed vessel, we may still find suitable values for C by modifying the 'corresponding speed' of the type ship, thus :—

$$K = K' \sqrt{\frac{L}{L'} \cdot \frac{1 - C_p}{1 - C'_p}}$$

where K, L, and C_p are the corresponding speed, length between perpendiculars, and prismatic coefficient respectively for the type ship, and K', L', and C'_p the desired speed, length, and prismatic coefficient for the proposed vessel.

Economical Speeds.

For each vessel there is a certain 'suitable' or 'economical' speed, determinable in relation to her length and fineness, above which she would be wasteful of power or 'overdriven' and below which she would be unnecessarily fine.

The following table (A) expresses these relations, and Table B gives possible values of the Admiralty coefficient on trial for vessels agreeing with Table A :—

TABLE A.

C_p. Prismatic Co-efficient.	$\frac{V}{\sqrt{L}}$ Speed Length Ratio.	C_p. Prismatic Co-efficient.	$\frac{V}{\sqrt{L}}$ Speed Length Ratio.
·61	·925	·73	·758
·63	·897	·75	·730
·65	·869	·77	·703
·67	·842	·79	·675
·69	·814	·81	·647
·71	·786		

TABLE B.

L. Length on Waterline.	C. Admiralty Coeffi-cient.	L. Length on Waterline.	C. Admiralty Coeffi-cient.
100	137	500	307
150	188	550	310
200	227	600	312
250	255	650	315
300	275	700	317
350	289	750	319
400	297	800	321
450	303	850	323

Table B assumes an efficiency, *e*, of about 55 per cent.; for large turbine work *e* appears to be about 50 per cent., so that in estimating shaft horse-power in such cases C should be taken at about 10 per cent. less than is given by the above table. For single-reduction geared turbines *e* = about 53 per cent.; for double-reduction geared turbines *e* = about 55 per cent.

The formula $C_b = 1{\cdot}06 - \frac{K}{2\sqrt{L}}$ has also been proposed as expressing a suitable connection between block coefficient and speed-length ratio.

Admiralty Coefficient applied to Fuel Consumption.

A variation of the Admiralty Coefficient much used by superintendent engineers, when comparing performances at sea, consists in substituting the daily fuel consumption in tons for horse-power in the formula $C = \frac{\Delta^{\frac{2}{3}} K^3}{P}$. We thus get;—

$$\text{Fuel Coefficient of Performance} = \frac{\Delta^{\frac{2}{3}} K^3}{T}$$

where Δ = mean service displacement in tons,
K = mean service speed in knots,
T = daily fuel consumption in tons.

Rudders.

The area of a vessel's rudder is determined by dividing the product of her length and load draft by about 30 to 40 in the case of warships, 60 to 70 for fast liners, 90 to 100 for slow cargo

tramps. The most efficient angle is about 35° from the middle line, at which angle the total pressure upon the rudder in tons is about $\frac{AK^2}{700}$ for single screw ships, $\frac{AK^2}{1000}$ for twin screws, where A is the rudder area in square feet and K the ship's speed in knots. The centre of pressure at 35° is found by assuming that the pressure on each elementary horizontal strip is applied at a point four-tenths of the breadth of the strip from its leading edge, summing the moments for each strip, and dividing by the total area.

Let h be the distance of the centre of pressure from the axis in inches, and P the total pressure upon the rudder in tons. Then T, the twisting moment in inch-tons, $= Ph$, and

$$D = \text{diameter of stock, in inches} = \sqrt[3]{\left(\frac{16T}{\pi F}\right)}$$

where F = maximum allowable shearing stress in material in tons per square inch.

$$\text{If } F = 5{\cdot}1,\ D = \sqrt[3]{T}$$

In practice the diameters of the rudder stocks of all classified vessels are determined by the rules of the Classification Societies.

Estimate Sheet.

When making preliminary estimates of dimensions, weights, power, etc., the following form will be found convenient:—

Number of Inquiry. Type of Vessel. Owners. Date.

Conditions.

Length × Breadth.

Type. Length × Breadth × Depth. Cubic Number.

S Steel Weight. Steel Coefficient.

W Wood and Outfit Weight. W. & O. Coefficient.

M Machinery Weight. H.P. per Ton.

D Deadweight.

$$\frac{\text{Displacement}^{\frac{2}{3}} \times \text{Speed}^3}{\text{Admiralty Coefficient}} = \text{Horse Power.} \qquad \frac{\text{Length} \times \text{Breadth} \times \frac{\text{Draft full}}{\text{Keel}}}{35} = \text{Block Number} = \frac{\text{Block Coefficient}}{\text{Displacement}}$$

For example, in figures :—

Inquiry No. 42. Cargo and Passenger Steamer. Messrs. Brown and Black. 3.3.30.

To carry 6000 tons and steam 13½ knots on 24 ft. draft. Class, 100 A1 at Lloyd's. Sixty first-class. 100 second-class.

	19200		
T.S.S.	400 × 48 × 30		5760
S.	2200	·382	
W.	850	·147	
M.	750	4·54	
D.	6000		

$$\frac{9800^{\frac{2}{3}} \times 13\tfrac{1}{2}^3}{313} = 3400 \text{ I.H.P.}$$

$$\frac{400 \times 48 \times \overset{24'\ 0''}{\underset{2''\ \text{keel}}{23'\ 10''}}}{35} = 13080 \times {\cdot}75 = 9800$$

These figures are arrived at by a process of trial and error-correction until a satisfactory balance is reached between weights and displacement, block coefficient and speed length ratio, horse-power and weight of machinery.

BASES OF ENGINE AND BOILER DESIGN.

Cylinder Ratios.

Considerations of weight and space usually limit the dimensions of cylinders for the machinery of high speed cross-channel vessels. For ordinary merchant and mail steamers these considerations are of minor importance; coal consumption however is of the utmost importance, and consequently a higher ratio of expansion of steam is utilised, involving larger cylinder dimensions, in order to obtain maximum economy of coal consumption. In fast passenger vessels with high revolutions per minute, four-crank triple-expansion engines are invariably adopted, there being one H.P., one M.P., and two L.P. cylinders. This arrangement admits of a satisfactorily balanced engine being obtained, reducing vibration to a minimum, and the weight of the moving parts of the L.P. cylinders is considerably reduced compared with the ordinary three-crank triple engine or four-crank quadruple. The following table of cylinder area ratios is in accordance with modern practice for various types of marine engines:—

TABLE SHOWING CYLINDER AREA RATIOS.

Type of Engine.	Boiler Pressure. Lbs. per Sq. In.	Ratio of Cylinder Areas.			
		L.P. / H.P.	2nd M.P. / H.P.	1st M.P. / H.P.	H.P.
Quadruple expansion . .	200 to 220	8 9	4·0 4·3	2·0 2·08	1 1
			M.P. / H.P.		
Triple expansion, ordinary merchant practice . . .	160 to 180	6·5 to 7·5	2·5 to 2·7		1
Cross-channel steamers . .	180 to 200	6·25	2·4		1
Compound engines, screw .	100 to 140	4 to 5	—		1
,, ,, paddle .	90 to 130	3·5	—		1

The reciprocating engine is now, however, being displaced by direct or geared turbines in all classes of vessels, from fast passenger and mail steamers and cross-channel boats to cargo vessels, even of the tramp class, owing to the reduction obtainable thereby in fuel consumption.

Mean Pressures and Expansion of Steam.

The total power developed in an engine may be varied by altering the point at which steam is cut off in the H.P. cylinder, and generally provision is made to enable the cut-off in each cylinder to be independently adjusted if necessary to equalise the powers developed in each cylinder. For the maximum designed power the cut-off in the H.P. cylinder takes place at from ·65 to ·75 of the stroke, and the total number of expansions of the steam is

$$= \frac{\text{Volume of L.P. cylinder}}{\text{Volume of H.P. cylinder at point of cut-off}};$$

or

$$\frac{\text{Ratio of } \dfrac{\text{L.P. cylinder area}}{\text{H.P. cylinder area}}}{\text{Cut-off in H.P. cylinder (expressed in fraction of stroke)}}.$$

The total expansion of the steam is usually considered with clearance neglected and neglecting also the fact that release takes place before the end of the stroke. In estimating the mean pressure obtainable in any multiple-stage expansion engine it is referred to the L.P. cylinder, the mean pressure thus obtained being that necessary if the whole of the power were developed in the L.P. cylinder. The actual referred mean pressure is, therefore, in the case of a triple expansion engine equal to

$$\text{Mean pressure in L.P. cylinder} + \frac{\text{Mean pressure in M.P. cylinder}}{\text{Ratio of L.P. to M.P. cylinder area}} + \frac{\text{Mean pressure in H.P. cylinder}}{\text{Ratio of L.P. to H.P. cylinder area}}.$$

The theoretical referred mean pressure may be calculated, assuming that the steam is moderately moist, the curve of expansion being a hyperbola. It depends upon the designed number of expansions and the absolute admission pressure of the steam.

Let Pa = absolute initial pressure,
Pm = absolute theoretical referred mean pressure,
r = total number of expansions,
$\frac{1}{r}$ = cut-off, or reciprocal of r,

then

$$Pm = Pa \frac{1 + \text{hyp. log. } r}{r}.$$

Pressure of Steam in Cylinders of Compound and Triple-expansion Engines.

The values of $\frac{1 + \text{Hyp. Log. } r}{r}$ for Various Expansions are given on page 1705.

The initial pressure, Pa, should be taken 5 to 10 lbs. below the absolute boiler pressure to allow for the drop between boilers and engines, and the back pressure, which must be deducted from Pm as found above, should be taken at not less than 4 lbs. per square inch absolute.

Diagram Factor.

Owing to the losses which occur while the steam is expanding in the various cylinders the actual referred mean pressure obtained from indicator diagrams is less than the theoretical referred mean pressure, and consequently the latter must be multiplied by a diagram factor which takes into account the losses due to clearance, condensation, radiation, friction of ports, compression, drop in pressure between the cylinders, and other losses. The value of this factor is obtained by experience, and, when possible, should be derived from engines similar to the one projected, and working under similar conditions. The values for various types of engines are approximately :—

Quadruple-expansion engines	·63 to ·68
Triple-expansion engines, merchant service	·6 to ·65
„ high-speed cross-channel engines	·56 to ·63
Compound engines	·63 to ·70

When cylinders are jacketed the diagram factors may be increased by about 5 per cent.

The power is usually divided equally among the cylinders of an ordinary compound, triple, or quadruple-expansion engine, and if N is the number of cylinders and P the referred mean pressure (*i.e.* theoretical mean pressure × diagram factor) the mean pressure in the various cylinders of a triple-expansion engine, for example, will be :—

$$\text{L.P. cylinder mean pressure} = \frac{P}{N}$$

$$\text{M.P. „ „ „} = \frac{P}{N} \times \frac{\text{L.P. cylinder area}}{\text{M.P. cylinder area}}$$

$$\text{H.P. „ „ „} = \frac{P}{N} \times \frac{\text{L.P. cylinder area}}{\text{H.P. cylinder area}}$$

In the case of four-crank triple-expansion engines the power developed in each L.P. cylinder is usually five-eighths that of the H.P. or M.P. cylinder.

Piston Speed.

The mean piston speed is usually reckoned in feet per minute and is equal to stroke in feet × 2 × revolutions per minute.

The power which may be obtained from a given weight of engine varies almost directly with the piston speed ; the wear and tear of the engine, however, is increased with the higher speeds on account of the increased inertia stresses involved

Piston speed may be increased either by increasing the stroke and keeping the revolutions constant or by increasing the revolutions, keeping the stroke constant.

By adopting the former method the cost, dimensions, and weight of the engines are increased, whilst by adopting the latter method there is practically no increase in any of the items mentioned. It is evident, therefore, that in cases where weight and space are limited high piston speed must be obtained by high revolutions; these have a limit, however, on account of the stresses due to the inertia of the reciprocating parts.

The piston speed and revolutions of engines fitted in various types of vessels are as shown in the following table :—

TABLE SHOWING PISTON SPEED AND REVOLUTIONS OF RECIPROCATING MACHINERY FOR VARIOUS TYPES OF STEAMSHIPS.

Description.	Number of Cranks.	Piston Speed in Feet per Minute.	Revolutions per Minute.

	3	550 ,, 650	60 ,, 100
Channel steamers	4	800 ,,1000	170 ,, 200
	3	750 ,, 900	130 ,, 180
Paddle steamers	—	550 ,, 650	45 ,, 55

(Also see remarks about propeller revolutions for geared turbines.)

Calculation of Cylinder Diameters.

In determining the diameter of cylinders required for an engine of a given I.H.P., the type of vessel for which the engine has to be designed to a certain extent determines the piston speed and cylinder ratios, due consideration being given to the boiler pressure, the number of expansions being increased as higher boiler pressures are adopted.

Having decided the piston speed and the mean pressure referred to L.P. cylinder as already described, the area of the L.P. cylinder may be calculated, and from the cylinder ratios decided upon the areas of the remaining cylinders are determined.

Let piston speed = S feet per minute;

referred mean pressure = P lbs. per square inch,

then,

$$\text{Indicated H.P.} = \frac{\text{Area of L.P. cylinder} \times P \times S}{33{,}000}$$

or

$$\text{Area of L.P. cylinder} = \frac{\text{I.H.P.} \times 33{,}000}{P \times S};$$

$$\text{Area of M.P. cylinder} = \text{Area of L.P. cylinder} \times \text{Ratio of } \frac{\text{M.P. cylinder area}}{\text{L.P. cylinder area}};$$

$$\text{Area of H.P. cylinder} = \text{Area of M.P. cylinder} \times \text{Ratio of } \frac{\text{H.P. cylinder area}}{\text{M.P. cylinder area}}.$$

Combined Recipro-Turbine Machinery.

In vessels of say under 18 knots the direct coupled turbine installations are not suitable, since the comparatively low rotational speed necessary for an efficient propeller necessitates for an efficient turbine a considerable increase in dimensions and hence increase in weight and cost. In such cases a combination of reciprocating engines and turbines was employed, there being two reciprocating engines to deal with the high-pressure steam and one or two turbines to expand the exhaust steam down to the lowest possible pressure. In the steamer 'Otaki' this system is credited with a saving of about 17 per cent. in the coal consumption; it has also been fitted to the White Star Liners 'Laurentic' and 'Olymp.c,' the Orient Liner 'Orama,' and other vessels.

In the 'Reina Victoria Eugenia' a four-shaft 'combination' arrangement was adopted, the two inner shafts being driven by reciprocating engines and the two outer shafts by low-pressure turbines. At low powers the reciprocating engines produced about three-quarters of the total power and the turbines one-quarter; at full output the proportions were about two-thirds and one-third respectively. The steam consumption was only about 11 lbs. per h.p. per hour or about 20 per cent. less than that required for quadruple expansion reciprocating machinery.

The revolutions of the reciprocating engines were about 113 per min., those of the turbines about 180. The sister vessel 'Infanta Isabel de Borbon' had the usual three-shaft combination the revolutions of the turbines at full power being 276 per min. and of the reciprocating engines 116 per min.

In a three-shaft combination installation with 92 revolutions per min. for the reciprocating engines and 250 for the turbines, the reciprocating portion of the machinery produced 56 per cent. and the turbine portion 44 per cent. of the total full power, but the propulsive effect of the turbine propeller is rather disappointing. This machinery has been displaced by the geared turbine.

TURBINES.*

The development of the steam turbine as a motor for ship propulsion has progressed rapidly in the last decade. In the earlier stages of its adoption, when the turbine was directly coupled to the propeller shafting, the high revolutions necessary to obtain suitable blade speeds for low steam consumption without abnormally increasing the size and weight of the turbines entailed small propellers which were inefficient except for fast vessels, and even in these the turbines were run at an uneconomically low speed in order to improve the propellers.

The introduction of single-reduction gearing between the turbines and propellers enabled advantage to be taken of high blade speeds and fairly efficient propellers for vessels of over about 16 knots speed, and for all speeds of vessels double-reduction gearing permits the turbine and propeller designers to select the revolutions most suitable for their individual purposes so as to obtain the maximum efficiency of turbine and propeller respectively. The revolutions of the most efficient propeller for a vessel depend on horse-power, speed and form of vessel, and should be worked out in conjunction with experimental results such as those published by Taylor and Froude, but the following method gives very satisfactory results for turbines, gearing and propellers :—

If

R = revolutions of propeller per minute;
SHP = shaft horse-power of each shaft;
V = speed of vessel in knots on trial;

then, $$R = C\sqrt{\frac{V^6}{SHP}}.$$

Note.—In 3 and 4 the speeds of the turbine vessels are higher than the corresponding vessels with reciprocating machinery. If the speeds had been equal the saving would have been greater than as recorded.

Arrangement of Turbines.

Turbine machinery may be arranged to drive one, two, three, or four lines of shafting.

In mercantile vessels with direct-coupled turbines three lines were adopted, the centre shaft being driven by a high-pressure turbine, the steam from which was exhausted into two low-pressure turbines driving the two wing shafts. Astern turbines were incorporated in the aft end of the l.p. ahead turbine casings, and during normal ahead running revolved idly in vacuum. A separate high-pressure steam connection was fitted to each astern turbine, and also to each low-pressure ahead turbine. When manœuvring in and out of harbour the wing turbines only were employed, each turbine being controlled independently of the other.

In some installations of turbine machinery in large mail steamers four shafts were employed and the steam expanded in series through an h.p. and i.p., and two l.p. turbines. This arrangement, while introducing more complication in the intermediate receiver connections, enabled a higher efficiency to be secured than in the usual three- or four-shaft arrangement.

In torpedo boats and torpedo destroyers the practice was to adopt a three-shaft arrangement similar to that described above. Most of the vessels fitted in this manner were provided with h.p. and i.p. cruising turbines in order to maintain economy at low speeds, and these turbines were cut out of action as the power increased.

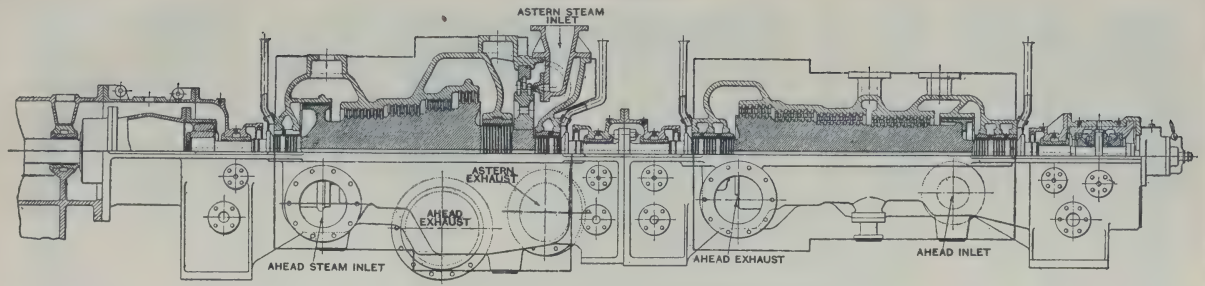

FIG. 8.—Parsons' Turbines, Section through H.P. and M.P. Turbines with H.P. astern incorporated.

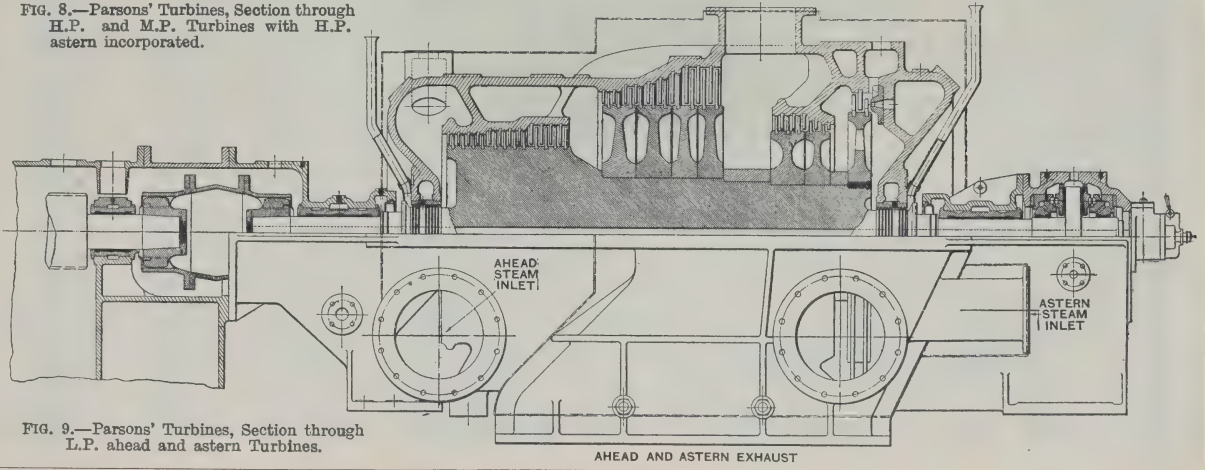

FIG. 9.—Parsons' Turbines, Section through L.P. ahead and astern Turbines.

More recent experience has shown that there are several objections to this arrangement, and in particular to the weight of these cruising turbines, and as a consequence the 'independent' type of turbine has been adopted. Where direct turbines are still fitted the installation usually consists of twin screws driven by turbines of the Parsons' or Brown-Curtis types, having the astern turbine incorporated in the same casing as the ahead turbine.

In light cruisers the machinery usually consists of two independent sets of single-geared turbines fitted in compartments separated by longitudinal or transverse bulkheads, and so arranged that in the event of damage to the one set the other will be available for use. Geared cruising turbines have also been fitted for low power.

In battle cruisers and battleships the turbine installation usually consists of two complete sets arranged in two or three compartments divided by longitudinal bulkheads. In the latter arrangement the h.p. turbines are placed in the wing compartments and the two l.p. turbines in a common central compartment, while in the former the bulkhead is placed between the l.p. turbines.

On each outer shaft there is a h.p. ahead turbine forward and an independent h.p. astern turbine aft. On each inner shaft there is a l.p. ahead turbine, having incorporated with it in the same casing a l.p. astern turbine. All four shafts are thus in use for manœuvring either ahead or astern, the steam exhausting from the h.p. ahead or astern to the l.p. ahead or astern turbine, as the case may be and from thence to the condenser.

With geared turbines each shaft is driven by an independent unit consisting of one h.p. ahead turbine and one l.p. ahead turbine with an astern turbine incorporated in the same casing with the latter.

With double-reduction gearing the high pressure unit is sometimes divided into an h.p. and i.p. in separate casings so as to reduce the length of rotor between bearings and enable higher revolutions to be run without 'whipping.' Where manœuvring requires greater astern power than can be transmitted by one pinion an h.p. astern turbine is fitted at the end of the h.p. or i.p. ahead turbine separately or in the same casing with a diaphragm to prevent astern steam entering the ahead turbine and vice versa. This arrangement is also preferred with superheated steam to minimise the change of temperature in the astern turbine when reversing.

For marine propulsion the two principal types which have been adopted are the Parsons and the Brown-Curtis. In the merchant service turbines of both types with single-reduction gear have been extensively fitted in high-speed steamers for cross-channel mail and passenger service, and the more recent development of double-reduction geared turbines is now being extensively adopted in vessels where the speed is lower, and on that account the propeller revolutions of single-reduction gear are not suitable.

The direct-coupled turbine is rarely fitted now owing to the many advantages and greater economy of the geared installations.

For naval service, so far as this country is concerned, either Parsons' turbines or Brown-Curtis turbines with single-reduction gearing are now being fitted in all battleships, cruisers, or torpedo-boat destroyers. With superheated steam it is found that an economy of about 1 per cent. in steam consumption is obtained for each 10° Fahr. of superheat.

With superheated steam and the latest aids to economy, turbine machinery is a successful rival to Diesel engines at large powers. The liner *Empress of Australia*, ex *Tirpitz*, originally fitted with turbo-hydraulic propelling machinery and water-tube boilers, was recently re-engined by the Fairfield S. & E. Co., Ltd., with single reduction geared turbines of the Parsons' type and cylindrical boilers with superheaters. The speed of the vessel was increased from 16½ to 19 knots and at the same time the fuel consumption decreased from 205 to 150 tons per day. The consumption of oil fuel for propelling purposes is less than 0·7 lbs. per s.h.p. per hour. As boiler fuel oil is usually much cheaper per ton than Diesel fuel oil, and the weight, first cost, and maintenance of a turbine installation less than Diesel's, turbine machinery is more economical and suitable for installations of this class for powers above 15,000 s.h.p.

The latest design of machinery for ocean liners consists of Parsons' turbines with single reduction gear, water-tube boilers of the Yarrow type generating steam at 500 lbs. pressure, and 750° F. temperature, stage feed heaters using steam bled from the turbines, and the majority of the auxiliary machinery electrically driven by current from Diesel-driven generators.

With this arrangement of machinery the consumption of oil fuel for all purposes does not exceed 0·65 lbs. per S.H.P. per hour. The earlier difficulties with water-tube boilers were largely due to impurities in the feed water, but these have been overcome by Mr. J. Johnson, of the Canadian Pacific Steamships, Ltd., by fitting one or two cylindrical boilers to generate steam for auxiliary and heating purposes, the condensate being used as make-up feed for the water-tube boilers. Condenser leakage has been practically eliminated by the use of Monel metal or cupro-nickel condenser tubes.

Parsons' Marine Turbines.

Longitudinal sections through typical Parsons' reaction turbines are shown in figs. 8 and 9, and these turbines would be used in the arrangement shown in fig. 13, page 2380, the H.P. and M.P. tandem turbine taking the place of the H.P. turbine shown in the figure.

A set of Parsons' turbines of 3,000 s.h.p. with double-reduction gearing is shown in figs. 10, 11, and 12, p. 2379.

PARSONS' TURBINES.

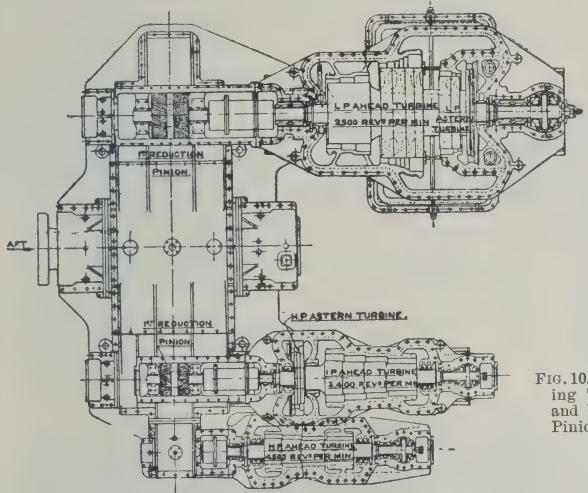

FIG. 10.—Plan View showing Turbine and I.P. and L.P. 1st Reduction Pinion Covers removed.

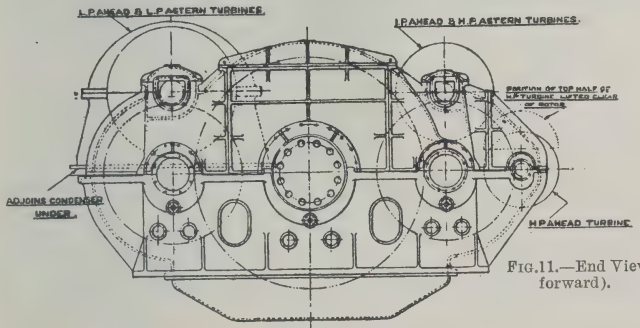

FIG. 11.—End View (looking forward).

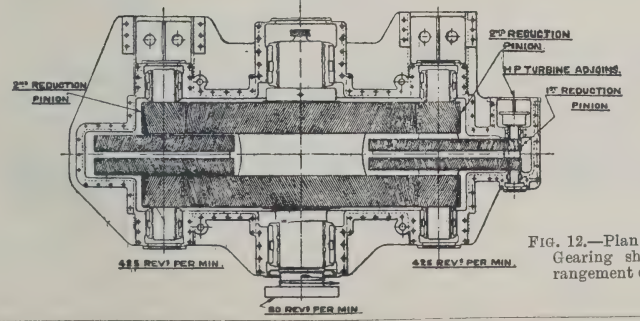

FIG. 12.—Plan View of Gearing showing arrangement of Wheels.

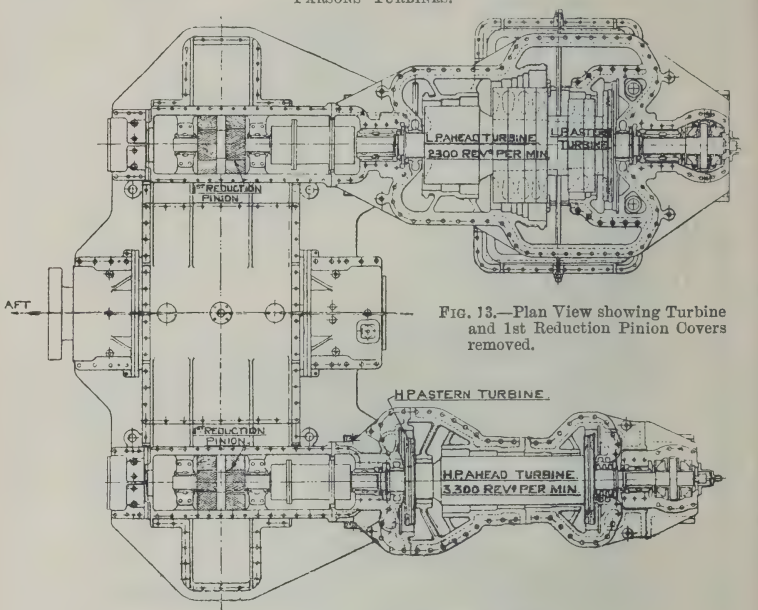

FIG. 13.—Plan View showing Turbine and 1st Reduction Pinion Covers removed.

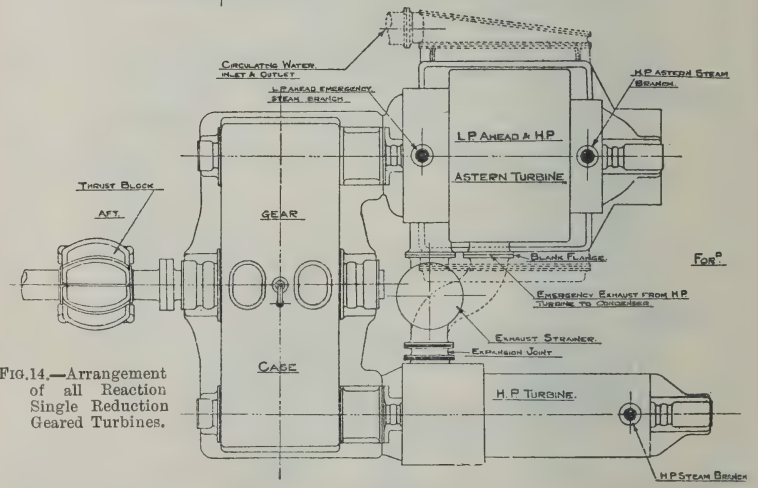

FIG. 14.—Arrangement of all Reaction Single Reduction Geared Turbines.

There is one h.p. and one i.p. ahead turbine each developing approximately one quarter of the total power and driving separate pinions geared to one first reduction gear-wheel. The l.p. turbine develops one half power and is geared to the first reduction gear-wheel on the opposite side of the main wheel. An h.p. astern turbine is incorporated in the same casing as the i.p. ahead turbine but separated from it by a diaphragm, and the l.p. astern turbine is also incorporated with the l.p. ahead.

Owing to the high revolutions at which turbines can run with double-reduction gearing, the desired blade speed can be obtained with a small diameter of rotor and consequently the end thrust due to steam pressure is low enough to be taken entirely on a thrust block of the pivoted type, thus dispensing with dummies and the leakage caused by them. In addition, the blade heights to pass the steam are greater than in large rotors of equal power, but as the clearance is not increased the percentage loss due to leakage past the tips is much less in the geared turbine. As a result of these and other advantages the steam consumption is much reduced from that required for direct-coupled turbines, and if superheat is used, say 200° F., the consumption for turbines only, exhausting to 28 inches vacuum, will be from 8 to 8½ lbs. per hour.

Figs. 11 and 12 show the arrangement of the double-reduction gearing for this set of turbines.

Fig. 13 shows an alternative arrangement with two turbines instead of three. There is one h.p. and one l.p. ahead turbine with a corresponding astern turbine in each casing.

This arrangement is simpler, but the consumption is slightly higher than in the three-turbine arrangement.

Fig. 14 shows a set of single-reduction geared turbines with one h.p. and one l.p. ahead turbine and an h.p. astern turbine incorporated with the latter.

This arrangement is suitable for low powers or where the propellers can be run at higher evolutions as in channel or shallow-draught steamers.

Brown-Curtis Turbines.

Figs. 15, 16, and 17 show a set of Brown-Curtis turbines for a double-reduction geared installation for one shaft of a liner.

The h.p. turbine is sometimes designed with three wheels each with two rows of buckets or moving blades, and at others with one two-bucket wheel and several single-bucket wheels. The m.p. and l.p. ahead turbines have single bucket wheels, and in the astern turbines there are usually two three-bucket wheels, or if a greater proportion of astern power is required, one three-bucket and two two-bucket wheels.

The turbines are arranged with the h.p. and m.p. in line and coupled together, driving one pinion of the gearing and the l.p. turbine driving a separate pinion. This arrangement enables the designer to choose the revolutions most suitable for each turbine.

The astern turbines are arranged with the first or h.p. stage in the low pressure end of the m.p. ahead turbine casing, but separated from it by a diaphragm, and the l.p. astern in the corresponding l.p. ahead casing exhausting through the common pipe to the condenser. The astern drive is thus distributed over both pinions, and especially with superheated steam the change in the casing temperature of the first stage when astern steam is turned on is not so great.

The casings and diaphragms are of cast iron, except where superheated steam is used, when the casing of the h.p. is of cast steel and the diaphragms of special bronze.

The rotors and wheels are of mild steel and specially designed to avoid 'whipping' and to withstand the stresses caused by the high speed of rotation. The blades or buckets are of special bronze capable of maintaining its strength at high temperatures, and the nozzles are formed of steel plates embedded in the diaphragms during casting. The rotors pass through glands at each end of the casing, which are packed with carbon rings to prevent the egress of steam at the high pressure or inlet of air at the low pressure stages.

The end thrust of the rotor is small and is taken up by a thrust block, usually of the Michell type.

Reduction Gear for Propulsion.*

The development of the turbine has led the way to the adoption of indirect transmission between the turbine and propeller, in order to utilise to the fullest extent the economy to be derived from running the turbines at high relative speeds and the propellers at reduced speed, as compared with direct-driven turbines. The importance of saving a few ounces of coal per h.p. per hour, and five per cent. or more in propeller efficiency in modern large power ships, either naval or mercantile, is obvious. In the former the radius of action with available fuel supply is increased, and in the latter a substantial reduction is made in the annual fuel bill.

The following systems have proved successful, and may be now considered beyond the experimental stage :—

(*a*) Parsons' mechanical gearing.
(*b*) Fottinger's hydraulic transformers.
(*c*) Electric transmission.

(*Continued on p.* 2386.)

* See also pp. 930, 1818.

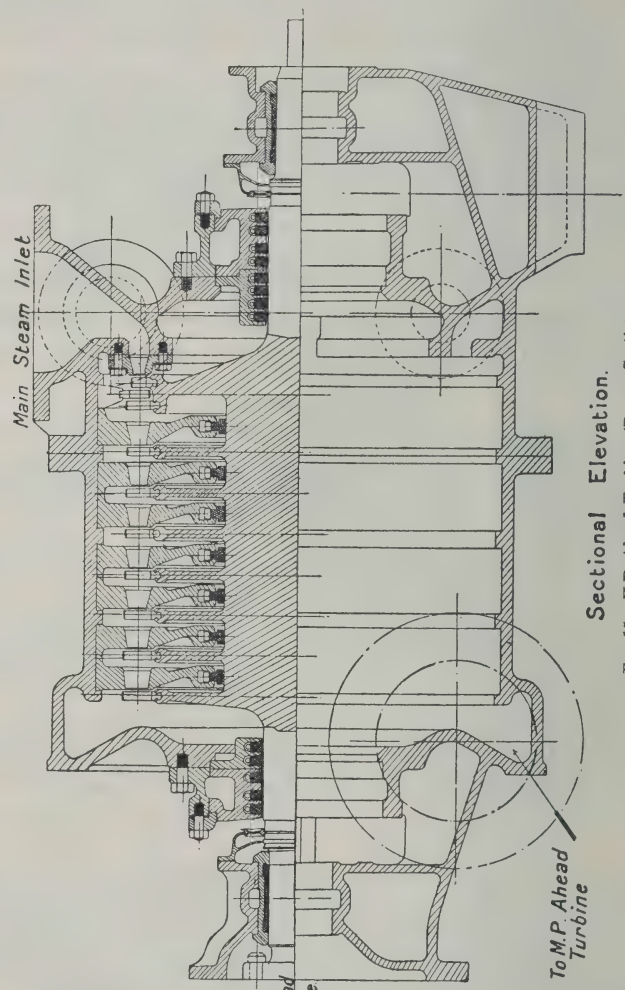

FIG. 15.—H.P. Ahead Turbine (Brown-Curtis).

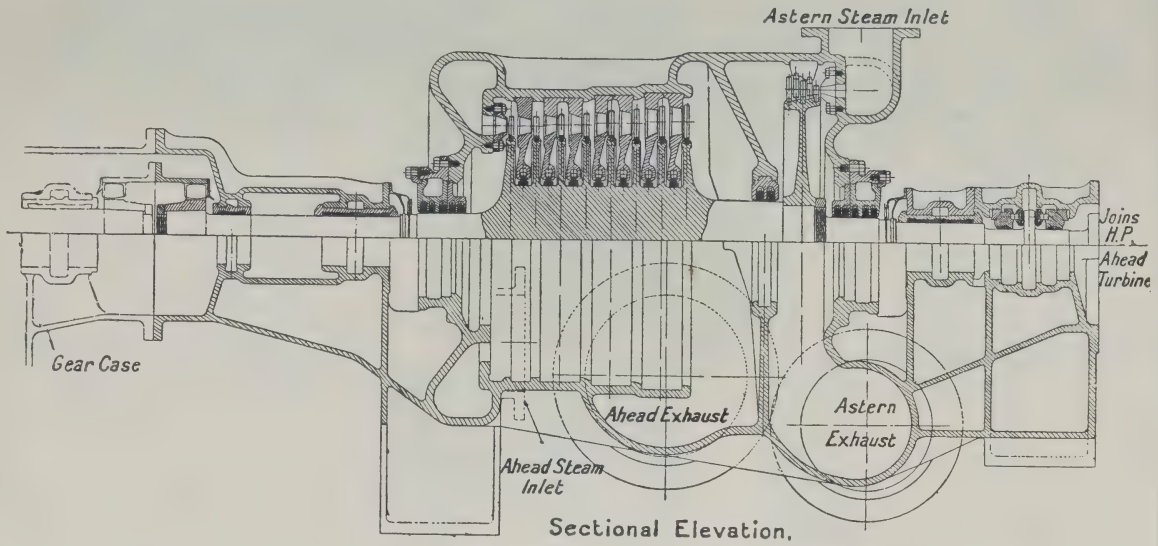

FIG. 16.—M.P. Ahead and H.P. Astern Turbine (Brown-Curtis)

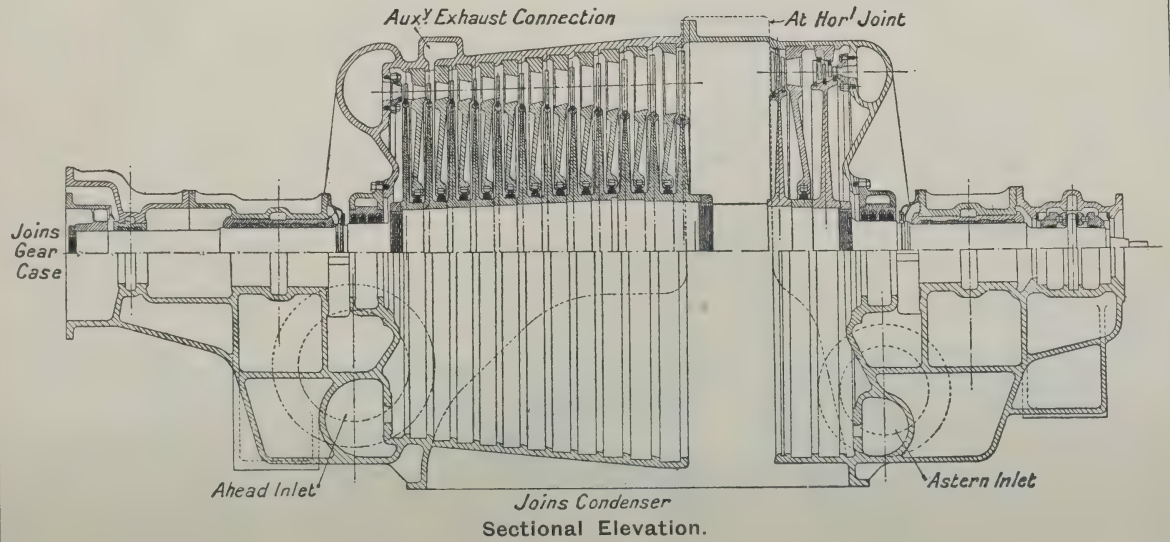

FIG. 17.—L.P. Ahead and Astern Turbine (Brown-Curtis).

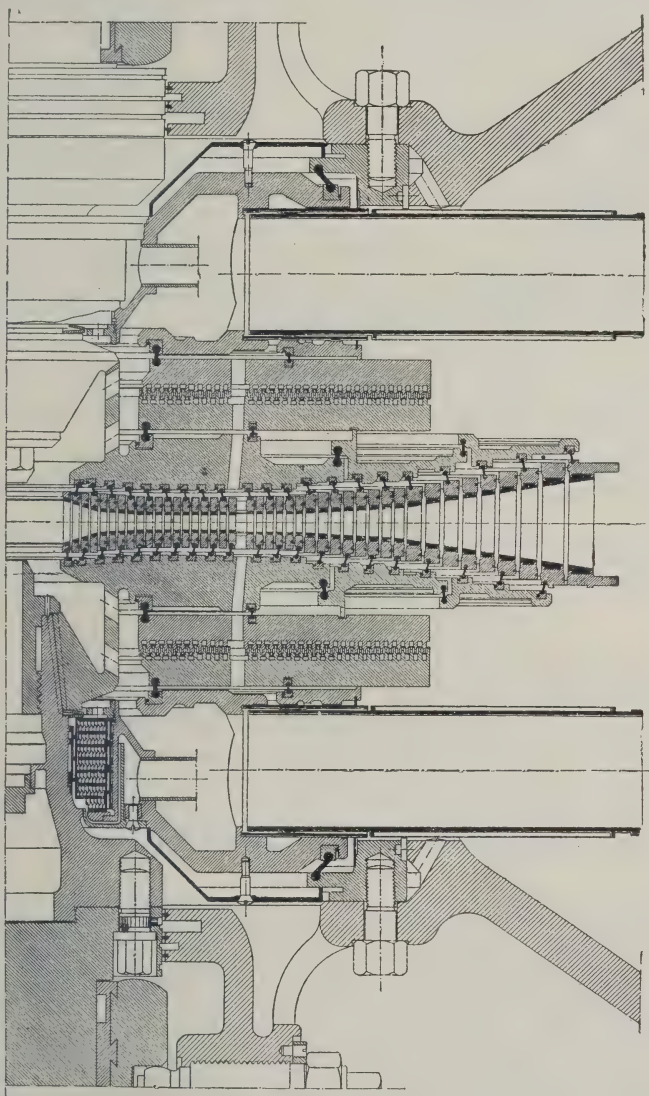

FIG. 18.—Longitudinal Section of a 1,000 K.W. Ljungström Turbine (Lower part).

The details of these systems are described in the following pages.

Each system will have certain fields of application where its particular advantages render its use desirable.

Some of the relative advantages and disadvantages of the systems are as follows:—

(*a*) MECHANICAL GEARING.

Advantages.

(1) Reduction in weight of installation from 10 to 15 per cent. as compared with direct-coupled turbines.

(2) Reduction in fuel consumption of 10 per cent. on same basis.

(3) High mechanical efficiency of gearing, 97 to 98 per cent. for double and single reduction gears respectively.

(4) Large speed reduction ratio permissible, so that greatest propeller efficiency can be obtained without impairing turbine efficiency.

(5) Simplicity of mechanism.

Disadvantages.

(1) Separate turbines for astern running are necessary which are only capable of developing about two-thirds of ahead power.

(2) Noise in engine room. This is very slight with the recent improvements in tooth cutting, and is not noticed outside of machinery space.

(3) Wear in teeth. With properly designed gears and properly cut teeth this is very slight.

(*b*) HYDRAULIC TRANSFORMERS.

Advantages.

(1) Astern turbines dispensed with and about 85 per cent. of ahead power available for astern running with reversible transformer.

(2) Absence of noise.

(3) Relatively no wear.

(4) Practically no limitation in power to be transmitted.

(5) Increased manœuvring power due to greater astern power and practically instantaneous reversal.

Disadvantages.

(1) Lower efficiency as compared with mechanical gearing, about 89 per cent.

(2) Limitation in speed reduction ratio, the maximum being about 6 : 1, and in consequence a reduction of efficiency of both turbines and propellers as compared with geared turbines, but not to the same extent as with direct-coupled turbines.

(*c*) ELECTRIC TRANSMISSION.

Advantages.

(1) Astern turbines dispensed with and full power available for astern working.

(2) Absence of noise.

(3) No wear and minimum cost of upkeep.

(4) No restriction in revolutions, so that highest efficiency of turbines and propellers can be realised.

(5) Great economy in multiple screw ships at low power, as one generator can be cut out entirely.

Disadvantages.

(1) Greater first cost than geared turbines.

(2) Higher consumption at full power than geared turbines—say 6 per cent.—due to transmission losses in generator and motor being greater than in gearing.

PARSONS' GEARING.*

This gearing consists of a large gear wheel with double helical teeth about $\frac{7}{8}$ in. pitch, coupled to the propeller shaft, and driven by either one or two pinions, coupled to the turbines. The connection between the pinion spindle and turbine spindle is by means of a claw coupling, which under running conditions permits of any slight lateral movement due to the expansion of the turbine rotor under steam being taken up. The gearing is completely enclosed in a cast-iron casing, which also forms the support for the bearings of the gear wheel shaft and pinion spindles. Jets of lubricating oil from the forced lubrication system impinge on the teeth at the point of contact of the pinion and wheel, and the spindles and shaft bearings are also connected to the forced lubrication system. The double helical gear ensures the transmission of pressure from one tooth to another without shock or vibration, and as the teeth are of true involute form complete line contact exists during the time they are in mesh. The pinions are made of nickel steel, having a tensile strength of about 40 tons per sq. in. with 25 per cent. elongation, and the gear wheels of carbon steel having a tensile strength of about 32 tons per sq. in. with

* See also pp. 930, 1818.

PARSONS' GEARING.

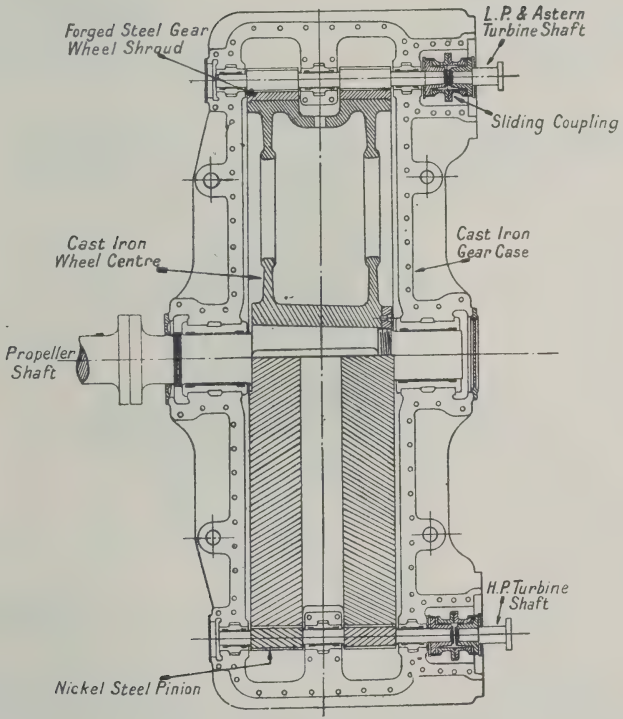

FIG. 19.—Plan with top casing removed.

26 per cent. elongation. Absolute accuracy in cutting the gearing is essential, and any corrective process or hand work after the gear is cut is inadmissible. The machines employed are the result of extensive and costly experiments, both in design and construction. In the double reduction gears the pitch of the teeth in the intermediate pinion and large wheel varies from $\frac{7}{16}$ to 1 inch.

With regard to efficiency, single reductions will go up to 98½ per cent., and double reductions up to 97 per cent.

The first steamer to be equipped with reduction gearing was the 'Vespasian,' a single-screw steamer of 2,150 tons. This gearing, as tested by Sir Charles Parsons, gave 98½ per cent. efficiency, and a fuel economy of about 13 per cent. was obtained. The cross-channel steamers, 'Normannia' and 'Hantonia' (with gearing made by The Parsons Marine Turbine Co., Ltd.), with a gear ratio of about 7 : 1, consumed only 43 tons of coal per trip, as compared with 70 tons per trip required by direct-driven turbine vessels of similar dimensions and speed, engaged in the same service.

Mechanical gearing for turbines has developed enormously in recent years, and is now being used extensively for ships of all powers and classes. Double reduction gearing makes it possible to run the turbines twenty or thirty times as fast as the propellers, with a consequent gain in overall efficiency.

Fottinger's Hydraulic Transformer.

The hydraulic transformer (fig. 20) consists of two centrifugal pump wheels, A, keyed to the primary shaft, which is driven by the turbine. On the secondary, or propeller, shaft three impulse reaction water turbine wheels are mounted, the after two, B and C, for ahead driving,

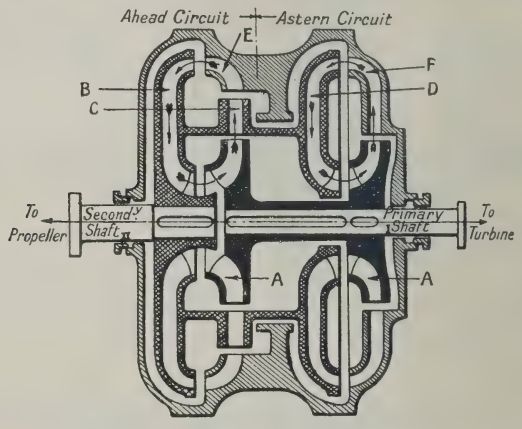

Fig. 20.—Fottinger's Hydraulic Transformer.

and the forward one, D, for astern driving. The wheels for ahead driving absorb the energy delivered to them from the water discharged by the pump wheel in two stages, the primary stage, C, being connected to the astern water turbine wheel, D. Having given up part of its energy in the primary ahead stage, the water moves in continuous compact flow through guide vanes, E, in the casing to the second stage ahead wheel, B, which absorbs the remaining energy in the water. The discharge from the second stage wheel flows back to the beginning of the circuit in the pump wheel, giving up to it the remaining energy of discharge. In the same way the astern driving wheel, D, receives its energy from the water discharged by the forward pump wheel guided into it by the stationary vanes, F, in the casing.

The vanes in the ahead and astern turbine wheels are spaced in opposite directions to each other, thereby giving the reversed motion.

A change valve, controlled by a lever, admits the water from either pump wheel to the corresponding turbine wheel to give the desired direction of rotation.

The wheels and vanes of the transformer are made of bronze, and the casings of cast iron.

The efficiency of the transformer decreases with an increase of speed reduction ratio on account of the higher velocities causing increased fluid friction.

Fresh water is used in the system, and on account of the work done upon it by friction during its passage through the vanes heat is generated. Part of this heat, which would otherwise be lost, is saved by using the water for feeding the boilers, the quantity of water in the transformer system being maintained by filling up with colder water from the air-pump discharge.

The Vulcan Diesel Hydraulic Drive.

The Vulcan gearing, fig. 21, which transmits the power of two Diesel engines to a common propeller shaft, consists of a large helical gear wheel mounted on the propeller shaft, and in which two pinions engage with gear ratio of about 3 : 1. These pinions are connected through liquid clutches to the crankshafts of two Diesel engines. The clutches, built under the Vulcan-Föttinger patents of the Vulcan Werke, each consist of a compartment for running ahead and a compartment for running astern.

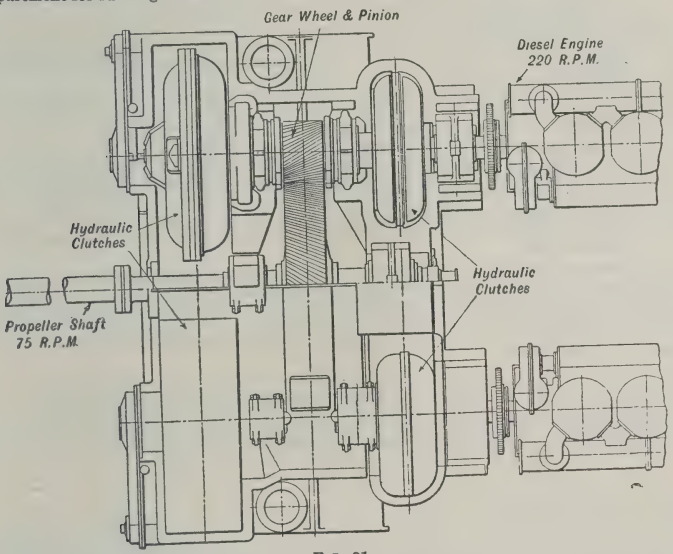

Fig. 21.

The engines are reversed by alternately filling and emptying the ahead and astern compartments by means of a reversing gear operated from the engineer's platform controlling the centrifugal pumps driven from the primary shafts. The driven pinions, and consequently the propeller shaft, run in the same or in the opposite direction to that in which the engine shafts rotate, according to whether the clutches for forward or for astern running are filled with liquid. When the propeller is reversing the Diesel engines require no attention as they run permanently in one direction.

The controlling mechanism is so arranged that the liquid or hydraulic clutches of both the Diesel engines are operated simultaneously. In the event of one of the engines requiring to be stopped during working, an arrangement is provided whereby the two compartments of its respective clutch are emptied and the engine cut out.

The efficiency of the Vulcan gearing is in normal ahead running 97 per cent. The power available for astern running is 65 per cent. of the ahead.

The gearing and the clutches are built together, forming one complete unit in a common cast-iron casing. The hydraulic clutches are of cast iron. The pinions and the wheel rim, which is shrunk on to the cast-iron body of the large gear wheel, are of special steel. The teeth are cut on a precision milling machine by the involute process. The shafts are of Siemens-Martin steel; all bearings are lined with white metal. The front bearing of the large gear wheel is constructed as a thrust bearing and takes up the thrust of the propeller shaft so that no additional propeller thrust block is required.

The liquid used for operating the clutches is lubricating oil. The bearings and teeth of the gear wheels are lubricated with the same oil by which the liquid clutches are operated. The lubricating oil and the oil which drips from the bearings of the gearing and from the clutches is caught in a collecting reservoir placed underneath the gearing. It is drawn from this collecting reservoir by a lubricating oil pump which pumps the oil through a filter and a collector back to the bearings of the gearing and to the teeth of the gear wheels. Oil-circulating pumps attached to the Diesel engines also draw the oil from this reservoir and deliver the oil to the compartments of the clutches as required.

Driving by high-speed Diesel engines and Vulcan gearing possesses *inter alia* the following advantages over direct drive :—

(1) Less weight, lower first cost and less space, particularly in height, with consequently better utilisation of the available space in the ship.

(2) As two Diesel engines drive on to each propeller shaft, the reliability at sea is increased in consequence of this engine standby, and it is therefore a practical proposition to build ships of 5,000 s.h.p. with a single propeller shaft.

(3) Each of the engines can be disconnected from the helical gear wheel by emptying its corresponding liquid clutch. The engine is started working again by simply refilling the liquid clutch so that it is picked up and carried on by the engine, which remains running.

(4) The engines are of the single-acting, non-reversible, four-cycle type. The thermal strains due to admission of cold air to the hot cylinders are obviated, as the engines run continuously in one direction when manœuvring.

(5) The liquid clutches have the property of completely eliminating all irregularities in the turning moment of the Diesel engines not only during normal working, but also at the critical torsional speeds, as the clutches transmit a uniform turning moment, otherwise only attained by turbine drive.

(6) The vessel may be run with as low a number of revolutions of the propeller as may be desired (five to twenty revolutions per minute), which is of importance when manœuvring.

Installations are being constructed by the Vulcan Company for two 10,000-ton d.w. single-screw vessels of 4,000 b.h.p. for the Hansa and the Hamburg Australian Lines. In these instances the propelling units will be of the four-stroke cycle, single-acting type, conforming to marine practice in having crossheads, but utilising steel castings for the main structural parts of the engines, such as bedplates, columns, and cylinders. Four engines can be applied very conveniently to a single shaft.

Electric Transmission of Power for Propelling Machinery.

The application of electricity for transmitting power between the prime mover and the propeller may be divided into two classes—viz. Turbo-electric and Diesel-electric.

TURBO-ELECTRIC DRIVE.

The electrical equipment required is an alternating current generator suitable for direct coupling to a high-speed turbine, a motor of suitable speed for direct coupling to the propeller shaft, a direct current exciter or an auxiliary generator, from which direct current can be obtained, and suitable control gear. The whole can be regarded as a reduction gear having a ratio of reduction determined by the relative number of poles on the motor and generator. Thus with a two-pole generator and a sixty-pole motor the ratio of reduction would be 30 to 1, and, as with mechanical gearing, any variation in speed is obtained by varying the speed of the prime mover.

Two types of alternating current motors have been used for driving propellers :—

(*a*) Induction machines, both slip-ring and squirrel-cage types.
(*b*) Self-starting synchronous motors.

All things considered, the self-starting synchronous motor is the most suitable for this class of work on account of the large air gap, simplicity of construction, accessibility of windings, high power factor, and efficiency. When starting from rest the synchronous motor functions as a squirrel-cage motor with its field unexcited.

s.h.p. account of its greater flexibility direct current is preferable for vessels up to about 3,000 On on one shaft ; beyond this power, owing to the limitations of voltage, the cables become excessively large.

Electrically driven ships in service have demonstrated their unquestionable reliability; the main driving power is transmitted magnetically across large air gaps, giving an elastic medium for absorbing shocks, and thus making it the simplest and most reliable form of speed reduction.

The turbine is of simple construction, being built in one casing and directly connected to the generator, thereby reducing the size of the seatings and eliminating distortion and misalignment troubles due to local straining of the ship. Bearings, shafts, shaft packings, valves and piping are reduced to a minimum, thus decreasing the friction and leakage losses. The astern turbine

is eliminated entirely in an electrically driven vessel, full power astern being available without reversing the direction of rotation of the turbine.

There is an absence of vibration and noise, as the machinery is perfectly balanced, with no rubbing contacts, and the quietness of the running is a feature of great importance in a passenger vessel. Manœuvring is very efficient with this type of power transmission, so that perfect speed control in heavy seas is maintained without danger of racing.

The cost of upkeep, as has been proved by ten years' experience with electrically driven vessels, is much less than with any other type of reduction gear.

The propeller efficiency may be kept very high as the electric drive lends itself practically to any desired speed reduction between the turbine and propeller, and each may therefore be designed to operate at a speed corresponding to its highest efficiency.

DIESEL-ELECTRIC DRIVE.

The Diesel-electric drive will be most suitable for double purpose vessels such as fruit and meat carriers, where a large amount of power is required for operating refrigerating plant, etc., and for dredgers, cable-laying ships, self-propelled floating cranes, and vessels of similar types.

In such vessels it is possible, by the application of electricity, to use the same prime mover for both propelling and auxiliary purposes, also to have a number of comparatively small engines each driving a generator, and a single motor direct coupled to the propeller shaft, which can thus be run at the most suitable and efficient speed irrespective of the speed of the prime mover, the electrical losses being largely offset by the more efficient propeller.

The Diesel engines for electric transmission are simpler in design than those which are coupled directly to the propeller shaft, as the engine speed has no relation to the propeller speed, and as the engines run in one direction only. The large air storage tanks, also, can be eliminated.

With the electric drive accurate and constant knowledge of the power output is always obtainable from meters on the control board; and in this manner the power required at any draft or trim under all weather conditions, the effect of dirty hull on the ship's resistance, etc., can be ascertained and studied.

Rules for the Dimensions of Steamship Shafts.
See p. 1005.

BOILERS.

In determining the principal dimensions of a boiler, or boiler installation, consideration must in the first instance be given to the system of draught employed, whether it is to be forced or natural draught, and since the quantity of steam which a boiler is capable of generating depends on the weight of coal consumed, it follows that the dimension which must first be decided is that of the grate area, the heating surface being proportioned from the grate area depending upon the type of boiler employed. The efficiency of the boiler largely depends on the rate of evaporation per square foot of heating surface, which should be kept as low as possible.

Coal Combustion.

The weight of coal which can be burnt per square foot of grate area per hour under varying conditions of draught is approximately:—

Natural draught . . .	16 to 20 lbs.	Forced draught 2 ins. air pressure	45 to 50 lbs
Forced draught ½ in. air pressure	20 to 25 lbs.	„ 3 ins. „	55 to 60 lbs
„ 1 „	30 to 35 lbs.	„ 4 ins. „	60 to 70 lbs

With cylindrical boilers and water-tube boilers for cruisers and battleships the maximum combustion per square foot of grate rarely exceeds 40 lbs. when working with closed stokeholds and 30 lbs. under Howden's system of forced draught; with the express type of water-tube boiler as fitted in torpedo boats and torpedo boat destroyers the combustion varies from 60 to 80 lbs. of coal per square foot of grate.

Boiler Surfaces.

The heating surface and grate area for a required boiler is determined by the method of draught employed, whether natural or forced, the kind of coal used on account of the difference in calorific values of different varieties of coal, and the type of engine to which steam is being supplied, quadruple expansion engines, for instance, requiring less boiler surface than compound engines on account of the greater economy in steam consumption per I.H.P. of the former.

Economy in coal consumption is obtained by working the boilers easily at low rates of evaporation. Where considerations of weight and space are of importance, as in naval and fast merchant vessels, the boilers are reduced in size, and forced draught is used to increase the rate of evaporation, with corresponding reduction in efficiency. In Howden forced draught the economiser effect of

the air tubes in the uptakes increases the efficiency so that this system compares favourably with natural draught and is much superior to the closed stokehold system.

The following table gives the average H.P. developed per square foot of grate, and the ratio of heating surface to grate area of different types of boilers and average consumptions of coal for various types of engines.

TABLE SHOWING PARTICULARS OF BOILERS OF VARIOUS TYPES OF STEAMSHIPS.

Draught.

The two systems of forced draught most commonly adopted are closed stokeholds and Howden's system (page 2124) with closed ashpits. In the former an air pressure is maintained in the boiler rooms by forcing in air with fans, all openings in the boiler room are closed down with doors, and air locks fitted for access purposes. With Howden's system the boiler room is open, no air locks being required, and the air is forced by fans over the surface of a nest of tubes, or Corrugated Plate Air Heater situated in the uptakes, through which the products of combustion pass on the way to the funnel. The air is raised to a temperature of about 250° F., or over, by the air heater, and passes through passages on either side of the uptake into a reservoir surrounding the furnace fronts, from which reservoir the air is admitted to the furnaces by valves in the furnace fronts, at the sides and the top, to the ashpit and above the fire respectively. Valves are fitted to control the admission of air above and below the fires: these must be shut before opening the furnace door to fire the boiler, otherwise the flame would be blown out into the stokehold. The proper use of the top valve prevents excessive smoke without reducing the boiler efficiency or the amount of evaporation per lb. of coal. Special strips of twisted steel

TURBOVANE
FANS FOR ALL PURPOSES

The illustration shows a turbovane fan (without the vane control previously shown in these pages).

These fans are made in an extensive range, of sturdy construction and high static efficiency.

The majority of installations as supplied to date in this country are naturally for mechanical draught in boiler plant, but in addition we have supplied fans for railway tunnel ventilation, road tunnel ventilation, and also for gas circulation.

ribbon called 'retarders' are placed in each boiler tube, causing the hot gases traversing the tubes to take a spiral course and be retained longer in close contact with the tubes than they otherwise would.

The latest type of furnace fronts has the side valves controlled by one handle, and is also fitted with a safety guard, so that the furnace doors can only be opened when the air valves are shut, thereby preventing the possibility of any flame coming back through furnace door when it is opened.

Fronts have also been developed for firing powdered coal, in conjunction with various patentees of powdered fuel firing systems. A specialty of the Howden type of furnace front for this class of work is the double ashpit door reducing the radiation to a small figure and giving much pleasanter stokehold conditions, while the circulation of a regulated subsidiary air supply around and through the inner door eliminates 'panting' and has a cooling effect, thus maintaining its length of service under otherwise onerous conditions.

On account of the abstraction by the air of what would otherwise be waste heat passing up the funnel a considerable measure of increased boiler efficiency is attained compared with the closed stokehold system, and the uniform condition of furnace temperatures which Howden's system ensures tends to reduce the wear and tear of the boiler.

A more uniform efficiency of furnace can be maintained with forced draught and it may be readily controlled to suit any desired rate of combustion, being quite independent in this respect of prevailing atmospheric conditions.

The Howden-Ljungström Air Preheater.

One of the most important inventions for the reduction of fuel consumption is the air preheater, which may be considered as a development of the Howden air-tube box. By this means 70 per cent. of the heat in the waste gases from the boiler can be recovered, so that a very considerable increase in efficiency is obtained without the disadvantages of excessive weight or corrosion as in the case of feed-water heaters.

The principle involved is exceedingly simple and effective. Briefly described, a large transmission surface is assembled in a rotating part in such a way that the elements are alternately traversed by the waste gases from the boiler and by the cold air to be used for combustion. The gases give up their heat to the elements, and, as these move round into the current of cold air, the heat previously absorbed from the gases is given up to the air. The process is continuous.

In actual construction, the elements consist of thin plates of metal placed close together and corrugated in order to obtain a very large surface. They are fixed in a rotor in such a way that the passages for the gas and the air between the places are parallel with the axis of rotation. The rotor is supported upon disc rollers fixed in a stationary envelope or casing, so that the power required to drive it is very small.

The casing is provided with inlets and outlets for the gases and for the air, which are separated from each other by diametral partitions above and below the rotor. In the upper section of the casing two fans are provided, one to force the cold air through the elements which are at the moment travelling through the air side of the heater, and the other fan to suck the gases through the elements on the gas side. The two fans are mounted on one shaft which passes through the upper partition and which can be driven by an electric motor or in any convenient way, the motor drive being taken by suitable gearing.

A most important feature of the heater is the ease with which the surfaces of the elements can be kept clean. A radial pipe with steam jets is fitted below the rotor, on the gas side, and steam is discharged while the rotor is revolving, so that every portion of the elements must pass through the jets, and no part of the surface can escape the scouring action of the steam. Every particle of soot is blown away, and the efficiency of heat transmission is thus maintained constant. It is necessary to operate the jets for fifteen seconds only every few hours, so that the consumption of steam for this purpose is negligible.

Figs. 22 and 23 show the arrangement of the air preheater with two cylindrical boilers, but it is also suitable for using with water tube boilers and furnaces of various types.

An arrangement in which the axis of the preheater rotor is horizontal and separate centrifugal fans are fitted has now been introduced as an alternative. In this case the fans may be situated remote from the preheater, possibly in the engine room or in a separate fan room as circumstances may decide.

The Howden Corrugated Plate Air Heater.

(Patent.)

The Howden Corrugated Plate Air Heater is built of a number of elements each, of which is composed of two corrugated steel sheets. The sheets are welded together at the top and bottom and thus brought to sharp edges, and at the ends the plates are offset to give the required spacing between each pair of elements. The ridges of the corrugations of the two plates forming an element are set opposite each other, the air passing through the tubes thus formed while the flue gases pass through sinuous paths between the various pairs of elements. On the air side the heater may be arranged multiflow by re-passing the air through the tubes on the counter flow system. On the gas side the heaters are generally single flow, and the confined tortuous paths through which the gases pass have been proved to give an exceedingly high rate of heat transmission.

THE HOWDEN-LJUNGSTRÖM PATENT AIR PREHEATER.

FIG. 23.

FIG 22.

For pulverised fuel firing, the heaters are adapted to pass the primary and secondary air, respectively, through a different number of passes so that any desired temperature can be obtained for either and, also, the heaters may be subdivided to furnish primary and secondary air at different pressures, or furnish primary air under suction and secondary air under forced draught, or *vice versa*.

The Howden Cellular Air Heater.

The cellular air heater embodies all the features of the tubular air heater with the following additional advantages :—

1. The heating surface for similar space occupied is approximately double that of a tubular heater.
2. The gases and air travel substantially in a contra-flow direction.
3. Due to 1 and 2, a higher transfer of heat from the flue gases is obtained.

The heating elements or cells are made of mild steel plate. Each element is carefully manufactured and gauged before assembling. Special precaution is taken to prevent warping of plates and each cell is made truly parallel.

The guide vanes in the air passages are so arranged to divide the incoming air into an equal number of streams which flow directly opposite to the path of the gases on the opposite sides of the elements. These guide vanes are made of steel strips hung on to ferrules secured to the heating elements. The vanes are designed to give the air a turbulent flow. By distributing the air equally over the surface of the plates in the manner mentioned, it ensures that there can be no short circuit of air and thus avoids any part of the plate becoming overheated.

The complete heater when assembled consists of a number of portable sections securely bolted together and which can at any time be removed for repair if necessary.

Furnaces and Firebars.

If forced draught is employed it is not desirable to have firebars longer than 6 ft. on account of the tendency for large quantities of air to pass through the firebars if the fire should burn into holes. With Howden's system 5 ft. 6 ins. is the maximum length of firebar generally adopted. In naval practice with modern water-tube boilers working at full power under a moderate forced draught of 0·5 in. to 0·75 in. of air pressure, grate bars having a maximum length of 7 ft. are frequently employed ; this, however, requires skilful firing, and extreme care to ensure the boiler efficiency being maintained at a maximum. For natural draught the length of grate bar should not exceed 6 ft. 6 ins., but increased boiler efficiency will be attained by using shorter bars, on account of the greater control over the fires. The diameter of furnaces for cylindrical boilers (figs. 26 and 27) should not be less than 32 ins., nor greater than 48 ins., and the number of furnaces which can be fitted in boilers of the following dimensions is :—

Boilers up to 9 ft. 0 ins. diameter	1 furnace	Boilers up to 15 ft. 6 ins. diameter	3 furnaces
„ „ „ 13 ft. 0 ins. „	2 furnaces	exceeding 15 ft. 6 ins. „	4 furnaces

The grate area of a cylindrical boiler is equal to :—Length of firebars × mean diameter of furnace × number of furnaces.

Length of Cylindrical Boilers.

The length of a cylindrical boiler is determined by the length of combustion chamber tubes or the furnace which is practically the same length as the tubes, the length of the combustion chamber and the water spaces at their backs. The combustion chamber measured horizontally should be as long as possible, and usually is about 30 ins. in single-ended boilers and from 50 to 57 ins. in double-ended boilers. The water space between the back of the combustion chamber and the back end-plate of the boiler should be from 5 to 7 ins. at the bottom and wider at the top, the taper being about $\frac{1}{2}$ in. per foot on the combustion chamber back.

Heating Surface.

The heating surface of cylindrical boilers consists of the external surface of the tubes, the length being measured between the tube plates, the surface of the furnaces above the firebar level, and the surface of the combustion chambers. The surface of the front tube plate on the boiler end, although in contact with the hot gases, is not usually reckoned as effective heating surface, and should not be included in the total heating surface of the boiler. The heating surface of a water-tube boiler is the total external surface of the tubes in contact with the fire and hot gases.

Diameter of Tubes for Cylindrical Boilers.

In forced-draught boilers the combustion chamber tubes are generally $2\frac{1}{4}$ or $2\frac{3}{4}$ ins. diameter, and in natural-draught boilers the diameter is 3 ins. to $3\frac{1}{2}$ ins., the increased sectional area being necessary to reduce the resistance to flow of the products of combustion.

Cylindrical Marine Boiler.

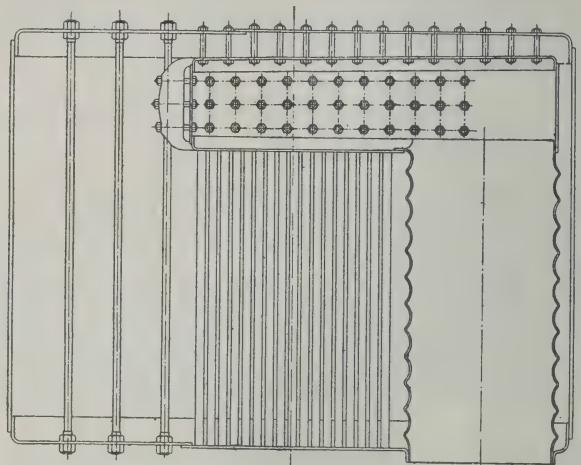

Fig. 25.

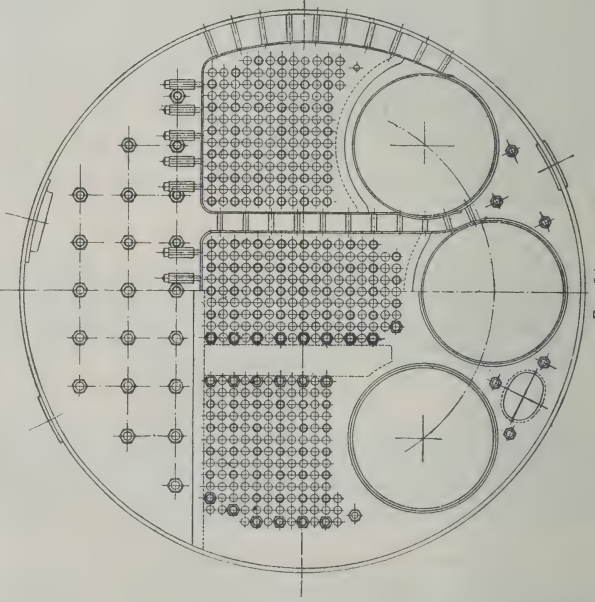

Fig. 24.

Thickness of Cylindrical Boiler Shells.

The shell plates of cylindrical boilers must be of the following thickness to satisfy the requirements of the revised rules of the Board of Trade, Lloyd's, British Corporation, and Bureau Veritas.

The thicknesses shown assume the steel to have a minimum ultimate tensile strength of 28 tons per sq. in., and the longitudinal joint to have double butt straps with an efficiency of riveting equal to 84 per cent.

THICKNESS OF SHELL PLATES IN INCHES.

WATER-TUBE BOILERS.

Water-tube boilers are divided into two distinct classes, viz. :—Large-tube boilers as fitted in merchant vessels, and small-tube boilers as fitted in cruisers, battleships, torpedo boat destroyers, and launches.

The principal advantages of water-tube boilers as compared with cylindrical boilers are :—

(1) Ability to use higher steam pressures (above 250 lbs.).
(2) Rapidity with which steam can be raised.
(3) Capability to endure forcing to a great extent.
(4) Reduced weight.
(5) Reduced space occupied.

The large-tube boilers are of the Babcock & Wilcox type (figs. 26, 27) and the Yarrow type, both of which have straight tubes, the former varying from 4 ins. to $1\frac{13}{16}$ in. outside diameter, according to requirements, and the latter $1\frac{3}{4}$ in. diameter. The tubes in the Babcock & Wilcox boiler are expanded into front and rear headers, which are sinuous in form and constructed of forged steel. Opposite each tube in the headers handholes are fitted, giving access for expanding, cleaning, and renewal when necessary. The front headers are connected at the top by short tube nipples to the steam drum, and by similar nipples at the bottom to the mud drum. Return tubes about 4 ins. diameter connect the rear headers to the steam space in the steam drum.

The Yarrow large-tube boiler is a development of the Yarrow express type, and is very similar in design and construction. It consists essentially of a central upper steam drum, and two smaller water drums, the latter being situated about the level of the firebars. The generating tubes are expanded into the steam drum and each of the water drums, a manhole being fitted in the front end of each drum for access when expanding or cleaning of the tubes is necessary.

WATER-TUBE BOILERS—EXPRESS TYPE.

The small tube or express type of water-tube boilers principally adopted in British naval practice are the Yarrow, the White Foster, and the Thornycroft type (fig. 28). The tubes of all these boilers are from 1 in. to $1\frac{1}{2}$ in. external diameter, and generally the two rows next the fire are at least $\frac{1}{8}$ in. larger in diameter and one wire gauge thicker.

The White Foster boiler has a similar arrangement of drums, casings, and furnace to that of the Yarrow type. The tubes, however, are bent in such a way that any one can be withdrawn and received through the manholes in the upper steam drum when required, without disturbing other tubes.

The modern Thornycroft boilers have one upper steam drum and two lower water drums, and are suitable for burning oil and coal, separately or combined.

The tubes are straight except for a slight curve at the lower end where they enter the water drums. The tubes can be inspected throughout the whole of their length by holding a light in the lower barrel. The lower water pockets being cylindrical can be made of solid drawn steel,

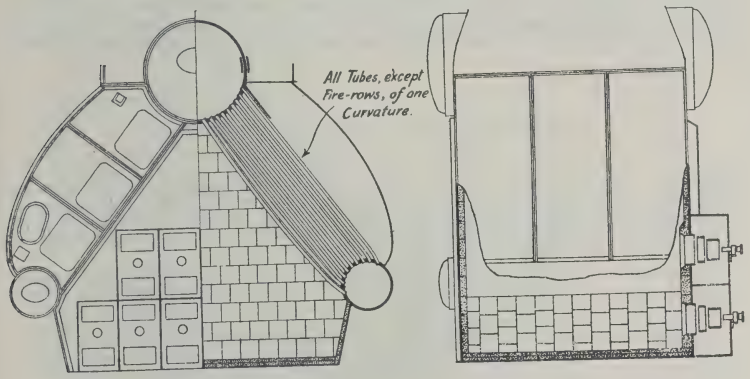

FIG. 28.

The Thornycroft Boiler.

(Oil fuel Burning.)

thus eliminating possibilities of leakage and also making a lighter and stronger construction. The tubes of any one diameter are all curved to the same radius, so that any tube will do for either row, which greatly simplifies the spares. This also allows of the lower drums being made smaller, thus saving weight.

THE YARROW WATER-TUBE BOILER WITH SUPERHEATER.

Figs. 29, 30 (page 2401) show this boiler, which consists of a top steam collector, as usual, and two lower water pockets. On the left-hand side is the superheater, and on this side of the boiler there are fewer rows of generator tubes than on the other side, where there is no superheater, it being thought desirable that the total heating surface and the resistance to the gases on both sides of the boiler should be approximately the same. In one of these boilers with a total heating surface of 6,700 sq. ft., 1,265 sq. ft. consisted of superheating surface; the total heating surface on the superheater side of the boiler being 3,453 sq. ft., and on the other side 3,247 sq. ft.

The superheater consists of a number of U tubes expanded into two longitudinal collectors, small doors being fitted so that access can be obtained to the tubes when required. The leading feature of the arrangement is that the superheater is placed on one side of the boiler only, and a damper is fitted in the up-take on the same side. If this damper is closed the whole of the gases are deflected towards the opposite side of the boiler, and no heated gases pass the superheater, the object being that if the main engines should be suddenly eased or stopped, or when raising steam, the superheater may be shut off, so as to prevent the tubes being damaged, or the steam being superheated to an excessive extent, owing to there not being sufficient circulation of steam. In this way one objection to the introduction of superheating for marine installations is overcome.

A further advantage of the arrangement is that, when the consumption of steam is suddenly reduced or stopped, not only does the damper prevent the superheater tubes from being burnt, but it also greatly diminishes the output of the boiler at the time when a reduced supply of steam

is wanted, because only about one-half of the heating surface comes into contact with the hot gases. To avoid the possibility of the damper getting distorted through over-heating, it is provided with a hollow spindle, to which air is admitted and which passes from thence between the two plates of the damper, escaping at the edge, and thus keeping the damper cool. This arrangement of damper has proved thoroughly successful under the most trying conditions.

At the maximum rate of evaporation with the damper open, namely, when burning 1·237 lb. of oil per square foot of heating surface per hour, the degree of superheat was 93·5° F.; 14·6 lbs. of water were evaporated per lb. of oil per hour, with a steam pressure of 242 lbs.

The results of other experiments indicate that in a properly designed boiler of the type described, it is possible to burn, without injury to the boiler, 2 lbs. of oil per square foot of heating surface per hour.

The 'Johnson' Marine Type Water-tube Boiler.

(Clarke, Chapman & Co. Ltd.)

The design of marine water-tube boilers is following the recent striking developments in land practice where, by the use of water-cooled furnaces, outputs have been doubled and even trebled without sacrifice of efficiency or durability. Similar progress in conjunction with the increased working pressures, superheat and high efficiencies already established in marine installations will effect remarkable economies in space, weight and cost.

The 'Johnson' Boiler (fig. 31, p. 2402) incorporates in a simple and compact form all features which modern practice and investigation has shown to be desirable. The furnace is a large cylinder, carefully proportioned to give the requisite travel and time for complete combustion of the fuel before egress of the gases, preheated air up to 500° F. being employed. As the furnace is practically enveloped by water tubes, the large surface exposed to radiation is prolific in steam generation, while avoiding the undesirable heat stresses inevitable in conventional types of water-tube boilers working at high ratings. Depreciation of brickwork is prevented and the rapid cooling and contraction of the furnace gases enables the largest amount of fuel to be burned per unit of furnace volume.

The drums are supported so as to permit of free expansion of the tubes, which are thus relieved of all strain at their attachments. The tubes have a simple curvature and can be easily brushed and sighted for a sufficient distance to enable the condition of their interior to be ascertained.

The boiler is suitable for all classes of naval and merchant vessels and can be constructed in units ranging from 1,000 horse power to 20,000 horse power capacity, single or double ended, side flow or double flow saturated or superheated steam and of special dimensions to suit shallow draught or other vessels of unusual proportions. It is expressly designed to burn Injected Fuel, solid, liquid, or gaseous, under natural or forced draught. It is extremely elastic in performance and responds immediately to sudden demands for steam, as there is not a mass of refractory to heat. It is suitable for high pressure and its capacity per ton of weight is unrivalled. Its efficiency is equal to that of orthodox types of water-tube boilers, while yielding a much greater output, and while the average rating on the heating surface is higher, the maximum rating of the furnace tubes is lower. Its construction is simple, and careful attention has been given to all details affecting maintenance and replacement.

Waste Heat Boilers.

See p. 2194.

Life of Marine Boilers.

The life of a marine boiler depends to a certain extent on the care and attention bestowed on it during the first few months of its existence, provided that the plates have been properly treated at the building of the boiler—that is, all mill scale removed and the plates kept dry and free from atmospheric corrosion. The mill scale, if not removed, has a very irritant action on the clean metal of the boiler, and is most hurtful to the plates if allowed to remain on them. The greatest care and attention is needed for the first period of working of new boilers to keep the new metal free from corrosion. It is advisable on the first voyage to put into the boilers, before closing them up, 5 lbs. of lime per 1,000 i.h.p., and afterwards for a period of about six days 2 lbs. of lime per day per 1,000 i.h.p. should be passed through the hotwell as milk of lime, and 1 lb. of lime per day per 1,000 i.h.p. during the remainder of the voyage.

Rules and Regulations with Reference to Boilers of Steamships.

STANDARD CONDITIONS FOR THE DESIGN AND CONSTRUCTION OF MARINE BOILERS.

A set of rules has been framed and agreed to by representatives of the Board of Trade, Lloyd's Register of Shipping, the British Corporation for the Survey and Registry of Shipping, and the Bureau Véritas International Registry of Shipping, and recommended for favourable consideration and adoption. An abstract of these rules is given on pp. 1563–1571.

Boiler Casings.

The casings of both the Babcock & Wilcox and Yarrow boilers are constructed of light steel plates and angles, and designed to avoid distortion due to the high temperature of the gases with which they are in contact. In way of the furnaces the casings are lined with brickwork, other parts of the casings are lined with asbestos millboard or some other non-conductor, to prevent radiation of heat to the stokeholds. In the Babcock & Wilcox type of boiler, wide use is made of 'Cellinsulate,' a special form of non-conductor which possesses greater resistance to heat transmission per unit of weight than any other form of lagging.

MARINE SUPERHEATERS.

SMOKE-TUBE TYPE.

The types of superheaters manufactured for marine boilers consist in principle of a series of loops or elements of solid cold-drawn steel tubing inserted in the smoke tubes of the cylindrical boiler and connected to suitable headers or collectors placed vertically in front of the boiler between the nests of smoke tubes. The saturated steam from the boiler stop valve enters the saturated

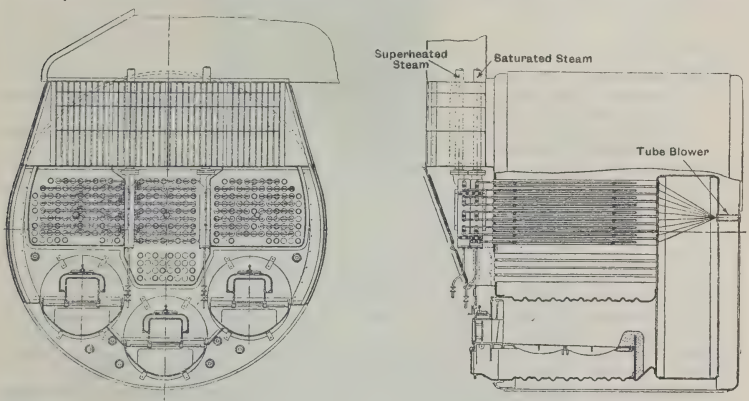

FIG. 32.—Three-Furnace Boiler, Forced Draught, with Smoke-tube Superheater.

steam header, the steam circulates through the elements and returns superheated to the superheated steam collector, and thence to the prime mover. The elements are, therefore, in the direct path of the gases flowing from combustion chamber of boiler to smoke-box. (See figs. 32 and 33.)

The elements are made from solid cold-drawn steel tubing, and the return bends are made integral with the tubing itself providing a clean, smooth surface, both internally and externally.

THE 'NORTH EASTERN' SUPERHEATER.

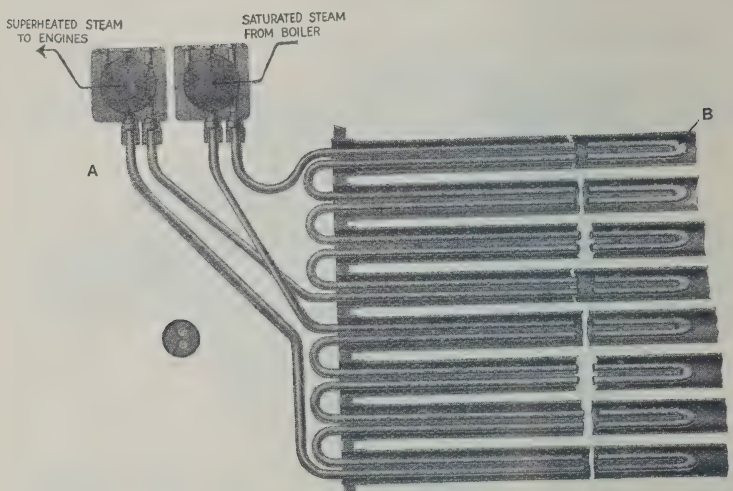

FIG. 33.—The 'North Eastern' Superheater.

Oil Fuel.

The advantages of fuel oil as compared with coal are as follows :—

(1) Reduction in weight and space occupied by the boiler installation.

(2) Increased evaporation of water per lb. of fuel in the ratio of about 14 : 9 as compared with good quality coal.

(3) Utilisation of remote parts of the ship and of constricted spaces, such as the double bottoms, for stowage of fuel.

(4) Less manual labour and greater rapidity in stowage.

(5) No reduction in speed due to cleaning fires, difficulty in trimming coal from remote bunkers, or exhaustion of stokers.

(6) Reduced wages bill for boiler room staff, no trimmers, and comparatively few attendants for the burners being required.

(7) A prompt and effective control of the steam output due to the mechanical supply of the fuel, permitting of more rapid changes of speed than is the case with coal.

(8) Absence of smoke if air supply is properly controlled.

(9) No trouble due to accumulation of ashes ; ash expellers or ejectors are dispensed with.

(10) In the case of naval vessels, fueling can readily be carried on at sea.

Both water-tube and cylindrical boilers are now adapted for burning oil fuel, the direct-pressure system being the one most generally in use for naval and mercantile service.

Pressure pumps fitted in the boiler rooms have suctions from the oil tanks, and discharge at a pressure of from 50 to 150 lbs. per sq. in. through cold filters having fine mesh wire gauze grids ; from thence the oil passes through a tubular heater, the oil being inside the tubes and heating steam outside. The temperature of the oil is raised to about 150° Fah. in the heater, and before finally reaching the burner it is passed through a second, or so-called hot, filter.

It is necessary to heat the oil in order to reduce its viscosity so that it can be atomised and forced through the fine passages of the burner, which are so designed as to give it a rapid whirling effect due to centrifugal force when liberated through tangential passages at the lip of the burner, and thus reduce it to a fine spray of conical formation. The air supply to the burner passes through directing slots cut in a steel truncated cone, 12 to 15 ins. diameter and about 16 ins. long. The burner is fitted at the centre of the entrance to the cone, and the admixture of the air passing through the slots with the oil spray from the burner produces almost perfect combustion.

In the case of naval vessels the closed stokehold system is adopted, the air pressure in the boiler rooms being controlled to suit the output of the burners. For cylindrical boilers in merchant steamers the Wallsend-Howden system (page 2163) with open stokeholds is now in extensive use. The arrangement of burners and air cones is similar to that described above, but the air supply is heated by the waste gases, as in the ordinary Howden forced draught system (page 2124) applied to coal burning. Each burner can pass from 400 to 600 lbs. of oil per hour, and it is possible to burn about 13 lbs. per cubic foot of combustion chamber. The area of the furnace front limits the number of burners which can be fitted, and it is desirable that the volume of the combustion chamber should be as large as possible.

(See also pp. 2149, 2438.)

EVAPORATORS.

For Fresh Feed Make-up Water for Boilers.*

With the high pressures of steam (usually from 150 to 200 lbs. per square inch) now carried in steam boilers for use with modern triple-expansion and other engines, it is found necessary to

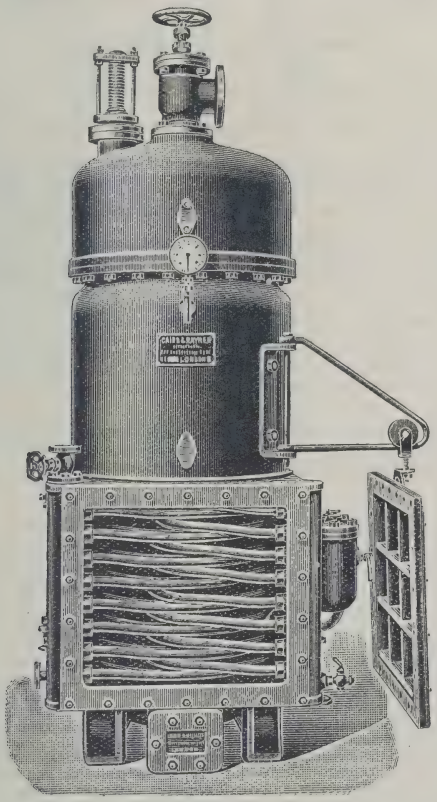

Fig. 34.

* Also used in connection with distilling condensers for producing fresh drinking water instead of the old way of distilling from the donkey boiler.

provide fresh feed-water for the make-up, in order to prevent the great deposit of scale on the heating surfaces which results from these high temperatures.

The quantity of auxiliary feed-water required amounts to from 1 to 5 tons per 24 hours per 1,000 h.p.

To provide this, evaporators have come into general use.

In these evaporators the sea water is boiled by the heat from steam passing through tubes immersed in the salt water. The condensed steam from these tubes is usually drained back to the condenser or hot-well, and so back to the boiler, and the secondary steam produced from the sea water is led to the main condenser, and is there condensed along with the exhaust steam from the engines, and thus delivered to the boiler as fresh feed-water.

The scale formerly left in the boilers is deposited in the evaporators, which are arranged so as to be easily cleaned when necessary.

Condensers and Water Heaters.

The Weir 'Uniflux' Condenser.

(No longer made. Replaced by 'Weir' Regenerative Condenser—see p. 1837.)

This design of condenser, introduced in 1909, has since become extensively adopted in this country for naval and high-class merchant steamers, and the high vacua attainable by its adoption when working in conjunction with the Weir 'Dual' type of combined wet and dry air pump has been an important factor in the improved efficiency of steam turbines.

The construction of the condenser introduces no novel features except as regards the pear-shape of shell which has been designed with the object of causing the exhaust steam to flow over the tubes at a uniform velocity without short circuiting, the steam inlet being arranged as far from the air-pump suction as possible.

The 'Dual' air-pump is of the beam type having one steam cylinder and two pump barrels, one pump for air and vapour and the other for water, air and vapour. Cold injection water is introduced at each stroke into the dry-air pump barrel to condense the vapour and cool the air, and in order to avoid the expansion of the air present in the water filling the clearance space of the dry pump at the moment of discharge the dry-air pump is arranged to discharge below the head valves of the wet-air pumps.

The combination of improved design of air-pump and condenser in conjunction with an increased supply of circulating water has resulted in a reduction of the condensing surface from 20 to 25 per cent. as compared with the condensing plant previously fitted.

The Weir Direct Contact Feed-Water Heater.

This system consists in taking a portion of the steam from the low-pressure receiver of the engine and utilising it to heat the feed water on its passage to the boiler. In actual practice on board ship, this steam is also supplemented by the exhaust from the auxiliary engines.

Fig. 35 shows a sectional view of the heater. The heating steam is taken from the low-pressure casing of the main engine, and the exhaust of the auxiliary engines is also led into the heater through the non-return valve B on the side of the apparatus. A perforated cylindrical waist piece forming an annular steam space round the heater, and surmounted by a conical spray piece, also perforated, is fitted to ensure the uniform mixing of the steam and water. A Weir direct-acting feed pump, or the main engine feed-pump, delivers the feed water into the heater through the spring-loaded valve D on the cover. The feed water is forced through this valve in a thin sheet, and is instantly heated by contact with the steam. The water is further broken up into fine spray by passing through the conical spray piece, thereby bringing the greatest possible surface into contact with the steam. As the pressure in the heater is generally much less than that of the entering water, the effect of this lowering of the pressure, and sudden heating of the water, is to liberate the air in the water, and this is removed to the condenser, or to the atmosphere, by a small cock K on the air vessel placed on the top of the heater. (In the case of twin-screw vessels fitted with one feed heater, the lever cock on the heater air dome is coupled up to both condensers by a T piece.) The feed water is thus rendered non-corrosive, and falls to the bottom of the heater at the boiling temperature corresponding to the pressure.

The combination, fig. 35, of the automatic regulating gear with the heater is a special feature of the Weir apparatus. The float E shown in the lower part of the heater is a pan, with water-tight bottom and sides, but open on the top. It is suspended on two levers, so as to move up and down with a parallel motion ; the top lever spindle is carried through the door at one end, and is

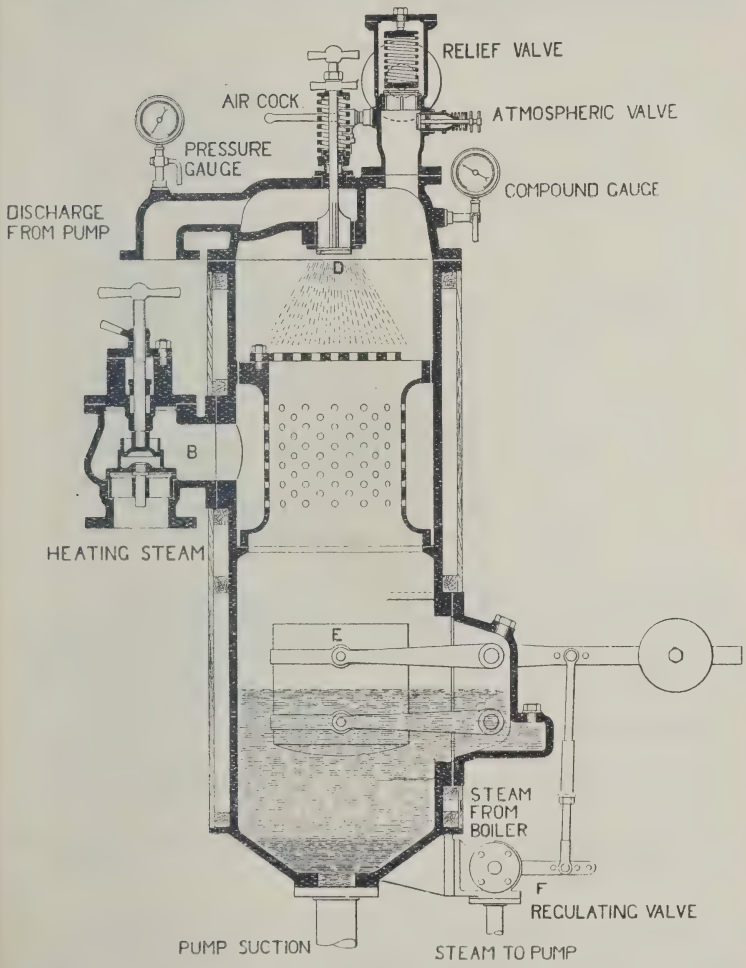

FIG. 35.

balanced by a lever and weight. The float is always full of water, and the weight is adjusted to balance when one-half is immersed in water. The weight lever is connected by a rod to another lever, which actuates the throttle valve F and controls the supply of steam to the pump drawing from the heater. When the water in the heater rises, the float is raised, and the throttle valve

opened, and, when the water level is lowered, the float follows, and the valve is closed ; the level of the water is thus kept constant in the heater, and the pumps are completely filled with water.

When feed heaters are placed on the discharge side of the feed pump they are necessarily subjected to the boiler pressure, and must therefore be of a very substantial character. Such heaters are always of the surface type.

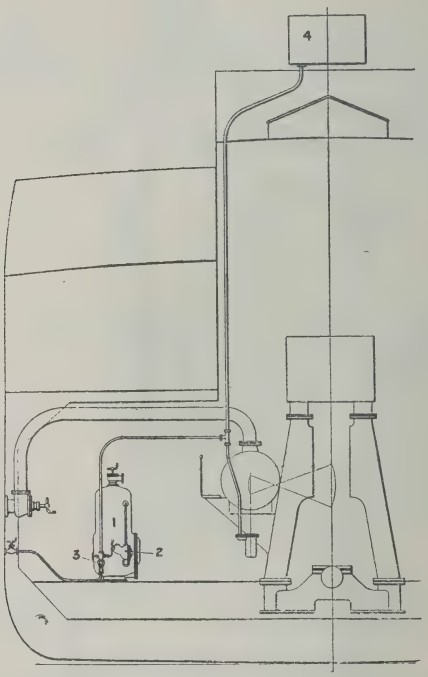

FIG. 36.—Arrangement on board ship of Evaporator with 'Weir' Feed Regulator and Brine Ejector.

1. Evaporator.
2. Feed Regulator.
3. Brine Ejector.
4. Sanitary Tank.

As affecting the engines, it is found that this system secures a fuel economy of from 5 to 8 per cent., according to the steam pressure carried, and the number of expansions in the engine.

Air Pumps.

PARAGON AIR-PUMP.

(G. & J. Weir, Ltd., Cathcart, Glasgow.)

This air-pump is a development of the well-known Dual Air-Pump, and is giving the same steadfast reliability in marine work that was characteristic of the Dual type of pump. It has been adopted by the leading steamship companies, and is shown in fig. 37.

The normal three-valve twin-barrel arrangement has been adopted, driven by a single steam cylinder. Both barrels deal with the water, *i.e.* the suctions are common, and each barrel draws its quota of condensate through the same suction pipe. On the side of each barrel and high up on the barrel is arranged a port, so positioned that when the bucket is at the top of its stroke, the port is in communication with the space under the bucket, and when the bucket has travelled on its down stroke a distance equal to its own depth plus the depth of the port, the port is in communication with the space above the bucket. Communicating with this port is a chamber which

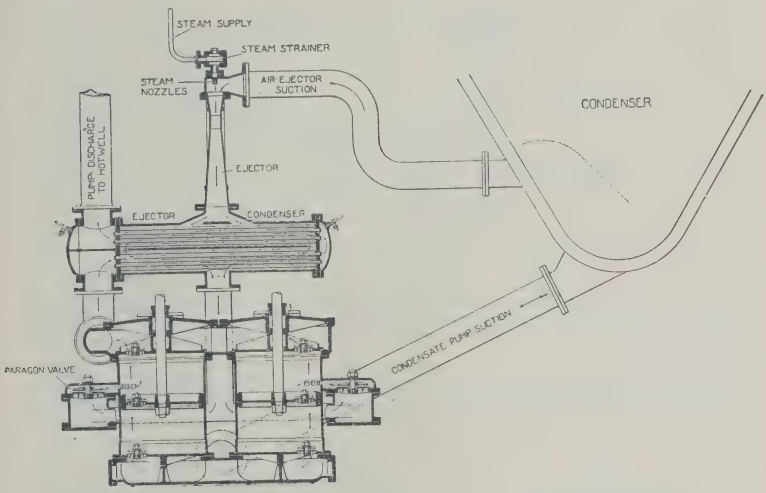

FIG. 37.

houses a non-return valve of a design similar to the pump valves. A branch pipe connects the two chambers with the augmentor condenser outlet. The augmentor condenser is of the tubular type with brass tubes ferruled into brass tube plates. The augmentor is fitted to the top of the augmentor condenser, and discharges into same. The steam discharged by the augmentor is condensed on the outside of the tubes by the condensate, which is discharged through the tubes by the air-pump; the heat in the augmentor discharge therefore is conserved in the condensate, which results in the economy of the apparatus being good. The steam nozzles are of the convergent divergent type, similar to those fitted to the air ejector.

This pump is capable of maintaining the highest vacua, and has a large air handling capacity for the size of the pump.

Experiment has shown that on a 19 in. × 15 in. pump the fall in vacuum was only 0·4 in. Hg, when a ¼ in. diameter air leak nozzle was opened admitting air to the condenser.

Bearings.

THE MICHELL BEARING.

Michell Bearings (thrust and journal) are largely used in modern marine practice, and are manufactured by Michell Bearings, Ltd., Newcastle-on-Tyne. There are in the British Navy alone ships aggregating over ten million horse-power fitted with main thrust blocks of this type, and in passenger and merchant ships the Michell Thrust Block is commonly used, both for reciprocating engines and steam turbines.

A standard thrust block used for light craft of all kinds is shown in fig. 38. This is self-lubricating, and can be arranged upon an extension of the engine-bed or upon a separate seating immediately aft of the crankshaft coupling. The oil level in the thrust block is usually kept just above the under-side of the shaft. The bearing surfaces are lubricated by the thrust collar

carrying oil upon its edge, and the oil is scraped from this by the scraper at top, thus giving a continuous cascade of oil on the pads. The pads are so pivoted that a film of oil is led into the space between pad and thrust collar, and this oil film can withstand a heavy pressure. A feature of the bearing is that as the speed increases, the pressure per square inch can be increased.

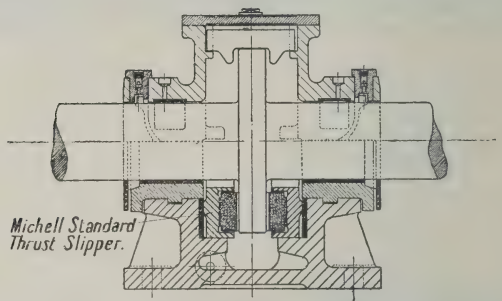

FIG. 38. Michell Slipper Type Thrust Bearing.

Michell thrust blocks have a single collar shaft with a series of pivoted pads arranged forward and aft, and it will be noticed from the illustration that the pads need only be in the bottom half of the bearing. Thrust blocks, however, can be designed to utilise an existing multi-collar thrust shaft.

Large engines are usually fitted with a thrust block arranged for continuous oil circulation, and in these blocks the upper as well as the lower portion of the body sustains thrust load. Oil is introduced into the space behind the pads and compelled to travel radially across the thrust faces. This oil can be cooled and used over and over. In these blocks the upper and

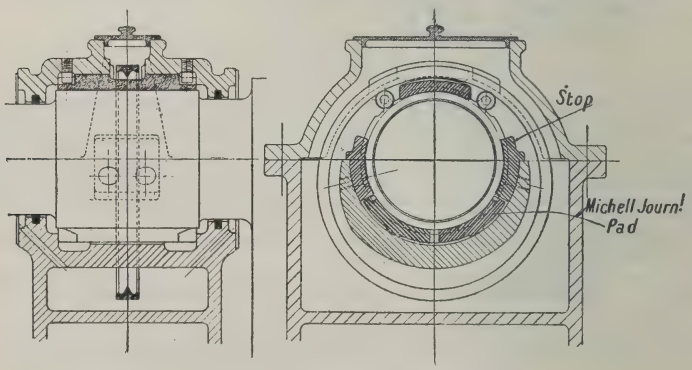

FIG. 39.—Michell Journal Bearing for Marine Oil Engine.

lower parts of the body are keyed together, and liners for adjustment are fitted behind each of the rings which carry the pads.

The Michell principle is also applied to journal bearings, and fig. 39 illustrates one as fitted to a marine oil engine. When speeds are high the ring lubrication is replaced by a continuous supply of oil from a pump. It will be noticed that the oil is taken on to the shaft by means of a ring, and this ring is always kept in a central position, even if the ship pitches, as the central art of the oiling ring is guided by grooves in rollers arranged upon the shaft.

Considerable economy in length is effected by this bearing, as a pressure of about 500 lbs. per square inch projected journal area is satisfactorily carried at any speed.

The pivoting principle, upon which all Michell bearings work, ensures, perhaps, the nearest approach possible to perfection in lubrication. Astonishingly high pressures are quite safely carried (under test as much as 5 tons per square inch has been successfully imposed), whilst speeds of any magnitude may be run by regulating the quantity of oil supplied. High speed is an advantage, inasmuch as oil film thickness increases with the speed.

Temperature Limits of the Michell Thrust Bearing.

The working limits of the Michell thrust bearing are fixed mainly by the temperature of the single thrust collar used. In designs prepared in 1908 lubrication was effected by simple jets of oil. So long as the rubbing speed did not exceed 30 ft. per second, these seldom gave trouble, but when the same plan was adopted for a longer bearing, in which the mean speed was 40 ft. a second, the bearing had to be scrapped. The plan was then adopted of running the bearing in a casing filled with oil, and through which oil was constantly pumped. This plan proved satisfactory as fitted to marine turbines provided with single-reduction gearing, where the rubbing speed seldom exceeded some 80 ft. a second. With the advent of double-reduction gears and consequent higher rubbing speeds, trouble was experienced. With the arrangement described, the immersion of the bearing in oil was relied upon both for lubrication and for cooling, but it was found that the temperature of the oil escaping from the casing gave very little indication of the temperature attained in the lubricating film. It was therefore decided to separate the functions of lubrication and cooling, by forming oil-circulating ports in the bearing through which a free flow of oil was maintained by the rotation of the collar. This not only provided unlimited lubrication for the pads, but, owing to the thorough circulation thus ensured, the temperature of the oil leaving the casing gave a fairly correct idea of the temperature of the collar. This was the vital factor in the whole problem. If the collar temperature exceeded about 150° F., there was a distinct danger of failure. At high rubbing speeds, a supply of oil ample for lubrication might be insufficient to keep the collar cool, and much more oil had to be supplied accordingly.

(*H. T. Newbigin, paper on 'The Crankless Engine,' The North-East Coast Institution of Engineers and Shipbuilders, February* 24, 1928.)

MARINE DIESEL ENGINES.

(Revised by James Thomson, M.I.N.A.)

The Diesel engine as designed for marine work differs in no essential principle from the stationary type; with each manufacturing firm there are certain modifications and peculiarities of construction. On the whole the two-stroke-cycle single-acting engine is considered to have best prospects for the future, but for the very large engines for marine purposes the double-acting two-stroke-cycle motor is expected to give best results, whilst a number of firms still adhere to the four-stroke-cycle single-acting principle for moderate powers.

The superiority of the Diesel engine for marine work in certain cases is not entirely due to its fuel economy. This must always be an uncertain matter, dependent on the relative prices of the fuels. The consumption of oil with a Diesel marine engine is practically the same as for the stationary type, and, generally speaking, with oil of a net calorific value of about 18,000 B.Th.U. per lb. or 10,000 calories per kg. the fuel consumption for marine work may be taken as 0·40lb. per b.h.p. hour for the main propelling engines. Unlike reciprocating steam engines, and steam turbines, the larger Diesel engines possess practically no advantage over smaller ones in this respect.

The fuel consumption of large steam turbine plants with superheat and modern appliances has been reduced so much that fuel rates and first cost, etc., must be carefully considered before deciding whether Diesel or steam turbine machinery is the most suitable for the required service.

Among the most important advantages of the Diesel engine for marine work is the reduced space occupied by the propelling machinery and bunkers. This permits of greater cargo-carrying capacity, or a smaller vessel for the same cargo, with a corresponding reduction of the cost of the hull, although at the present time the cost of a Diesel engine is in excess of a steam engine and boiler plant. A vessel equipped with Diesel engines has from 10 to 15 per cent. extra cargo-carrying capacity as compared with a steam engine, and this is materially increased if the amount of fuel carried is reckoned on the basis of the same radius in both cases, when considerable extra bunker space is rendered available for cargo in the Diesel ship. With special precautions, moreover, the fuel oil can easily be carried in the double bottom of the ship, which allows a further gain in space. In war vessels the advantage of the economy in fuel with Diesel engines will no doubt be utilised by increasing the possible radius, which may be taken at 2 to 3 times that of a steam vessel with geared turbines owing to the relative high economy at lower powers, this being a feature of the Diesel engine as compared particularly with the steam turbine.

In a Diesel ship the number of attendants in the engine room required is less than in a steam vessel, being usually in the neighbourhood of $\frac{2}{3}$. Firemen are entirely dispensed with, the handling of fuel is easy, rapid and clean, whilst the astern power is equal to the ahead, which is not the case in turbine vessels. A list of engine room staff for various motor ships is given on page 2438.

For the same speed a single screw vessel equipped with Diesel engines usually requires slightly more power than when propelled by a steam engine for similar conditions, as the revolutions are too high for the most efficient propeller, but this does not apply to multiple screw ships when the speed exceeds 12 knots.

The weight of Diesel machinery for large powers is usually greater than steam turbine machinery.

Types of Marine Diesel Engines.

There are three distinct types of Diesel marine engines, the first two are the single-acting engines of the four-stroke-cycle and two-stroke-cycle type respectively, whilst the third is the double-acting engine.

The four-stroke-cycle motor is slightly more efficient, but the two-stroke-cycle single-acting engine has the advantage of reduced weight and space, simplicity in reversing arrangements and cheapness of manufacture. It necessitates the employment of scavenge pumps which reduce the overall efficiency of the motor. Larger powers can be developed in single cylinders, and although the limit is not yet certain, it is anticipated that 3,000 h.p. can be produced from a single cylinder. Up to the present 2,000 B.H.P. is the highest power that has been attained in a single-acting two-stroke-cycle motor per cylinder.

The reason for the employment of the double-acting two-stroke-cycle engines is to obtain the maximum power per cylinder. The chief difficulty encountered with the double-acting engine is to get rid of the heat in the cylinder, and there is also the question of the most convenient method of operating the valves in the bottom cover of the cylinder. It is stated that these troubles have now been satisfactorily overcome.

As regards the two-stroke-cycle single-acting type, the chief difference in the design of different manufacturers, apart from details of the reversing gear, is in the method of the provision of the scavenge air. In some engines scavenge valves are employed, fitted in the cylinder cover, and through these the scavenge air enters the cylinder, whilst in other types ports are provided at the bottom of the cylinder usually extending half-way round the circumference, opposite the ports for the discharge of the exhaust. Scavenging through ports presents some difficulties in regard to cleaning out all parts of the cylinders thoroughly, and various arrangements are employed to make it more efficacious, some of these being described later. With valves, the scavenging is excellent, but the valves must be large, and they add to the complication of reversing. The scavenging pumps usually work at a pressure of $1\frac{1}{2}$ to 6 lbs. per square inch, above atmosphere, and the power they absorb is from about 5 to 10 per cent. of the output of the engine. The power developed by a single-acting two-stroke cycle Diesel engine is about twice that of a four-stroke cycle engine of equal cylinder dimensions.

The question of reversing Diesel engines is not one of particular difficulty, the only requirement being a variation in the time of opening of the different valves. In the four-stroke-cycle engine this includes the exhaust valve, which is omitted in the two-stroke-cycle type, whilst if in the latter scavenge ports are provided, the matter is further simplified by the absence of scavenge valves. There are various methods of reversing, which, however, practically do not differ at all in principle, the arrangement being to alter the times of openings of the various valves relative to the crank shaft. In one arrangement which is commonly employed, a single cam shaft is provided on which are fixed two separate sets of cams, one for the ahead motion and one for the astern, each valve thus being capable of operation by either of the two cams. For reverse running the cam shaft can slide in a longitudinal direction, and this motion brings the astern set of cams underneath the levers operating the valves, so that the valves are thus set for going astern. Before the cam shaft can be moved, the rollers of the valve levers have to be moved clear of the cams in order to let them pass under.

A second method of reversing consists in having two separate cam shafts, on one of which the cams for ahead running are mounted, and on the other those for the reverse, and either cam shaft is set in a position for its cams to actuate the valve levers, according as it is required to run ahead or astern. There are various other means adopted for reversing, such as by a rotation of the cam shaft relative to the crank shaft, and utilising the same cams for both directions which necessitates special setting of these cams. In another design a combination of this method and the first is adopted, whilst there are certain other special arrangements, one of which is described later.

The method of injection of the fuel into the cylinders is receiving great attention at present. In the past injection by high pressure air was almost universally adopted, but 'solid injection,' by which is meant the injection of the oil under very high oil pressure through a nozzle which breaks the oil into a fine spray capable of great penetration, has been very successfully fitted on many types of engines. The efficiency of oil burning may be slightly lower than with air injection, but the injection air compressor is dispensed with, and the power saved compensates for any such decrease in the efficiency of burning the fuel.

In the earlier designs of solid injection the fuel valve was opened and closed by a cam, as with air injection, but in the later designs the oil-pump for each cylinder is set so that the discharge pressure automatically opens the fuel valve and injects the fuel into the cylinder when the piston is in the proper position. With this arrangement on a two-stroke port-scavenging engine the only valves operated by cams are the air-starting valves, and automatic valves with remote control can also be employed for this purpose, so that the design of the engine is considerably simplified, and accessibility for overhaul much improved.

Burmeister and Wain Type.

The engine designed and constructed by Messrs. Burmeister & Wain, of Copenhagen, and by Messrs. Harland & Wolff, may be taken as a typical four-stroke-cycle marine Diesel motor. It is built with six or eight cylinders, according to the power, the engines of the 'Glenapp' and several other boats having each eight cylinders, and developing about 2,600 i.h.p. at 115 revolutions per minute.

As is now common in most Diesel engines, and will, no doubt, be generally adopted in the future, external crossheads with water-cooled guides are employed, which, although increasing the height, are of considerable advantage in dismantling and for facility of inspection. An enclosed crank chamber is used, but at front and back there are readily removable covers.

The engine may be considered as arranged in two sets of four cylinders, which is convenient for the placing of the valve gear and manœuvring mechanism described later. The valves are fitted in the cylinder cover, as is generally the case, and each cylinder has a starting air valve, fuel inlet valve, exhaust valve, air inlet valve, and relief valve. The cam shaft carrying the cams which operate the levers controlling the valves is not situated on a level with the top of the cylinders, as is common in many four-cycle engines, but at about half the height of the engine. Each of the valves, except the relief valve, has two separate cams for its control on the cam shaft, one for ahead and one for astern running. In order to reverse the engine, the valve levers are lifted and the cam shaft moved longitudinally a distance equal to the cam width, so that, on dropping the valve levers once more, they are now immediately above the astern cams and are in a position for running in the opposite direction. The sliding of the cam shaft is accomplished by means of a disc carried on it, which moves in a slotted drum on an auxiliary shaft, the slot slanting from left to right. The auxiliary shaft can be turned by means of an air motor controlled from the starting platform, and in turning the cam shaft moves to the left or right, according to the direction of rotation of the auxiliary shaft. The actual operation of the valves from the cams is carried out by having long hollow vertical rods, whose upward and downward motion causes the rocking levers at the top to actuate the valves. It may be mentioned that, contrary to usual practice, the injection valves open inwards towards the cylinders. The drive of the cam shaft is through helical gearing and a vertical intermediate shaft, direct from the crank shaft. Sometimes a direct gear drive is adopted, and in some cases a chain drive is used.

The question of the number of fuel pumps for pumping the oil to the injection valves is somewhat controversial, the majority of manufacturers preferring to have one pump per cylinder, whereas others think it desirable to minimise the number as far as possible. A small hand pump is employed for pumping the oil up to the valves when required, the usual overflow cocks being fitted.

In Diesel engines driving generators the governor controls the amount of fuel admitted to the cylinder by acting upon the suction valves of the fuel pump, and holding them open a longer period during the pressure stroke, if it is required to reduce the oil supply, while in marine engines hand-control is effected in the same way. In this engine the control is from the starting platform and a governor is fitted, which is only for the purpose of preventing the speed rising above the designed revolutions per minute, by cutting off the fuel altogether in all cylinders but one. Forced lubrication is adopted for the engine, and the oil is water-cooled and circulated continuously.

High-pressure air for injecting the fuel is provided by a vertical three-stage air-compressor, driven direct by a crank at the forward end of the crankshaft. These compressors are of ample capacity, and their delivery is controlled to suit the immediate requirements of the engine by throttling the first-stage suction, or by leaking off at the end of the first compression.

The cylinder covers and jackets are cooled by fresh or salt water, and the pistons by fresh water, salt water, or oil. It may be mentioned here that some designers and owners prefer to avoid the use of sea-water for cooling purposes, owing to the possibility of deposit of scale, etc., but the matter is largely an open question.

In a number of the later B. and W. engines mechanical injection of fuel has replaced the air-injection system. The fuel valves are automatic, and the quantity of oil delivered is varied by altering the stroke of the pump plunger, which is cam operated and spring returned.

Fig. 40 shows a section of a 2,000 b.h.p. single-acting Burmeister and Wain motor of the latest type, and figs. 41 and 42 (pages 2415 and 2416) give illustrations of the control arrangements for this motor.

NORTH-EASTERN MARINE DIESEL ENGINE.

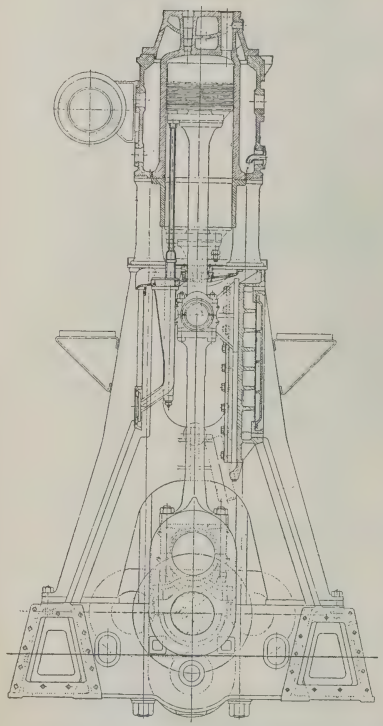

FIG. 44.—Sectional elevation of North-Eastern-Werkspoor, Single-Acting Engine (Four-stroke).

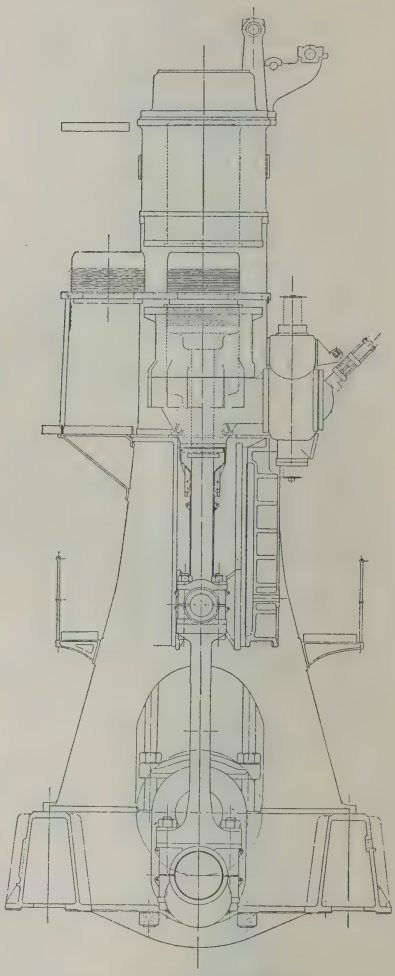

FIG. 45.—North-Eastern-Werkspoor Four-Stroke Double-Acting Engine: method of withdrawing piston.

Double-acting Type.

These engines have been built in sizes up to 10,000 b.h.p. in eight cylinders at 125 r.p.m. The air compressors are independent of the main engine and driven by separate Diesel engines.

The pistons are cooled by oil, and there is a gland between the bottom cover and the crank chamber.

The camshaft is chain-driven, and one camshaft operates the valves in the top and bottom cylinders.

Burmeister and Wain Two-stroke Engines.

Messrs. Burmeister and Wain have recently developed two-stroke engines both double- and single-acting. The outstanding feature of the design is that the exhaust ports are situated at the cover end and are controlled by a smaller diameter auxiliary piston, having a stroke about one-fifth that of the main piston. These auxiliary pistons, which develop about 10 per cent. of the power of the engine, operate through links and levers to an auxiliary crankshaft, which drives on to the main shaft by chain.

North-Eastern Diesel Engine—Werkspoor Type.

The first engine of this type was constructed by the Werkspoor Company of Amsterdam, and installed in the *Vulcanus* in 1910. North-Eastern Marine Engineering Co. was the first of British marine engine-builders to take out a licence to build this type of engine, since when engines varying from 1,000 b.h.p. up to 5,000 b.h.p. have been built, both for British and Continental owners, with very successful results.

Single-Acting Engines.

The motor, figs. 43, p. 2417, and 44, p. 2418, is usually of six cylinders, and, except for a few special features, is of the standard single-acting four-stroke type of engine.

The chief point of difference lies in the cylinder construction, the North-Eastern-Werkspoor engine having a continuous cooling surface from liner to crown of cylinder, this construction giving highly efficient cooling to the combustion chamber, there being no liner joint to interfere with the circulation. The arrangement also allows the valves to be spread further apart, giving more space for circulation between the valve ports.

Another point of difference lies in the arrangements for operating the valves and the method of reversing. There is one camshaft on which the cams for ahead and astern working respectively are mounted in pairs for air starting, fuel injection, induction, and exhaust. This shaft does not move in a fore-and-aft direction during reversal, but the lever which transmits the motion from the cam to the valve is mounted eccentrically on the reversing shaft. The axis of the eccentrics and the shaft on which they are mounted are not parallel, so that when the shaft is rotated through an angle of 180° the rollers are lifted from one set of cams and placed on the other. This is a totally distinct method from that already described, in which the camshaft is moved longitudinally, and illustrates the diversity of the arrangements which may be employed for reversing Diesel engines.

The camshaft is driven by connecting rods from cranks on a countershaft to cranks on the camshaft, the countershaft being driven at half engine speed by spur gearing from the engine crankshaft.

A light type of engine is built with the cylinders entirely supported by steel columns and diagonals, but the standard design has the cylinders supported on cast iron 'A' frames, the cylinder beam, columns, and bedplates being held together by heavy through-bolts running from top to bottom of the engine.

The main running gear has forced lubrication, and is totally enclosed in an oil-tight casing with large doors, particularly easy to remove.

The compressor is of the three-stage type, usually direct driven from the forward end of crank shaft.

A special feature of the engine is the arrangements made for inspecting the pistons. This consists of the lower part of the liner being readily detachable, so that the piston when lowered is exposed for inspection and rings can be changed in a few minutes. In addition, the cylinder bores can be examined without disturbing any of the main running gear in the crank case or the valve gear.

This company has recently installed the Buchi system of exhaust turbo-charging in the M.V. *Raby Castle*.

Double-acting Engines.

The North-Eastern-Werkspoor double-acting Diesel engine has been jointly developed by Werkspoor and North-Eastern Marine Engineering Co., Ltd., the experimental work being carried out on a large single-cylinder engine at Wallsend.

The engine, which is illustrated in fig. 45 (page 2418), is of normal design as regards the main running gear and framing. The bottom combustion space has the important feature that combustion takes place in a separate chamber away from the piston rod, which is therefore not subjected to the extreme combustion temperature. This chamber is also utilised to house the valves, which are thereby rendered more accessible for operation and overhaul.

The lower portion of the cylinder is capable of being lowered by means of the main crosshead, thus exposing the piston (see fig. 45).

Sulzer Marine Diesel Engines.

Messrs. Sulzers' experience of both four-cycle and two-cycle engines has led them to adopt the two-cycle engine for all marine work, and they have standard designs of 4, 6, 8, and 10 cylinder marine engines developing from 300 to 7,200 b.h.p., the latter being a unit of 8 cylinders, or 900 b.h.p. per cylinder.

The Sulzer two-cycle engine has important differences from the other engines described. Chief amongst these is the method of scavenging through a double row of ports, the upper row of which is above the exhaust port opening and is controlled by means of a valve.

On the downward stroke of the piston, the upper row of scavenging ports is first uncovered, but the valve controlling these ports remains shut and the exhaust commences to take place only when the piston has descended further and uncovered the exhaust row of ports

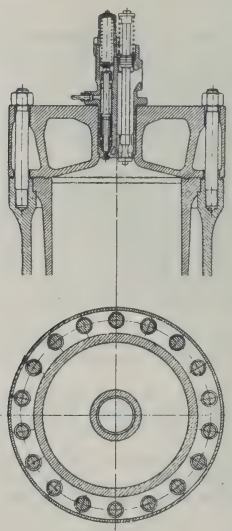

Fig. 46.—Sulzer Cylinder Cover.

Scavenging commences as soon as the lower row of scavenging ports is uncovered and continues through both rows of ports, the control valve for the upper ports having been opened by the pressure of the scavenging air, and air is admitted through the upper ports to the cylinder, after the exhaust ports are closed, as long as the scavenge air pressure exceeds the pressure in the cylinder.

Not only is the scavenging much improved in this manner, but it will be seen that it is possible to obtain a supercharge of air, *i.e.* a slight increase above the atmospheric pressure in the cylinder at the commencement of compression.

Messrs. Sulzers have found that the good combustion obtained by this method of scavenging, and also the simplicity of the cylinder cover design (fig. 46) enables them to maintain with safety a higher mean pressure in their two-cycle engines than in four-cycle engines.

The power for a given size of cylinder on the Sulzer two-cycle type is more than double the power of a similar size cylinder on the four-cycle type, both being assumed to run at the same piston speed.

The fuel consumption is also practically the same as the best four-cycle engine when working under service conditions, *viz.* 0·42 lb. per b.h.p. hour, including scavenge blowers.

For some engines a direct driven scavenging pump is fitted between the h.p. air compressor at the end of the engine and the main engine cylinders.

In the latest type of Sulzer engine the scavenging pumps are in the form of independent rotary blowers electrically driven. This is an advantage from the constructional point of view, and the arrangement has the further gain that the scavenging pump may be speeded up independently of the main engine when it is desired to increase the power. This does not involve any increase in the size of the electric generating sets where electrically driven winches are installed, as these latter are only running in port when the scavenging pump is idle.

An engine, when made with separate turbo-blowers, develops 3,200 b.h.p., working at approximately the same indicated mean pressure and piston speed as the 2,900 b.h.p. engine with reciprocating scavenge pumps.

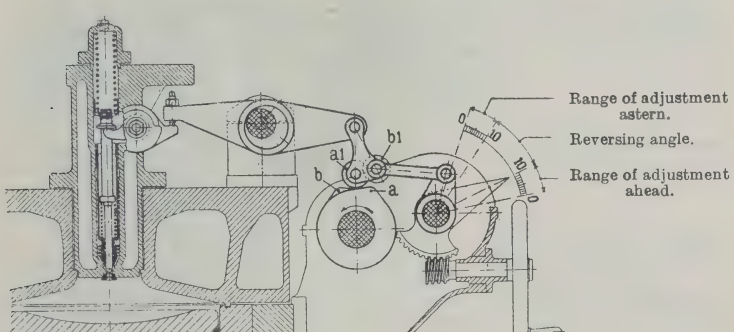

FIG. 47.—Sulzer Reversing Mechanism.

Reversing is carried out with a minimum requirement of power, and is effected by bringing a second set of rollers and cams into operation (fig. 47). Each starting and fuel valve therefore has one cam and roller, a and a^1, for running ahead, and another, b and b^1, for running astern. The hand wheel shown in the above illustration brings a and a^1 or b and b^1 into operation in accordance with the required direction of running.

The weight complete of Sulzer Diesel Marine Engines is approximately 2 cwt. per h.p., *i.e.* 10 h.p. per ton.

Submarine engines of Sulzer two-cycle type have been built developing 4,000 h.p. in 8 cylinders, these engines being the most powerful marine Diesel engines in the world of the light type.

The first large passenger liner driven by Diesel engines is the *Aorangi*, which has engines of the Sulzer type, manufactured by the Fairfield Shipbuilding and Engineering Co., Ltd., at Govan.

THE DOXFORD OPPOSED-PISTON MARINE OIL ENGINE.

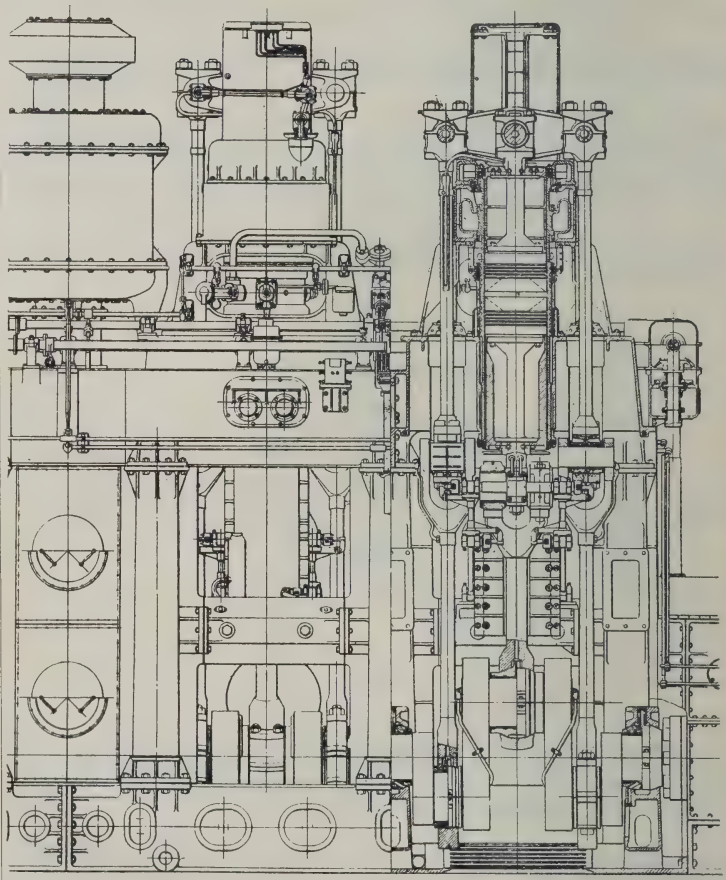

FIG. 48.

The Doxford Engine.

Messrs. Wm. Doxford & Sons, Ltd., have completed a number of motor vessels, and have now built and are building an aggregate h.p. of 400,000, consisting of four cylinder types, single screws, 6,000 i.h.p. at 95 revs.; twin screws, 12,000 i.h.p. at 120 revs.; quadruple screws, 15,000 i.h.p. at 125 revs.; and three cylinder types, single screw, 2,800 i.h.p. at 93 revs., all of the opposed piston two-stroke type operating on the Doxford system of airless injection.

Fig. 48 (page 2422) shows part of the four-cylinder type engine, four of which were fitted into M.S. *Bermuda*, in each cylinder of which there are two pistons working. The lower piston is coupled by crosshead and connecting-rod to a crank below the centre line of the cylinder, and the upper piston acts upwards to a transverse beam extending fore and aft beyond the walls of the cylinder, and coupled by two side connecting-rods to two crankshafts, with the two side cranks arranged at 180° to the centre crankpin.

The stroke of the lower piston is more than the stroke of the upper piston, being inversely proportional to the respective reciprocating weights, whereby a complete balance is obtained.

The fuel is injected between the pistons when they are together, from two fuel valves diametrically opposite each other, and when combustion takes place the pistons are driven apart, thus exerting an almost perfect turning moment on the crankshaft without re-actional load on the main bearings or framework of the engine.

The products of combustion are exhausted through ports round the whole circumference at the top of the liner, which ports are controlled by the upper piston. At the end of the stroke, corresponding ports are uncovered by the lower piston in the bottom end of the liner, to control the scavenging air, thus the entire cylinder is scavenged on the 'Uniflow' principle; the covering of these ports at the beginning of the return stroke traps the remaining air, which is thus compressed ready for the injection of the fuel and repetition of the cycle.

Fuel injection is on the Doxford 'Solid Injection' principle, and the fuel oil is injected transversely across the cylinder in the form of a fan, from each valve placed diametrically opposite, the fan forming a curtain right across the combustion space. The air which is entrapped between the two pistons receives through suitably arranged ports a rotating motion whereby the air is fed through the curtain of fuel oil, so that very efficient combustion is obtained without the oil impinging on to the piston or cylinder walls. The two pistons are, moreover, hollow, and form between them practically a complete spherical space, the surfaces of which are kept at 1000° F., thus greatly assisting the burning of the heaviest grades of boiler oil.

The elimination of exhaust and induction valves, with their liability to defects, is a great advantage, and in dispensing with the cylinder cover many defects of jointing and cooling are obviated. Also, the absence of the high-pressure compressors removes the most delicate part of a Diesel engine, and the danger from possible explosions in the injection air line is completely avoided.

The valve gear is very simple, consisting of one camshaft in front and one at the back of the engine. Both are driven by spur and bevel wheels direct from the thrust shaft. The front camshaft has two sets of cams for the fuel and air starting valves for ahead and astern running, either of which is brought into operation by sliding the cam shaft by means of a hand lever. When going ahead, the front and back fuel valves are in operation, but when going astern only the front fuel valves come into use, giving approximately 60 per cent. of full power, which is equal to the resistance obtainable from the propeller. A hand-wheel controls the air-starting valves and the fuel valves. By rotating the hand-wheel, the air-starting valves are brought into contact with their cams, and air is admitted to the respective cylinders. By a further rotating of this hand-wheel, the air-starting valves automatically come out of action and the fuel valves are thrown into use, and by further rotating the hand-wheel, the speed and power of the engine is regulated. The small hand-wheel controls the suction valves of the fuel pump for regulating the required fuel oil pressure.

An Aspinall governor operates the injection fuel valves, and at the same time acts upon the fuel pump suction valves; thereby racing under any condition is completely prevented.

The cylinder liners and pistons are all cooled with fresh water, and forced lubrication is employed in the crank chamber throughout.

Messrs. Doxford have run extensive trials on one of their four-cylinder 3,400 i.h.p. engines, submitted to the Trial Committee appointed by the Naval Arch. and Inst. of Mech. Engrs., and have proved a consumption of 0·4 lbs. per b.h.p. on 0·96 British Mexican fuel oil, and a mechanical efficiency of 89 per cent. Recently further improvements have been made, and an engine which was exhibited at the North-East Coast Exhibition was submitted to Professor C. J. Hawkes, M.Sc., who proved the consumption on Anglo-Persian oil to be 0·35 lbs. per b.h.p. per hour.

Messrs. Doxford claim to be the first to introduce aboard vessels centrifugal treatment of fuel oil, thus enabling shipowners to burn any brand of fuel oil that may have to be taken aboard.

Scotts' Two-Stroke Marine Oil Engines.

One of the outstanding features of the two-stroke marine oil engine, manufactured by Messrs. Scotts' Shipbuilding and Engineering Co., Ltd., of Greenock, is that means are provided for recovering a portion of the heat contained in the exhaust gases, and also for utilising the whole of the heat passing through the cylinder jackets for the generation of steam. The steam thus raised may be utilised in various ways. For example, in the machinery of the *Dolius* it is admitted to the underside of the combustion cylinder pistons to augment the power, and assists also in driving the scavenge air-blower, which is a separate unit. In the case of the larger engines fitted in the *Eurybates*, the steam is used in separate cylinders, contributing power to the main crankshaft and also supplying the whole of the power necessary for driving the turbo-blowers which deliver the scavenge air to the main engines. In both of these cases starting of the main engines is accomplished by steam pressure, and the arrangements have been very successful in service. To meet the demand for a cheaper engine, however, a modified design is available in which the steam generated by waste heat is used solely for driving the turbo-blowers, and the main engines are started by means of compressed air, as usual on Diesel engines. A cross-section of part of a six-cylinder engine of this type to develop 3,000 b.h.p. at 105 r.p.m. is shown in fig. 49. Each cylinder is 27 ins. diam, with a 45-in. stroke, and works on the two-stroke cycle with port scavenging and solid injection of fuel. A rotary valve of simple form is fitted at the exhaust gas outlet from each cylinder, having a supercharging effect. This permits the use of a short-skirted piston, which minimises weight, friction, and height of engine, and allows inspection or cleaning of the ports from the space below. These valves are driven by spiral gears from the crankshaft, have provision for expansion, and the spindles run in bearings suitable for the temperatures prevailing. The fuel pumps are grouped together at a convenient position and driven by a train of wheels from the crankshaft. One pump is provided for each cylinder. The plunger is actuated by a crank and delivers oil at 4,000 to 6,000 lbs. per sq. in. pressure to automatic jets situated at the cylinder head. An automatic air starting valve is also fitted on each cylinder, the manœuvring gear being grouped at the control panel eblow. No camshafts with overhead driving gear are required, so that the engine is extremely free from gear, with consequent ease of operation and overhaul. Fresh-water cooling arrangements are applied to the pistons, the water being introduced and taken away through the medium of trombone pipes attached to the cross-heads, with an independent pump for circulating under pressure. For the top ends of the main connecting rods a special type of bearing is fitted, originated by the makers, which renders it unnecessary to supply high-pressure oil to this part. All working parts inside the crankcase are supplied with forced lubrication, and mechanical lubricators are fitted for the cylinder liners. Starting air is stored in receivers, replenished by independently driven air compressors. The engine is of rigid construction, and through bolts are provided to transmit the combustion load from the cylinders to the bedplate.

Possessing a high mechanical efficiency, this type of engine is economical in fuel consumption, and requires no auxiliary power for driving the scavenge air-blowers.

In cases where no waste-heat recovery is required, a similar engine is supplied, with scavenge pumps direct or independently driven, and water circulation for the cylinder jackets, retaining the same general construction.

Messrs. Scotts also manufacture four-stroke engines of large powers of a type developed by them in association with Messrs. The North-Eastern Marine Co., and Messrs. Alfred Holt & Co., the well-known Liverpool shipowners. These engines follow usual four-stroke practice and are of very substantial construction.

Vickers' Engine.

Messrs. Vickers, Ltd., of Barrow (now part of Vickers-Armstrongs, Ltd.), were the pioneers of the solid or airless injection type of Diesel engine, and have built these engines in a wide range of powers for submarines and for commercial marine purposes.

The engines are of the four-stroke single-acting type, and the commercial engines have external crossheads, water-cooled pistons, and the crankcase is separated from the cylinders by an oil-tight diaphragm.

The fuel pumps have four or more units discharging to a common main from which the spray valves derive their fuel supply. The spray valves are mechanically operated, the duration of opening being variable according to the load.

Reversing of Vickers engines is usually arranged by means of a sliding shaft with two sets of cams, one set for ' ahead ' and one for ' astern ' running. The reversing gear first lifts the valve actuating levers clear of the cams, then slides the camshaft along, and finally lowers the levers to contact with the second set of cams.

SCOTT TWO-STROKE MARINE OIL ENGINE.

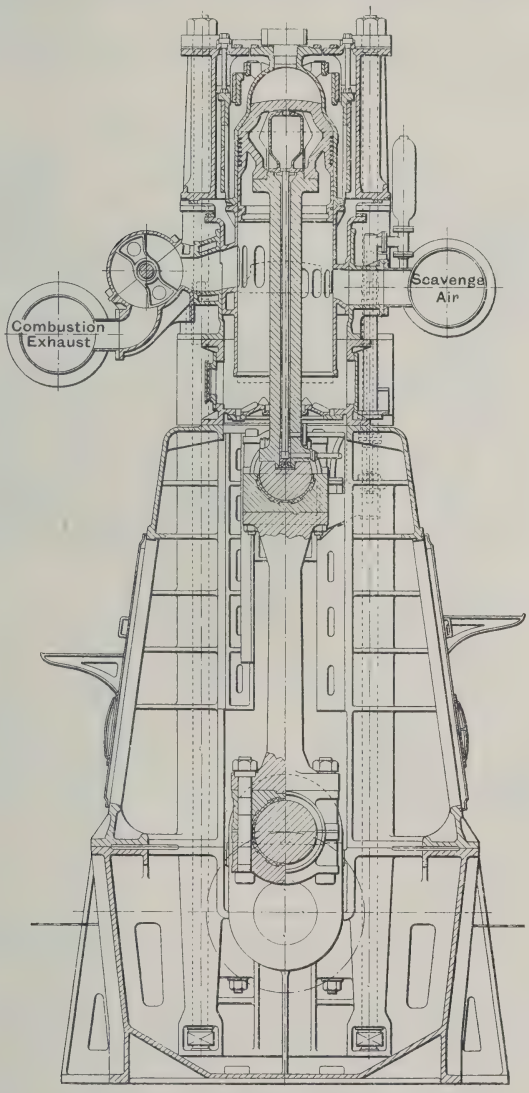

FIG. 49.

VICKERS' FOUR-STROKE MARINE OIL ENGINE.

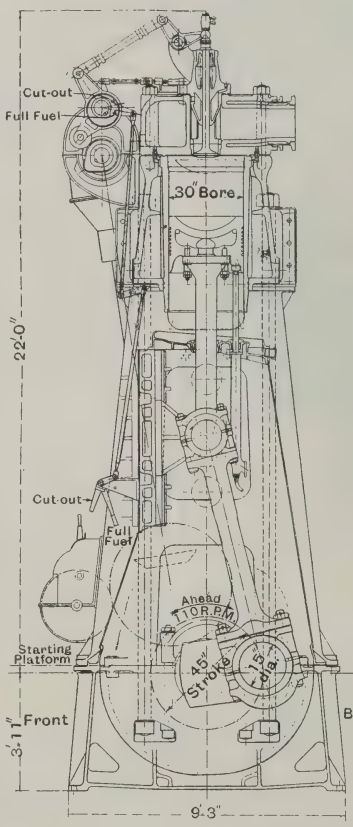

FIG. 50.

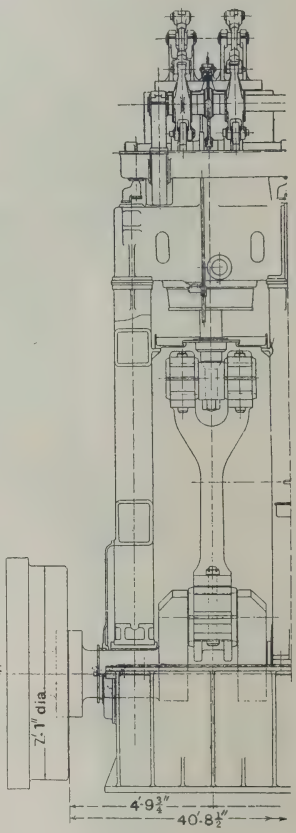

FIG. 51.

The cylinder covers for the larger engines are made with a detachable steel plate on the combustion side, this plate having clearance in the securing holes to allow for expansion relative to the main body of the cover.

The illustration (figs. 50 and 51) shows a portion of the largest engine of this type, which has six cylinders, 30-in bore and 45-in. stroke, and develops 2,000 b.h.p. at 110 r.p.m.

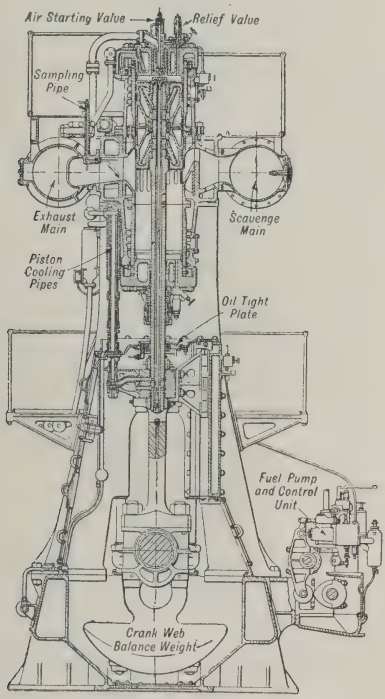

FIG. 52.—Richardsons-Westgarth Double-acting Engine.

M.A.N. ENGINE.

The engine designed and constructed by Messrs. Maschinenfabrik Augsburg-Nürnberg, and also built under licence by Messrs. Vickers-Armstrongs, Barrow, is of the two-stroke cycle type, both single- and double-acting.

The outstanding feature of these engines is the patented scavenge system. The exhaust and scavenge ports are above one another. The scavenge ports are so shaped and directed that the air current is directed towards the piston and then flows along the opposite side of the cylinder to the cover. It is there deflected and follows the exhaust gases to the exhaust ports.

The efficiency of this system is demonstrated by the fact that the scavenge pressure required is very low, about 1¼ lbs. per sq. in.

These engines are supplied either with air-blast or solid injection.

The illustration fig. 53 shows a typical section view of the M.A.N. double-acting engine.

The highest-powered Diesel engine in service is a non-reversing M.A.N. double-acting engine, built by Messrs. Blohm and Voss, and installed in the Hamburg Electricity Works.

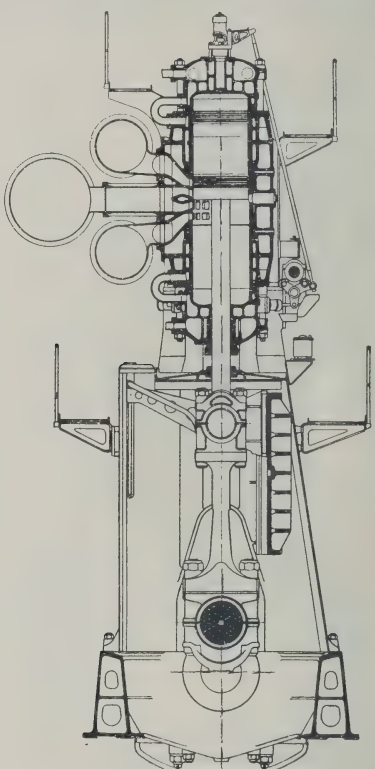

FIG. 53.—M.A.N. Double-acting Engine.

This engine has nine cylinders 33·9 in. in diam., and 59-in. stroke, and develops 15,000 b.h.p. at 94 r.p.m.

THE RICHARDSONS-WESTGARTH ENGINE.

Messrs. Richardsons, Westgarth & Co., Ltd., of Hartlepool, have produced a double-acting two-stroke cycle engine, which is noteworthy in many respects, and the first unit built for sea service was fitted in the oil tanker *Irania*, which sailed on its first voyage in April 1929.

The engine is all-British in design, and is worked on the airless injection principle, with controlled fuel pump delivery and automatic fuel valves.

The principal features of the engine are shown in the view of the *Irania's* engine (fig. 52).

The liner is fixed at its centre and free to expand at both ends, the cover-joint being a spring loaded lead alloy wedge ring. A special heat-insulating ring extends into the combustion chamber a few inches and fits closely against the liner walls up to the point reached by the piston. This

protects the walls of the liner in way of the fuel jets and also reduces the heat rejection to the cooling water. The top and bottom cylinder covers are interchangeable, the passage for the piston rod in the bottom cover is arranged to house the starting air valve in the top cover.

The top and bottom pistons are interchangeable and are secured to the piston rod by an external nut. Cooling water enters the piston rod at the crosshead by way of telescopic pipes, and passes in series through the lower and upper pistons and thence back outside the conveyor tube.

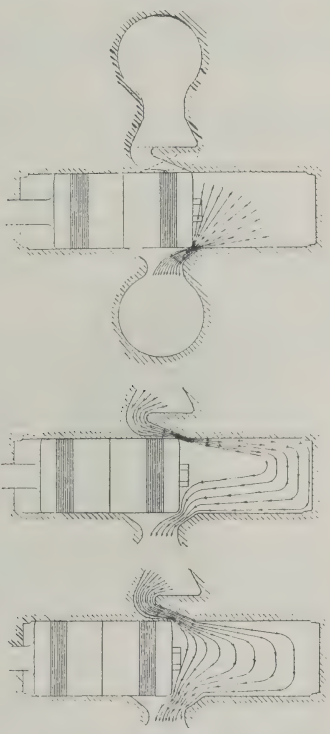

FIG. 54.—Scavenging Arrangement.

Fig. 54, shows a diagrammatic arrangement of the scavenging, in which alternate ports deliver air to top and bottom cylinders respectively. The air is directed towards the combustion space, and the length of liner is kept to a minimum.

The scavenge pump is of original design with two cylinders driven at three times the engine speed by spur gearings from the thrust shaft. The scavenge valves are chain-driven rotary type.

The fuel pump is cam operated and spring returned, and is driven from a camshaft at the crankshaft level. The time of opening of the injection valves is controlled by altering the time of closing of the pump suction valve, while their rapid closing is effected by the opening of a spill valve, the timing of which is also under control.

Two injection valves are fitted vertically into each cylinder cover. Each valve has five jets, four of which spray horizontally—two each side of the piston rod or nut, and the fifth one vertically. the oil from this fifth jet being finely atomised by a rotary motion, while the four horizontal jets have greater penetrating power.

The starting valves in the cylinders are automatic, the opening of the valves being controlled by timing valves operated by cams on the fuel pump camshaft.

F.I.A.T. Engines.

These engines are of Italian design, and generator engines of this type are constructed by the Fiat British Auxiliaries Ltd.

A wide range of single-acting engines have been manufactured to meet the requirements of generators, submarines, and the marine service; and an experimental double-acting has been exhaustively tested.

The scavenge ports which are uncovered at the same time as the exhaust ports are controlled by multiple plate automatic valves, which have replaced the earlier piston type. The convex piston top helps to direct the scavenge air to the top of the cylinder.

The piston heads and cylinder covers are of cast steel instead of cast iron, and the cylinder cover extends downwards into the liner, so protecting the heavy liner flange from the heat of combustion.

The cylinders are entirely separated from the crank chamber by a diaphragm plate, the piston rods passing through light shifting-boxes into the crank chamber. The object of this is to prevent any carbonised oil from the cylinder walls or any water leakage from the telescopic tubes from mixing with the oil in the crank chamber, but it has the disadvantage of adding considerably to the height of the engine.

Krupp Marine Diesel Engines.

Two-Cycle Single-Acting Marine Engines.

The Krupp two-cycle marine Diesel engine is built for powers from 1,300 b.h.p. up to 6,500 b.h.p. Two complete ranges are constructed. The first with a stroke bore ratio of about 1·85 and the second with a stroke bore ratio of about 1·5, both working at a piston speed of 810 ft. per minute. A section through a 2,500 s.h.p. engine having six cylinders 26·7 ins. diam. by 51·1-in. stroke running at 90 r.p.m. is shown in fig. 55.

A special feature of the engine is the scavenging arrangement. The working cylinders are cast in pairs, each block being rigidly bolted together and to the columns. There is one double-acting scavenging pump for each pair of cylinders. The pumps are mounted directly to the side of the cylinder blocks and in line with one of the cylinders. The casting incorporates the scavenging trunk, and the receivers of the several pumps are interconnected. Large suction discharge valves are fitted in the pump housing. This arrangement permits extremely short air passages from the pump to the working cylinders, so that fluctuations in pressure usually experienced in long scavenging trunks are avoided. For efficient scavenging only 28 per cent. in excess of the swept volume of the cylinder is necessary, and at full load the scavenging air pressure is about 1·4 lbs. per sq. in.

The arrangement of the ports in the cylinder liner is such that the scavenging air enters at the back, and the exhaust ports are arranged on either side, which gives good scavenging as there is less chance of the scavenging air blowing straight through the exhaust ports without first scavenging the cylinder.

The drive of the scavenge pump is taken from the crosshead by means of a heavy forged steel bracket. This bracket also carries the piston cooling inlet and outlet telescopic pipes. These two pipes work in a chamber outside the crank case and are connected with fixed piping to the piston head. The piston itself is made in two pieces, the top portion being of forged steel without internal ribbing, and the load is transmitted through the walls to a heavy flange at the top of the piston head. The piston skirt, which is of special cast iron, is secured at the bottom to a similar flange on the piston rod.

The cylinder cover is a simple and light casting, and is secured to the cylinder heads by means of a cast-steel ring which bears on a stepped flange, so that the stresses from the holding-down bolts are evenly distributed. It is provided with a central opening to accommodate the valve housing, which carries only a fuel, starting air, and relief valve. The cylinder covers, valve housings, and pistons are cooled by sea-water, a special device being arranged to ensure intensive cooling at the top of the liners and in the covers. At the forward end of the engine is a three-stage air compressor, providing the air for injection and for filling the starting air storage bottles.

The camshaft is on a level with the top of the cylinders and is driven by a vertical shaft. Ahead and astern cams are provided, and the operation of reversing is accomplished by a longitudinal displacement of the camshaft. The starting air valve is so arranged that air can only enter the cylinder provided the pressure in the latter is not greater than 20 atm., so that both fuel and starting air can be admitted during the same stroke. The starting-air cam only controls the closing of the valve, and this arrangement allows for quick starting and economy in the consumption of starting air.

The reversing gear is connected to the engine-room telegraph answering lever in such a manner that a movement of the lever from the ahead to the astern side of the dial sets the reversing control gear in the astern position. The operation of starting the engine by the controls automatically moves the camshaft to the correct position and opens up the supply of both starting and injection air.

The pressure of the injection air is automatically controlled to suit the engine speed, as is also the air compressor suction, so that when charging the storage air bottles the compressor adapts itself to the increased load and at the same time maintains the requisite injection air pressure. Each cylinder has its own individual fuel pump, the pumps being accommodated in a common housing, and are driven from the vertical shaft. The engine is lubricated throughout with forced

lubrication. The crosshead bearings are supplied with oil at high pressure by a small pump mounted directly to each crosshead, the pumps being worked by bell-crank levers operated by the movement of the connecting-rod top end.

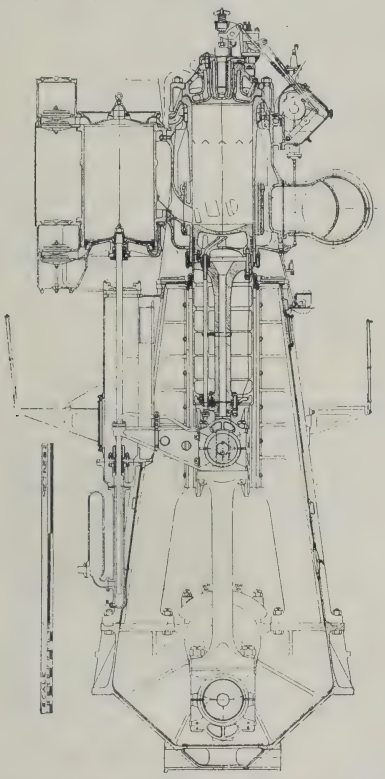

FIG. 55.—Section through Working Cylinder of Krupp Two-Cycle Engine.

On trial the Krupp two-cycle engine shows a fuel consumption of about 0·40 lb. per b.h.p. hour at full load, and a mechanical efficiency of about 78 per cent. The engines work at a normal m.i.p. of 82 lbs. per sq. in.

KRUPP FOUR-CYCLE MARINE ENGINES.

These engines are of the trunk piston type and work on the airless injection principle. They are designed for powers ranging from about 100 b.h.p. to 3,000 b.h.p., and are directly reversible. As before, two ranges of standard engines are constructed, the first with a stroke bore ratio of about 1·75, and the second with a stroke bore ratio of about 1·5, the piston speed in each case being about 1,000 ft. per minute.

The engines are of the totally enclosed type, the cylinders and crank cases of the box pattern being mounted on an oil-tight bed-plate. Forced lubrication is employed throughout, and in engines of the larger sizes pistons are cooled by oil. In the smaller types the pistons are fitted with a special cast-iron mushroom insertion piece, which is insulated from the remainder of the piston and acts as a heat accumulator, thus ensuring reliable ignition.

As in the two-cycle engine the camshaft is on a level with the top of the cylinders and reversing is accomplished by a longitudinal displacement of the shaft. Reversing mechanism is controlled

as before by the engine-room telegraph answering lever. The same type of automatic starting air valve is employed, so that the fuel and starting air can be admitted during the same stroke, thus facilitating very quick manœuvring.

The Krupp four-cycle marine engine shows on trial a fuel consumption of about 0·39 lb. per b.h.p. hour and a mechanical efficiency of 80 per cent. at full load. The engines normally work at a mean indicated pressure of 94 lbs. per sq. in.

The Tosi Diesel Engine.

These engines are of the enclosed design four-stroke cycle type, and are noteworthy for the elegance of their appearance.

A large number of engines have been supplied for submarines and other work in sizes up to 4,000 b.h.p., and they give a fuel consumption of 0·4 lb. per b.h.p. at full power.

Before standardising the four-stroke cycle engine, Messrs. Franco Tosi constructed a two-stroke cycle engine, so that they could take comparative tests. The latter engine had six cylinders and developed 1,300 b.h.p. when running at 300 r.p.m. The results of the tests showed that their eight-cylinder 1,450 b.h.p. engine was much more economical in fuel.

The outstanding feature of the Tosi design is a director valve fitted in conjunction with a combined valve in the cylinder head, which alternately admits air to the cylinder and allows the exhaust gases to escape from it, depending on the position of the director valve. In this way the cylinder valve is kept cool and free from carbon.

The latest Tosi engines are arranged for supercharging.

Double-acting Beardmore-Tosi engines have been installed in the converted steamer *Wulsty Castle*, driving the propeller shaft at 80 r.p.m. through Vulcan hydro-mechanical gearing, the engine speed being 250 r.p.m.

See also p. 1898.

The 'White' Diesel Engine.

The Diesel engines made by Messrs. J. Samuel White & Co., Cowes, were first used for submarines, and they are now supplied for all marine purposes.

One of the White 450 b.h.p. two-stroke cycle engines was subjected to severe tests in order to prove its capabilities as regards power, flexibility, and endurance. A 72-hour full load trial was satisfactory, and it was proved that the engine did not require vigilant attention. The exhaust was practically invisible. At the end of this run the engine was slowed down to two-thirds speed and manœuvring trials were conducted. It was seen that 14 cubic feet of air at 900 lbs. per sq. in. was sufficient for starting and reversing the engine 42 times, the pressure of air going down to 90 lbs., which was insufficient for starting.

As an example of flexibility, the tests to determine the minimum speed consistent with smooth running of the engine are interesting. The speed was gradually reduced from 400 down to 150 r.p.m. with suitable power and without alteration to fuel pumps, etc. It was found that 150 r.p.m. could be maintained without fluctuations, and with a steady blast pressure of 630 lbs. per sq. in.

The White engines are vertical, with stepped pistons, the working piston having a clearance of about 0·024 in. and relying for gas-tightness wholly upon its rings, while the lower portion fits the cylinder liner and takes the side thrust of the connecting-rods; this lower portion is always comparatively cool, and hence is easily kept effectively lubricated. An important feature of the latest design is the rotating scavenge valves, the sleeve within which they work forming part of the reversing mechanism of the engine.

Other Types of Marine Diesel Engines.

Among the other British makers of Diesel engines for marine work are Messrs. Harland and Wolff of Glasgow and Belfast, and John Kincaid & Co., Greenock, on Burmeister and Wain design; Messrs. Barclay Curle, Glasgow, and Richardson, Westgarth, Hartlepool, on the Doxford design; and Messrs. Armstrong-Whitworth, Newcastle; John Brown & Co., Glasgow; Wm. Denny Bros., Dumbarton; Fairfield Shipbuilding and Engineering Co., Glasgow; Alexander Stephen & Sons, Glasgow; Wallsend Slipway, Newcastle; and Workman Clark, all on the Sulzer design—all of these makers are well known in marine engineering, and in many instances embody in the engines they manufacture modifications from the patentees practice, to meet the special requirements of a marine installation, and in this way uphold the high traditions of British marine practice.

Diesel Engines for Submarines.

Practically all the European and American navies are now solely relying upon Diesel engines for the propulsion of submarines on the surface. These motors are of totally distinct type from those of the ordinary marine engine owing to the necessary high speed in order to reduce the weight sufficiently. They usually run at 400 to 500 r.p.m., and they are now constructed in powers up to 1,300 b.h.p. In the German and several other European Navies the Krupp two-cycle engine was employed, and also that of the M.A.N. Co., which is likewise of the two-cycle single-acting type. The former is a six-cylinder machine with two scavenge cylinders in the

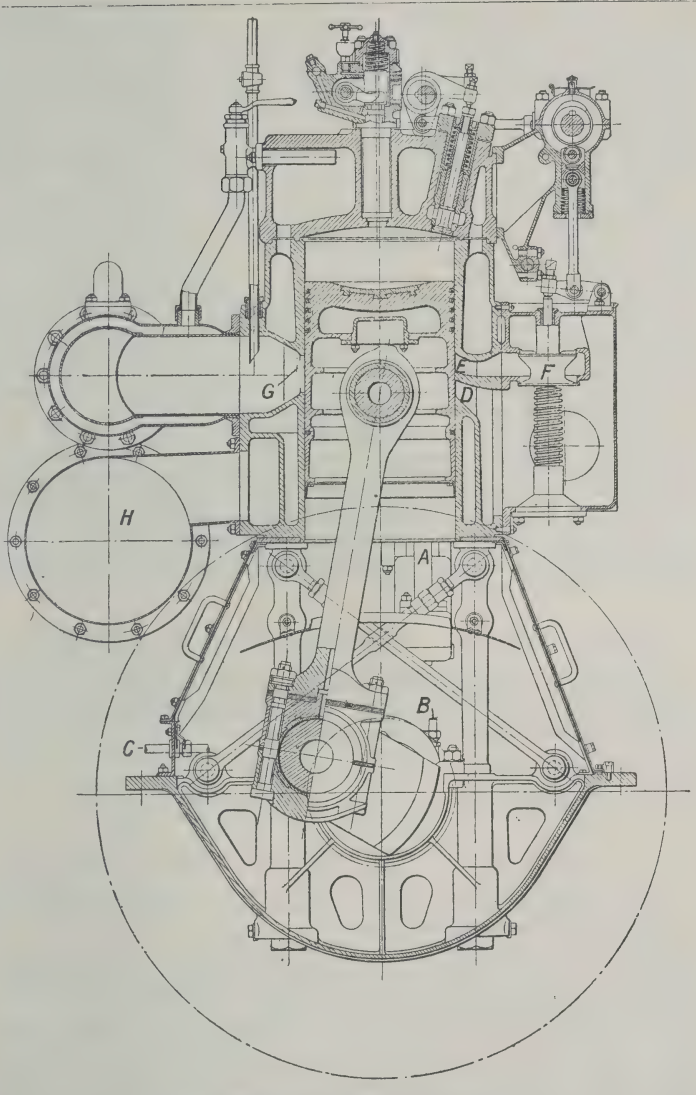

FIG. 56.—SULZER SUBMARINE DIESEL ENGINE.

centre driven direct off the crankshaft, whilst in the latter the scavenge pumps are arranged directly beneath each working cylinder. The air pumps for air injection are also driven off the engine, so that it is practically self-contained. The weights of these motors are low, and usually somewhere in the neighbourhood of 40 to 60 lbs. per b.h.p. For the British Navy the Vickers type is usually employed, which is a four-cycle twelve-cylinder motor of about 1,200 b.h.p. In this engine, solid injection of fuel is always adopted—that is, the injection by mechanical means instead of compressed air. The advantage of this is that no air compressor is required, which is very desirable in a submarine. Although the engine as a Diesel engine is not quite so efficient as with air injection, the absence of air compressor renders the overall economy about the same as in other types of motors. It is doubtful, however, whether such heavy fuel may be satisfactorily employed as with the other engines, and Broxburn shale oil is generally used in these submarines. Two-cycle engines have also been designed for operation with mechanical injection.

Other types of Diesel engines are now used in British submarines, and one of the first of the two-cycle types to be employed for the purpose is the F.I.A.T., which was installed in the first submersible built by Scott's Shipbuilding and Engineering Co. In this engine the scavenge pumps are arranged beneath the working cylinders as with the M.A.N. engine previously mentioned, the pistons being stepped in the ordinary manner. Other types of two-stroke Diesel motors will be installed in British submarines, if they have not already been so fitted.

In order to keep the piston speed of submarine engines within the limits which it is not desirable to exceed (from 900 to 1,100 ft. per min.), it is usual to make the ratio of the stroke to the bore very much less than with the ordinary mercantile type of motor. Frequently the stroke is made equal to the diameter of the cylinders, and is very seldom more than 10 per cent. greater. In this way it is possible to construct Diesel for submarine purposes almost equal from the point of view of reliability to the slow-running types. High-speed engines of 1,300 h.p. have been constructed for installation to submarines, and others of over 2,500 b.h.p. in eight cylinders have been designed, and are possibly now being built for the same purpose.

A particularly important type of submarine Diesel engine is illustrated in fig. 56. This is a Sulzer motor as employed in several navies, and mainly follows along the lines of the slow speed mercantile Diesel motors built by the same firm and described in the preceding pages. The most notable feature is that port scavenging is employed and the method of introduction of an extra supply of scavenging air through valve controlled auxiliary ports is the same as in the larger sets. It had been thought that the high speed of rotation (350–500 r.p.m.) might render this system inefficient for submarine engines, but this does not appear to be the case. Motors of this design are being built in powers up to 4,000 b.h.p. per engine.

In their latest submarine motors the F.I.A.T. Company have also adopted the port scavenging arrangement, and engines of 1,300 h.p. in eight cylinders built according to this principle have already been installed in Italian submarines.

Output, Dimensions, and Weights of Diesel Marine Engines.

The design of Diesel engines in regard to the main dimensions of cylinders, etc., is not yet on a very definite or exact basis, mainly owing to the variations of mean effective pressure in the cylinders, and the uncertainty regarding the best speed of revolution. The output of a cylinder varies with the diameter, the stroke, the mean effective pressure, and the speed of revolutions. In general terms it may be expressed as follows:

B.H.P. = KD^2LNn, where K = a constant; D = diameter of cylinder; L = stroke of piston; N = revolutions per min.; n = number of cylinders.

Taking the dimensions of the cylinders in inches it is found that for four-cycle engines the value of K varies between 0·00007 and 0·00009, a good average figure being

$$K = 0{\cdot}00008.$$

For two-cycle engines the value is between 0·000125 and 0·000155, the average being

$$K = 0{\cdot}00014.$$

As the mean effective pressure varies between 70 and 105 lbs. per square inch, and is sometimes higher, it is evident that cylinder dimensions are no absolute criterion of the exact output of a Diesel engine at a constant speed of revolution.

The piston speed in two- and four-cycle engines is approximately the same, namely, about 3 to 4 metres per sec., or 580 to 780 ft. per minute, with the ordinary marine motors. It does not often exceed these limits, except in high-speed engines of the type employed in submarines, when it may be as much as 1,100 ft. per minute. In the Burmeister and Wain double-acting four-cycle type the piston speed is about 1,200 ft. per minute.

The ratio of stroke to bore is a matter of wide variation, and in some cases is as low as 1·3 and others as high as 1·8. This latter figure is common in two-cycle motors with valve scavenging. Some types of four-cycle motors have a ratio of 1·4 and others 1·8.

The weight of Diesel marine engines varies as a rule between 200–300 lbs. per b.h.p., but is reduced to 60–70 lbs. per b.h.p. in submarine motors. Four-cycle engines are heavier than two-cycle, but the difference is not very marked, except in special cases, average figures being 300 lbs. and 250 lbs. respectively. This includes air compressors, scavenge pumps (in two-cycle motors) and various bilge, oil, and circulating pumps driven direct by the engine.

Power of Diesel Marine Engines.

The following tables give details of the dimensions and powers of some of the types of Diesel marine engines as now built :—

Type of Engine.	B.H.P.	Diam. Ins.	Stroke. Ins.	R.p.m.	No. of Cylinders.
Two-Cycle Single-Acting Engines.

The Büchi System of Exhaust Turbo-Charging.

The Büchi system of Exhaust Turbo-Charging (which is the invention of Dip. Ing. Alfred Büchi of Winterthur, Switzerland) is a pressure intake system which is a recent considerable advance in four-stroke Diesel engine practice ; it has so far found application principally to marine propelling engines, but stationary engines of as little as 350 b.h.p. and as much as 3,000 b.h.p. have been successfully turbo charged.

The principal advantages of the Büchi system are :—

1. For given cylinder dimensions, a normal power 50 per cent. greater than that of the ordinary Diesel engine with the same maximum cylinder pressures and therefore the same maximum loading of the working parts.

2. Greatly increased safe overload up to 30 per cent. or more, reckoned on the increased power.

3. Equal or lower combustion and exhaust gas temperatures and less heat carried away in the cooling water, due to the special method of passing excess scavenging air over the piston head through the cylinder and valves.

4. Complete combustion at all loads.

5. Increased mechanical efficiency ; reduced fuel consumption of from 4 to 5 per cent. at normal load, up to 20 per cent. at low load, and lower lubricating oil consumption, due to smaller pistons, bearings, etc.

6. The extraordinary flexibility due to the automatic increase or decrease of the quantity and pressure of the charging air with rising or falling load.

As the cylinder of the ordinary Diesel engine is limited in its power output by the quantity of air aspired and the amount of oil which can be effectively taken up by that fixed quantity of air, it has always been of necessity infra-charged ; the Büchi system has for its primary object the overcoming of this weakness, which it effects to the extent indicated above, while at the same time reducing the cylinder heat stresses, the fuel consumption, and generally improving the working and behaviour of the engine.

The complete turbo-charged internal combustion engine set comprises the internal combustion engine, an exhaust gas turbine, and a pump or blower to supply air to the cylinders of the engine for the triple purpose of charging, cooling, and scavenging. In the arrangement so far found most practicable, the Diesel engine is treated as an independent prime mover of normal speed of revolution, and the turbine is also arranged as an independent unit directly driving a turbo-blower ; thus engine, turbine, and blower run at their most efficient speed of revolution, no gearing is necessary, and the turbine and blower can be placed in any suitable position subject only to a suitable lead for the exhaust piping from the engine to the turbine.

The quantity of air delivered by the turbo-blower to the cylinders is sufficient, and is proportioned for perfect combustion at all loads, even up to 100 per cent. over the power rating of ordinary Diesel engines of the same bore, stroke, and revolutions, and the present normal rating of the Büchi charged engine for continuous running is 50 per cent. above that of the ordinary Diesel of equal bore, stroke, and revolutions. The maximum pressures in the cylinders are the same as in the ordinary Diesel but, combustion lasting longer, the increased power is shown by the flattening of the diagram, indicating higher mean pressures.

The turbo-charged engine effectively responds to demands for increased power over a wide range, and this remarkable flexibility depends on the fact that as, at higher loads, the pressure in the exhaust pipe becomes greater, the revolutions of the turbine rise, thus increasing the quantity and pressure of the air delivered by the blower. As a consequence combustion is always complete, and even at 30 per cent. overload (calculated on the increased output due to charging) the exhaust is absolutely clear.

As the maximum cylinder pressures are not augmented, with the exception of a very slight increase of certain crankshaft dimensions, the bearings and other frictional surfaces of the Büchi turbo-charged engine of 50 per cent. higher rating are the same as those of the ordinary Diesel. Professor Stodola in his report on the test of a four-cycle Diesel engine normally rated at 850 b.h.p. (Büchi charged at 1,275 b.h.p.), put at his disposal by the Swiss Locomotive & Machine Works, Winterthur, Switzerland, says :

' The fuel consumption was 0·391 lbs. per b.h.p. hour with fuel with the low heat value of 18,240 B.T.U. per lb.'

' The same type and size of engine running as an ordinary Diesel without turbo-charging has a fuel consumption of 0·408 lb. per b.h.p. hour, or in other words, turbo-charging lowered the fuel consumption of the engine tested by approximately 4 per cent., due to the improvement of the mechanical efficiency from 72 per cent. to 80·2 per cent.'

Notable as are the increase of power of flexibility, and of mechanical efficiency attained by the Büchi system, it is remarkable, and indicates the success of the system, that the increases should be accompanied by lower heat transference to the cooling water, and reduced heat stresses, due to the temperatures of the combustion gases being no more, and those of the exhaust even less, than in ordinary Diesel engines.

Professor Stodola in the report referred to above remarks that :

' Another remarkable effect of the system is the reduction of the amount of heat passing through the walls of the piston, cylinder, and cylinder head, *i.e.* 1,620 B.Th.U. per b.h.p. hour at full load. Assuming that the whole of the heat carried away in the piston cooling water passes through the piston head, the B.T.U. per sq. ft. per hour are :

$$Q_1 = \frac{530 \times 1,275}{15 \cdot 89} = 42,500 \text{ B.Th.U. per sq. ft. per hour.}$$

' The average amount of heat transmitted through the cylinder liners is only 27,300 B.T.U. per sq.ft. per hour, which is far less than the figure for ordinary four-cycle Diesel engines, and in two-cycle engines the heat transmission is naturally much higher still.'

These results are due to the passing of a large quantity of air through the valves and over the piston head to exhaust which thoroughly scavenges and is highly effective as a cooling medium.

For the explanation of how it is possible to get the increase of output which characterises the Büchi system, with the relatively low-charging air pressure, the change of state of the exhaust gases and the intake and exhaust strokes must be considered.

The change of state of the exhaust gases from the cylinder to their state at the turbine inlet may be explained in the following simplified way. The pressure in the cylinder may be conceived as dropping instantaneously to the pressure at the turbine inlet. Hence there is a drop in pressure at constant volume, thereby producing a decrease in temperature and a high velocity, with which the gases exhaust into the exhaust manifold, where the kinetic energy is transformed at constant pressure again into heat.

The suitable and necessary degree of pressure fluctuation in the piping between the engine and the turbine is attained by correctly proportioning the inlet area of the turbine, the above-mentioned piping, and by special timing of the inlet and outlet valves. To avoid interference of the exhaust and scavenging periods of the different cylinders in a multi-cylindered engine more than one exhaust pipe to the turbine is provided.

The intake and exhaust strokes are arranged in such manner that effective exhausting, scavenging, and filling of the combustion cylinders shall occur. This is made possible by the artificial pressure variation, referred to above, in the exhaust piping between the Diesel engine and the turbine, which is not, however, noticeable on the ordinary indicator diagram, owing to the small spring scale. The charging pressure before the inlet valve remains nearly constant. The exhaust pressure on the other hand shows marked fluctuations due to the special conditions provided ; a big drop of pressure occurs at the end of the exhaust stroke when the cylinders empty themselves to a high degree, the minimum pressure being about 2–3 lbs. per sq. in. gauge. During that period the charging air pressure is higher than the pressure in the exhaust piping to the turbine, when it is possible therefore to scavenge the cylinders with pre-compressed cold air which enters through the inlet valve and exhausts through the outlet valve. The compression space is thereby swept absolutely clear of exhaust gases, and the hot cylinder walls and the valves are thus effectively cooled, so rendering possible the low temperature at the beginning of the compression stroke. As this action occurs at the t.d.c. when the cylinder volume is very small, being only the compression space or about 8 per cent. of the swept volume, and because the exhaust pressure has much decreased, the scavenging just described is especially effective. Tests have shown that it is possible to blow 25 to 30 per cent. and even more of the air delivered by the blower, in the scavenging period, through that space, amounting in effect to refilling it three or more successive times with fresh and relatively cold air. In its influence on the temperatures of the working cycle and the possible increase of power this scavenging and cooling effect is of decisive importance.

Compared with the ordinary Diesel engine the exhaust turbo-charged engine shows a relatively low mean temperature, as at the end of the exhaust stroke and at the beginning of the suction stroke an effective cooling of the cylinder walls occurs.

As the compression ratio is less than in the ordinary Diesel engine the rise of temperature during compression is much less also. Then if, for combustion, the amount of fuel introduced is also in the same proportion to the volume of air in the cylinder for both types of engine it is obvious that the rise of temperature during combustion must be the same in both cases, whence it follows that the combustion temperature of the turbo-charged engine is lower. During expansion the temperatures in both types of engine are about the same because combustion in the turbo-charged engine lasts longer, and at the beginning of the exhaust stroke the temperatures are equal, but again at the start of the scavenging period the temperature of the turbo-charged engine drops far below that common in ordinary four-cycle Diesel engines.

These conditions of the working cycle of the exhaust turbo-charged engine result in a lowering of the mean temperatures of the working cycle by as much as 194° F. (90° C.). This lower temperature in its relation to the heat stresses in the walls of the cylinders is very important, but its value is increased by the fact that the Büchi charged engine, power for power, is much smaller than the ordinary Diesel, and heat tension in engines of small dimensions for a given power is lower, and less dangerous than in those of larger size.

It has been thought that in exhaust turbo-charged Diesel engines, as a greater quantity of fuel is injected corresponding to the greater amount of charging air, there follows an increase of the heat stresses in the walls of the cylinder covers, pistons, and cylinder liners ; but tests such as that by Professor Stodola already referred to, prove that the heat transfer through the cylinder walls is less than in the ordinary four-cycle Diesel engine.

The improvement in the power-weight ratio of the exhaust turbo-charged engine led to its early application to marine work, and its obvious value for work at high altitudes and its general advantages have brought it into use for land installations.

Diesel Marine Engines in Service.

The progress of the development of marine engines was considerably retarded by the war period, and at the end of 1918 the largest Diesel engines fitted in any merchant vessel were the twin-screw engines made by Messrs. Harland and Wolff of Glasgow for the motor vessel *Glenapp*, a vessel of 7,374 tons gross.

The Fairfield Shipbuilding and Engineering Co. completed a large passenger and cargo vessel in 1924, with four screw engines of 12,000 b.h.p. of the Fairfield Sulzer type. The *Aorangi* is 600 ft. long, with a service speed of 17 to 18 knots. This vessel is on service between Canada and Australia, and has conclusively demonstrated that the Fairfield Sulzer Diesel engine is entirely satisfactory for propelling ocean liners.

According to Lloyds Daily Index, dated July 30, 1929, there is a total of 812 motor ships above 2,000 tons in service, of which 545 ships, aggregating 3,316,955 tons gross, are driven by four-stroke engines, and 267 ships, aggregating 1,870,129 tons gross, by two-stroke engines.

Of the four-stroke engined ships 398, aggregating 3,437,019 tons gross, have Burmeister and Wain type engines, and 147 other types of four-stroke engines. Of the two-stroke vessels 105, aggregating 761,731 tons gross, have Sulzer engines, 56 of 571,059 tons gross Doxford engines, 28 of 251,966 M.A.N. engines, and 78 of 485,373 have other types of two-stroke engines.

The following table of typical vessels illustrates the advance which has taken place in the construction of Diesel engines :—

Name.	Tons.	Twin or Single Screw.	Date of Construction.	Cylinders.		Stroke.
				No.	Diam.	
'Vulcanus'	1,179	Single	1910	6	15½	23
'Selandia'	4,950	Twin	1912	16	20⅞	28
'Juno'	2,345	Single	1912	6	22	39⅜
'Siam'	5,296	Twin	1913	16	23½	31½

'Asturias'	22,000	Twin	1925	16D.A.	33	59
'Augustus'	32,000	Four	1927	24D.A.	27½	47¼

Oil Fuel for Diesel Engines.

(See also FUELS Section, page 2149.)

The fuel most commonly used in Diesel engines is that known as the residual oil, which is obtained by the process of distilling the crude oil when the lighter spirits are carried over, and the residual remains. Some crude oils are, however, directly used in Diesel motors, and in particular Texas oil, which does not contain sufficient proportion of petrol and other lighter oils to warrant its distillation. The only oil fuel which is unsuitable for employment is that from an asphaltum base, and it is for this reason that Mexican fuel oil is not as a rule employed for these motors without special treatment. Besides Texas oil, that from the Californian, Persian, Trinidad, Galician, Roumanian, and Russian oilfields is satisfactory for use in Diesel motors. Tar oil, which is obtained from the distillation of tar, is also very largely utilised in Germany, where the duties on imported oils are excessive, and often render the employment of Diesel engines unprofitable. Tar oil has a higher specific gravity than the petroleum fuel (usually in the neighbourhood of unity or slightly over), and has a lower calorific value, so that the consumption of an engine using this fuel is greater than when running on the ordinary oil. It is very viscous and, therefore, often requires heating, whilst some slight modifications have usually to be made in the fuel injection arrangements in order that an engine should run quite satisfactorily on tar oil. The usual method is to allow the injection of a small quantity of a lighter fuel oil before the main body of the tar oil passes into the cylinders through the pulveriser. It is claimed, however, that some motors run without any modification whatever, but this should not be taken as a general statement.

For information relating to Diesel engines for land installations, see page 1893.

LLOYD'S RULES FOR MARINE INTERNAL-COMBUSTION ENGINES. See page 1926.

HIGH PRESSURE AIR COMPRESSORS FOR MOTOR SHIP AUXILIARY DUTIES.

Fig. 57 shows a typical Weir three-stage, single-acting, twin-crank, motor-driven air compressor, for a delivery pressure of 1,000 lbs. per sq. in. In this machine the first and second stages are formed by means of a differential type piston, the air passing from the first stage of compression through the first stage intercooler and thence to the annular space forming the second stage. After second stage compression and cooling, the air passes to the third stage situated at top of the machine, where, when third stage compression is completed, the air is delivered through the after-cooler and oil and water separator.

The coolers are of the tubular type, the air passing through copper tubes expanded into rolled brass tube plates. Arrangements for the longitudinal expansion of the tube units are provided, and all troubles associated with tube packings are completely eliminated.

The pistons are of high-grade cast iron fitted with cast-iron rings of the Ramsbottom type. With the perfected lubricating and cooling arrangements in the Weir compressor, the wear on these cast-iron rings over long periods of running is practically negligible, the tool marks being visible after years of running.

The air valves are of special design, the valve plates being made in a steel alloy, heat-treated to obtain the correct degree of hardness. The lift of the valve is exceedingly small, preventing undue shock and noise and obtaining a high degree of efficiency. As a special precaution the valve seats are made in mild steel perforated with small holes, this type being superior to the usual

cast seat with annular slots, as the former design makes it practically impossible for fragments of a broken valve to enter the cylinder with destructive effect. The assembled valve units are arranged round the cylinder heads in such a manner as to reduce the cylinder clearance to a minimum, and give a resultant high volumetric efficiency.

The motion work generally is robustly designed to meet the high stresses generated in reciprocating air compressor machinery. The crank webs and connecting rod jaws are cut from solid mild steel forgings and machined all over. The crosshead and piston rod are forged in one piece, and tapers are provided on the rod to take the pistons.

As in best modern practice, forced lubrication is applied to all bearing surfaces, the crankcase bearings being served through a special system of oil ducts by an oil pump of the oscillating disc type. Cylinder lubrication is effected by a mechanical sight feed lubricator, feeding minute quantities of oil at the correct points on the cylinder walls, and maintaining the thin even oil film so necessary with comparatively high-temperature conditions.

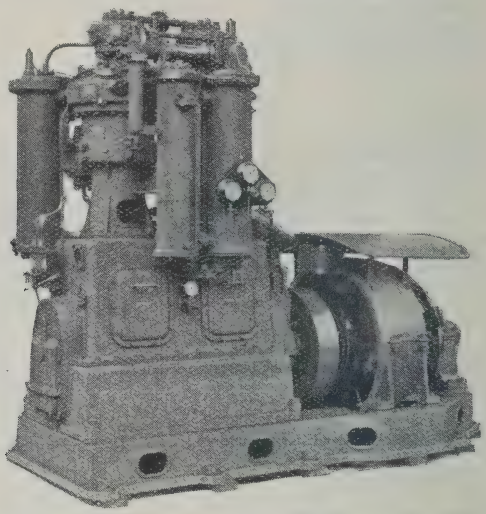

FIG. 57.

The balancing of these compressors has received careful consideration, the weights in all case being designed to effectively balance the forces set up by the reciprocating parts.

The circulation of the water spaces is carried out by a plunger type water-pump driven from the compressor crankshaft. This pump is of a very compact and positive design, and has a cast-iron body and gun-metal plunger with valves of the Kinghorn type.

The foregoing description is typical of compressors largely supplied for motor ship auxiliary duties, *viz.* Diesel engine air-blast injection, manœuvring, etc.

Compressors dealing with oxygen and other industrial gases for delivery pressure ranging to 6,000 lbs. per sq. in. are constructed, and may be arranged for drive either by electric motor, independent steam engine, tandem steam engine, or oil engine.

Metals for Propellers.

A properly designed bronze screw will give a very marked increase of speed (as much as *half a knot*) as compared with an iron or steel propeller, this being due to reduced scantlings, smoother surfaces, etc. Whilst the efficiency of a bronze screw continues unimpaired, that of an iron or steel propeller diminishes, through the pitting and corroding of its surface. In the case of solid screws the reduction in weight as compared with a cast-iron screw ranges from 10 to 20 per cent.

Nearly all vessels of any size or pretension are now fitted with bronze propellers. The metal has a tensile breaking strength of about 32 tons per square inch with about 20 per cent. elongation, and a transverse strength of over 7,500 lbs. per square inch. All warships as well as many merchant steamers are fitted with bronze propellers. Cast-steel propellers cost about twice as much, and bronze propellers about six times as much, as those of cast iron.

The *Bull's Metal Company* have with great success combined the study of Bronze Propeller designs with that of material, manufacture, and finish, large numbers of ordinary Bronze Propellers having been replaced with Bull's Metal propellers, giving, it is stated, a very material increase in speed on a reduced consumption of coal.

The *Delta Metal Co. Ltd.*, supply their special corrosion-resisting 'Delta' propeller bronze for casting propellers and propeller blades.

(See also Section XI., METALLURGY, p. 2659.)

Elements of Propulsion.

If a vessel (without propeller) moving at a speed of V feet per minute experiences a total resistance of R pounds, a force R must be applied continuously by means of a thrust or tow-rope pull in order to overcome the resistance and maintain the speed. The power required is RV foot-pounds per second and is called the Tow Rope Power or Effective Power.

$$\text{Effective Horse Power, E.H.P.} = \text{R.V.} \div 33000 = \cdot 00\dot{3}0\dot{7}\ \text{RK.}$$

If the thrust is delivered by a screw propeller working behind the ship, it is found that the action of the propeller increases the resistance. This increase is called the 'Augment of Resistance.' T, the total thrust of the propeller, must therefore be equal to R + Augment = R + A, and T − A = R. The augment of resistance can therefore be regarded as a deduction from the thrust: it is alternatively called the 'Thrust Deduction' and is written A = tT, where t is the 'Thrust Deduction Fraction.'

$$\text{T} - t\text{T} = \text{T}(1 - t) = \text{R}$$

$(1 - t)$ is called the Thrust Deduction Factor.

If a vessel is being towed at a speed of K knots, the skin friction sets the adjacent water in motion, and at the stern there will be found a 'wake' current moving in the same direction as the ship at some speed W knots. The stern, and with it the propeller, will therefore be moving at a speed K − W relatively to the wake water, and this speed is called the 'Speed of Advance.' Froude compares wake speed with speed of advance, and writes $\text{W} = \omega\,(\text{K} - \text{W}) = \omega\text{K}'$.

$$\text{Wake fraction} \quad \omega = \frac{\text{W}}{\text{K} - \text{W}} = \frac{\text{W}}{\text{K}'}$$

$$\text{Wake factor} \quad 1 + \omega = \frac{\text{K}}{\text{K} - \text{W}} = \frac{\text{K}}{\text{K}'}$$

$$\text{Wake per cent.} \quad 100\omega.$$

Taylor compares wake speed with ship speed, and writes—

$$\text{W} = \omega\text{K}$$

$$\text{Wake fraction} \quad \omega = \frac{\text{W}}{\text{K}}$$

$$\text{Wake factor} \quad 1 - \omega = \frac{\text{K} - \text{W}}{\text{K}'} = \frac{\text{K}'}{\text{K}}$$

$$\text{Wake per cent} \quad 100\omega.$$

If a propeller having a pitch P and making N revolutions per minute is working behind a ship and producing a thrust T with a torque Q in the shafting just forward of the propeller, the ship's speed being K and the speed of advance of the propeller K′ = K − W, the work obtained will be RK (E.H.P.) and the work expended 2πNQ, which we can call the 'Received Horse Power Behind' R.H.P.$_b$. The efficiency η is therefore $\frac{\text{E.H.P.}}{\text{R.H.P.}_b} = \frac{\text{RK}}{\text{R.H.P.}_b} = \frac{\text{T}(1 - t) \times \text{K}'\,(1 + \omega)}{\text{R.H.P.}_b}$.

TK′ is called the 'Thrust Horse Power' (T.H.P.) and the product $(1 - t)\,(1 + \omega)$ the 'Hull Efficiency,' being the product of one factor $(1 - t)$ representing the effect of the propeller on the hull and another $(1 + \omega)$ representing the effect of the hull on the propeller. If we write—

$$\text{Hull Efficiency} = h = (1 - t)\,(1 + \omega)$$

we have

$$\text{Screw Efficiency Behind} = \eta = \frac{\text{T.H.P.}}{\text{R.H.P.}_b}\,h.$$

Now if the same propeller be mounted on a shaft alone, without ship or model, and run in open water at the same revolutions N, and its speed of advance adjusted until it gives the same thrust T, we can fairly assume that the speed of advance so found must be the same as the speed of advance when in place behind the ship. We are thus able to determine the wake speed. The torque is not necessarily the same as when behind the ship, though it is usually not very different, so we call the power in the shaft 'Received Horse Power in the Open,' R.H.P.$_o$, and the 'Efficiency in the Open,' $\odot$, is $\frac{\text{TK}'}{\text{R.H.P.}_o} = \frac{\text{T.H.P.}}{\text{R.H.P.}_o}$.

The ratio $\frac{\text{R.H.P.}_o}{\text{R.H.P.}_b}$ is called the 'Relative Rotative Efficiency,' r.

Finally therefore, we can write—

$$\eta = \frac{\text{T.H.P.}}{\text{R.H.P.}_b} h = \frac{\text{T.H.P.}}{\text{R.H.P.}_o} \times \frac{\text{R.H.P.}_o}{\text{R.H.P.}_b} h = \odot rh,$$

or screw efficiency behind = screw efficiency in open × relative rotative efficiency × hull efficiency.

S.H.P., the 'Shaft Horse Power' (or B.H.P., the 'Brake Horse Power'), is the power in the shafting just abaft the engine. The shaft line efficiency l is the ratio $\frac{\text{R.H.P.}_b}{\text{S.H.P.}}$. The mechanical efficiency of the engine m is the ratio of S.H.P. to the indicated horse power (I.H.P.).

$$\therefore \quad \text{S.H.P.} = m \times \text{I.H.P.}$$

$$\text{R.H.P.}_b = l \times \text{S.H.P.} = l \,.\, m \,.\, \text{I.H.P.}$$

$l \times m$ is the 'Transmission Efficiency,' $f = \frac{\text{R.H.P.}_b}{\text{I.H.P.}}$

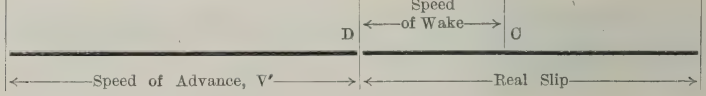
The overall propulsive efficiency or propulsive coefficient, e,

$$= \frac{\text{E.H.P.}}{\text{I.H.P.}} = \frac{\text{E.H.P.}}{\text{R.H.P.}_b} \times \frac{\text{R.H.P.}_b}{\text{I.H.P.}} = \eta f = \odot rhf.$$

η is sometimes called the 'Quasi-Propulsive Coefficient.'

A propeller having a pitch P and making N revolutions per minute would advance a distance PN if there were no slip. On account of slip, however, it actually advances a lesser distance V′ called the 'speed of advance.' The difference is called slip, so that slip = PN − V′, and the 'slip ratio' $s = \frac{\text{PN} - \text{V}'}{\text{PN}} = 1 - \frac{\text{V}'}{\text{PN}}$. If the thrust is T and the torque Q, the efficiency $= \frac{\text{TV}'}{2\pi\text{NQ}} = \frac{\text{TP}\,(1-s)}{2\pi\text{Q}}$.

When attached to a ship the apparent speed of advance is the ship's speed K knots or V feet per minute, where $\text{V} = 101\frac{1}{3}\text{K}$. The apparent slip is PN − V. On account of the presence of the wake stream, however, the true speed of advance of the propeller through the water surrounding it is K − W(= K′) knots or V′ (= $101\frac{1}{3}$K′) feet per minute, and the real slip is PN − V′. Let AB represent to scale the 'Speed of the Propeller':



AC the speed of the ship V, and CD the speed of the wake.

$$\text{Then apparent slip ratio} = \frac{\text{CB}}{\text{AB}}$$

$$\text{Real slip ratio} = \frac{\text{DB}}{\text{AB}}$$

$$\text{Froude's wake fraction} = \frac{\text{DC}}{\text{AD}}$$

$$\text{Taylor's wake fraction} = \frac{\text{DC}}{\text{AC}}$$

(*W. J. Luke.*)

Law of Comparison for Model Propeller Experiments.

If a model propeller $\frac{1}{n}$th of the size of the ship's propeller is run at $\sqrt{n}$ times the revolutions and its speed of advance adjusted so that both screws are working with the same slip ratio, the thrust

of the ship's propeller will be n^3 times that of the model, the torque n^4 times, the powers $n^{3\frac{1}{2}}$ times, and the efficiencies equal.

	Model Propeller	*Ship's Propeller*
Diameter	d	$D = nd$
Pitch	p	$P = np$
Revolutions	r	$R = n^{-\frac{1}{2}} r$
Speed of Advance	v'	$V' = n^{\frac{1}{2}} v'$
Slip Ratio, s	$1 - \frac{v}{pr}$ =	$1 - \frac{V'}{PR}$
Thrust	t	$T = n^3 t$
Torque	q	$Q = n^4 q$
THP = U	$\frac{tv'}{33000}$	$\frac{TV'}{33000} = n^{3\frac{1}{2}} \frac{tv'}{33000}$
RHP = P	$\frac{2\pi vq}{33000}$	$\frac{2\pi RQ}{33000} = n^{3\frac{1}{2}} \frac{2\pi vq}{33000}$
Efficiency	$\frac{tv'}{2\pi rq}$ =	$\frac{TV'}{2\pi RQ}$
ρ_U (Rho-U)	$\frac{ru^{\frac{1}{2}}}{v'^{2\frac{1}{2}}}$ =	$\frac{RU^{\frac{1}{2}}}{V'^{2\frac{1}{2}}}$
ρ_P (Rho-P)	$\frac{rp^{\frac{1}{2}}}{v'^{2\frac{1}{2}}}$ =	$\frac{RP^{\frac{1}{2}}}{V'^{2\frac{1}{2}}}$
δ (Delta)	$\frac{dr}{v'}$ =	$\frac{DR}{V'}$

The last three functions are the same for all similar propellers working at the same slip ratio. ρ_U and ρ_P depend on revolutions, power and speed, which are given quantities in the initial stage of propeller design. The results of systematic propeller experiments are usually plotted on some function of Rho as base, since this is independent of diameter. For each of a series of pitch ratios, a curve of efficiency and a curve of some function (such as δ) involving the diameter are plotted, from which the most suitable diameter and pitch ratio can be found for the given power, revolutions, and speed of advance. Taylor has published four 'Rho-delta' diagrams obtained by combining and averaging his own propeller experiments with those of Froude, Durand, and Schaffran. These were reproduced in *The Shipbulder*, January 1925.

Metals for Marine Engines.

Delta Bronze Nos. I. and IV. alloys (see Index), Phosphor bronze, and Phosphor white lining metal No. II. are especially suitable for various parts of marine engines: the latter metal (phosphor white) has a higher fusing point than good Babbitt metal, thus allowing a bearing to heat without causing the metal to melt, a matter of some importance at sea.

Delta Bronze No. IV., a malleable bronze of great strength and tenacity, is specially adapted to replace steel in cases where a material of the highest corrosion-resisting qualities is desired. For this reason it is employed on a very large scale in the form of forgings or extruded or rolled rods, etc., for air and circulating pump rods, shafts, plungers, spindles, thrust block bolts and other parts of marine engines. For particulars of corrosion-tests, see p. 174.

Phosphor-bronze sheet is superior to copper in withstanding the action of sea-water. In a comparative experiment made at Elankenberghe, lasting over a period of six months, between the best English copper and phosphor bronze, the following results were arrived at: the loss in weight due to the oxidising action of the sea-water averaged for copper 3·058 per cent., while that of the phosphor bronze was only 1·158 per cent.

For lining bearings, crank-pin bushes, and other parts, exclusive of crosshead bushes, the following alloy has been found to give good results after extended experience in hard ocean steaming :—12 parts tin, 1 part copper, 1 part antimony, mixed in the following way : 6 parts tin alloyed with 1 part of antimony, and 6 parts tin with 1 of copper, and the two mixed together. For lining crosshead brasses the following harder alloy has been found to give good results : 85 per cent. tin, 5 per cent. copper, and 10 per cent. antimony.

The *Eyre Smelting Co., Ltd.*, who have made a special study of bearing metals for marine engines, supply a particular alloy of white metal which is stated to give good results in the big end bearings of Diesel engines. For the small end bearings the company supply a mixture of phosphor bronze, which is largely used in this country and on the Continent.

Painting Ships' Bottoms.

Ordinary oil paints are not suitable for this purpose, particularly because the drying of each coat of oil paint takes a longer time than owners can afford to allow vessels to remain in dock ; besides, these paints possess little or no power to prevent fouling. The practice, therefore, is to use what are termed ' compositions,' which are usually applied in two coats.

The composition paints have to be used in combination. The anti-corrosive, as a preservative and insulating coating, should be applied when the bottom is well scraped and dried. The anti-fouling composition contains powerful poisons and can be applied almost immediately after the primary coating, and the vessel can be floated as soon as the painting is completed, although it is desirable to allow the compositions a few hours to harden before the vessel enters the water.

It is very important to remove all rust or scale on the plates, as when such is not done corrosion is likely to continue beneath the surface and will eventually throw off any paint that can be applied. The ingredients in the best compositions are very expensive and are consequently not used to any extent in the manufacture of the cheaper brands.

The careful *stirring* up of these compositions is an essential point too often overlooked. The more valuable ingredients are heavy, and tend to form a sediment at the bottom of the drums, which requires to be carefully worked up. Much also depends upon careful painting—a thing which is unfortunately very difficult to arrange for in many of the dry docks owing to hurried and inefficient work.

Concrete Vessels.

A concrete weighing but 110 lbs. per cub. ft. and having a crushing strength after 28 days of 4,000 lbs. per sq. in., has been employed in the construction of reinforced concrete vessels of large tonnage, in America, for the United States Government. The aggregate itself, although light and cellular in structure, is not porous. The lighter quality will actually float on water, and as a test the United States Shipping Board authorities kept an amount of aggregate floating in water for some months, and it was demonstrated that the absorption was very small.

The aggregate is made from clay, calcined in kilns in a similar manner to that employed in the manufacture of bricks, the fundamental difference being that the heat (about 2,000° F.) is applied in a comparatively short time of 30 hours. This relatively sudden application of heat causes the material to swell, forming a clinker. The clay may be pressed into bricks and partially dried and stacked in kilns in the ordinary manner, care being taken to provide sufficient room around the bricks for expansion during burning. The size of the brick adopted in the United States is 8½ ins. by 4½ ins. by 2¾ ins. During burning, the bricks run together and form a solid mass of clinker, which is allowed to cool for about 3 days, in order to ensure a high degree of toughness. The cooling of the material is then completed by water, which causes the mass to split into pieces suitable for handling, and it is also found that this greatly facilitates the unloading of the kilns. The material may also be calcined in cement rotary kilns, the clay in this case being pressed into lumps of suitable size.

After burning, the product is crushed to the desired size. During the operation a proportion of the lightest aggregate is reduced to dust. This, however, is used to take the place of the sand or crushed stone in ordinary concrete, the constituent parts being carefully selected and graded. Light pneumatic hammers are used to vibrate the shuttering during ramming, materially assisting the flow of the concrete around the steel reinforcement, and producing a dense and impermeable material.

A number of reinforced light concrete oil tankers and cargo steamers of 7,500 tons deadweight have been under construction in various parts of the United States. These vessels are 434 ft. long. (*W. L. Scott, ' Engineering.'*)

When wood is used as a reinforcing material for concrete it should be impregnated with magnesium chloride, and the wood must be so placed that any change in the cross-sectional area does not affect the durability of the structure. If the latter precaution is overlooked the concrete may crack. Small strips of wood are better than larger ones, and rushes appear to be excellent for the purpose, especially for thin-walled structures such as ships.

(*Beton u. Eisen.*)

Lloyd's Rules for Ferro-Concrete Vessels.

No definite rules have as yet been formulated, but in regard to the quality and testing of steel to be used for reinforcements these are the same as given in Section 3 of the Rules of the Society, for Steel Ships. The cement should comply with the requirements of a recognised standard specification for Portland cement or the equivalent thereto. In the matter of the preparation of the concrete, the proportions of the cement, sand, and aggregate have been left to the individual constructors to submit their proposals for the consideration of the Committee, as these depend to some extent on the local facilities for obtaining sand and gravel, the quality of which varies in different districts.

In the design of vessels to be built of ferro-concrete, it is considered that concrete is incapable of withstanding any of the main tensional stresses, and the steel reinforcements embedded in the concrete must therefore be of sufficient strength to take up all the tensional stresses produced in the structure due to strain from longitudinal bending.

Lloyd's Tentative Regulations for the Application of Electric Arc Welding to Ship Construction.

(*Abstract.*)

Before welding, the surfaces to be joined must be fitted close to each other.

All butt and edge connections are to be lapped or strapped.

With lapped connections the breadths of overlaps of butts and seams and the profiles of the welds are to be in accordance with the following table :—

Thickness of plate. Inches.	Width of overlap seam and butt. Inches.	Throat thickness. Inches.
·40 and under	$2\frac{1}{4}$	·28
·60	$2\frac{1}{2}$	·38
·80	$2\frac{3}{4}$	·48
1·00	3	·50

Intermediate values may be obtained by direct interpolation, and for thicknesses below ·40 the throat thickness is to be about 70 per cent. of the thickness of the plate.

See also ' Electric Welding,' p. 2779.

(Contributed and revised by Alwyne Meade, Assoc.M.Inst.C.E., author of 'Modern Gasworks Practice.')

Parliamentary.

The public supply of gas in this country is governed largely by local Acts, but in general by the Gasworks Clauses Acts of 1847 and 1871, the Sale of Gas Act of 1859, and the Gas and Water Works Facilities Acts of 1870 and 1873, and most recently by the Gas Regulation Act (1920). London companies are, in addition, under the regulations of the Metropolitan Gas Act (1860). Under the Public Health Act of 1875, the local authority may become its own gas supplier, or may purchase an existing undertaking by agreement. Thus gasworks are controlled by—

(*a*) Statutory companies.

(*b*) Non-statutory companies.

(*c*) Local authorities.

The supply of gas in Scotland is, for the most part, in the hands of the local authorities. In England local authorities predominate as owners in the counties of Yorkshire and Lancashire, and in the North generally, but in the Home and Southern counties private ownership is the general rule. In addition to the Acts named above, the supply of gas in Scotland is governed by the Gas Acts of 1864 and the Burghs Gas Supply Acts of 1876 and 1893.

The obligations of the gas undertakings in the way of standards of quality were somewhat modified by an order made by the Minister of Munitions in June, 1918, as to the manufacture and production of gas, compliance with which order by the gas undertaking protected the undertaking from any forfeiture for failing to comply with its statutory obligations with regard to the illuminating power or the calorific power of the gas supplied, provided that in any even gas of a lower calorific power than 450 B.Th.U. gross was not supplied to the consumers.

It may be said that a new era in the supply of gas was marked by the introduction of The Gas Regulation Act of 1920. The commodity is no longer sold on a basis of cubic feet, but in terms of 'Therms.' In other words, the consumer now pays for the useful energy only, i.e. British Thermal Units; accordingly, the incombustible constituents in gas have no longer any commercial value. The standard 'Therm' is equivalent to 100,000 B.Th.U. Thus, if 10,000 cubic feet of gas are registered on the consumer's meter, and the 'declared' or normal calorific power of the gas is 500 B.Th.U. per cubic foot, then the number of B.Th.U. consumed is 5,000,000, or 50 Therms.

The main provisions of the Act are as follows :—

(*a*) The obligation to charge consumers on the heat unit basis.

(*b*) The adjustment of the 'standard' or 'maximum' price (on the heat-unit basis) to meet the additional expenses of manufacture and distribution arising from post-war conditions.

(*c*) Powers are given to the Board of Trade to limit the proportion of inert constituents in the gas, if thought fit; but the committee appointed to examine the question of incombustibles recommended that no limit should yet be imposed.

(*d*) There is an obligation to supply gas at 2 ins. water pressure in mains or services of 2 ins. diameter and upwards.

One of the most noteworthy provisions of the Act is the latitude which is given to gas undertakings in connection with the quality of gas supplied. The old standard of illuminating power has completely given way to calorific power, and the producer is permitted a free choice in the type of gas he distributes. He must, however, declare at what calorific power he is prepared to supply, consumers' appliances must be adjusted by him to consume the 'declared' variety of gas to the best advantage, and, in order to preclude excessive fluctuations in quality, certain penalties are imposed when the heating value falls below a prescribed limit. As regards the machinery for carrying out the Act, powers are given to the Board of Trade to grant facilities which in the past have entailed formal application to Parliament.

An important feature of the Act is that it empowers the Board of Trade to make amending orders revising the standard or maximum price if at any time it is shown to the satisfaction of the Board that the costs incidental to the production and supply of gas have substantially altered by reason of circumstances beyond the control of the gas undertakings. The effect of this was experienced some few years ago in the London area, when on the application of the London County Council the standard prices of certain undertakings were substantially reduced. More recently, however, on the application of certain gas undertakings themselves, increases in standard prices have been approved, and in addition Bills have been introduced which permit of the payment of a minimum dividend irrespective of the price of gas.

The Act prescribes that the quality of the gas distributed shall be determined by a calorimeter of the recording type which gives a continuous record of heating value. For some years recording calorimeters were not insisted on, and the system of periodical spot testing is still generally in force. The Gas Referees, however, commenced to prescribe the installation of recording calorimeters in certain cases as from the commencement of 1928, the two calorimeters specified for the purpose being the Fairweather and the Boys.

A non-statutory company operates as the result of established practice, or under the goodwill of the local authority. Its position is in many respects similar to that of a statutory company, but before opening roads for the laying of mains permission must be obtained from the district or county authority.

Statistics of Gas Undertakings in Great Britain and Ireland.

The following table shows the total number of gas undertakings which have existed in the United Kingdom during various years since 1901. It should be noted that the total number of separate undertakings has undergone decrease during the last twenty years, this being due to the policy of amalgamation which still continues. It is noticeable, too, that while undertakings owned by private companies and individuals have undergone a decrease, those owned by local authorities have increased, showing the tendency for the town authorities to take over undertakings from private ownership.

Year.	Owned by Companies & Private individuals.	Owned by Corporations & Local Authorities.	Total Number of Undertakings.
1901	1,349	265	1,614
1905	1,330	285	1,615
1907	1,322	297	1,629
1908	1,322	296	1,628
1909	1,330	296	1,626
1910	1,339	302	1,641
1911	1,320	308	1,628
1912	1,316	311	1,627
1915	1,281	320	1,601
1916	1,263	323	1,586
1917	1,256	322	1,578
1918	1,252	325	1,577
1919	1,252	325	1,577
1921	1,229	330	1,559
1922	1,220	321	1,551
1924	1,155	331	1,487
1926	1,134	332	1,466
1931	1,058	338	1,396

The largest gas undertaking in the world is the Gas Light & Coke Co. of London. This Company distributes more energy per annum than all the public electricity supply stations in Great Britain added together. The third annual report of the Electricity Commissioners shows that the authorised electricity undertakings of the United Kingdom generated, in the year ending March 1923, 4,600 million Board of Trade units of electricity, or 15,690,600 million B.Th.U. (156·906 million therms), while the Gas Light & Coke Co. supplies its consumers annually with over 237 million therms.

The largest gasworks in the world is the Beckton station of the above company. During a year, over a million and a quarter tons of coal are carbonised at this works, and the maximum daily output of gas amounts to over 70 million cu. ft. The Beckton works were opened in 1870, and have a total area of 475 acres. There are 14 retort houses on the works, and the water-gas plant is capable of an output of 27 million cu. ft. per day. There are upwards of 50 miles of standard gauge railway on the works, and the rolling stock consists of some 14,000 wagons and 40 locomotives.

Number of Gasworks in Great Britain.

In 1931 the total number of gasworks in operation in Great Britain and Ireland was 1,396. The total is made up as follows :

In England and Wales—	
Companies and privately owned	839
Local authorities	244
In Scotland—	
Companies and privately owned	158
Local authorities	74
In Ireland—	
Companies and privately owned	61
Local authorities	20
	1,396

Gas Made in Great Britain.

The quantity of gas made in Great Britain during 1927 was 314,582 million cu. ft. This was 3·1 per cent. in excess of that made in 1926. It is a remarkable fact that in the past twenty years the gas consumed in Great Britain has increased by nearly 67 per cent., while the total number of consumers (which now number 9,200,000) has increased by 58 per cent. The total amount of coal carbonised for the production of towns' gas now amounts to 16,500,000 tons per annum, in addition to which some 1,500,000 tons of coke and 100,000,000 gallons of oil are utilised for the manufacture of water gas. The gas industry also produces approximately 200,000,000 galls. of tar per annum, the greater proportion of which is dehydrated and used for road purposes.

The capital employed by the statutory gas undertakings alone amounts to some 150,000,000*l.*, and the total length of street mains employed runs to some 45,000 miles.

Consumption of Gas per Head of Population.

In the larger towns the average consumption of gas per head of population varies from 6,000 to 10,000 cu. ft. per annum. In smaller towns it ranges between 2,500 and 7,500 cu. ft. Gasworks statistics are, however, generally based on the consumption per consumer, which figure, for consumers through ordinary meters, approximates to 42,000 cu. ft. per annum, and 15,000 cu. ft. for those taking the gas through 'slot' meters. In addition, there will be an appreciable consumption for public lighting, and about 5 per cent. of the whole output will be written off as 'unaccounted for.' In straggling districts with long lengths of mains the latter figure may reach so much as 10 per cent. Taking the country as a whole, the average consumption per consumer at the present time works out at almost exactly 30,000 cu. ft. (say 150 therms) per annum.

Capital Expenditure on Gasworks.

This item varies considerably in accordance with the size of the installation and the price of labour and materials. In pre-war times, however, a concern promoted for the erection of a modern works with the accompanying distribution plant found it possible to complete the scheme for 600*l.* per million cu. ft. sold per annum. For smaller country works, the outlay was very much greater, varying from 750*l.* to 1,000*l.* per million cu. ft., or even more.

The following figures are the latest available for the undertakings named :

	Per million cu. ft. per annum.		Per million cu. ft. per annum.
Gas Light & Coke Company	433*l.*	Bristol Gas Company	433*l.*
Croydon Gas Company	562*l.*	Birmingham (Corporation)	329*l.*
Brighton & Hove Gas Company	437*l.*		

It is, perhaps, more accurate nowadays to rate capital expenditure on the therm basis in lieu of the cubic foot basis. As an example of how this method compares with the figures given on p. 2451 it may be mentioned that the capital of the Gas Light & Coke Company is now 1*s.* 9*d.* per therm, and that of the Croydon Gas Company 2*s.* 2*d.* per therm.

It is a somewhat surprising fact that at the present day the expenditure on the district mains, etc., is generally rather greater than that laid out in the erection of the works. Of the total outlay approximately 55 per cent. will be expended on the district, 38 per cent. on the works, and the remainder on Parliamentary, promotion, and engineers' expenses.

General Rules relating to Capacity of the Apparatus, etc.

LAND.

The area of land required for the erection of the works will amount to at least 2½ acres per million cubic feet of gas per maximum diem.

(NOTE.—The make of gas per maximum diem is calculated by dividing the total annual production by the factor of 240.)

RETORT HOUSE.

Dependent upon the size of the unit, i.e. the number of retorts set in each arch or section. The make per retort per 24 hours for different types of units is given in the following table :—

STOP-ENDED OR 'SINGLE' RETORTS.

	Therms per diem.
Length 9 to 10 ft., section 15 ins. round	15 to 20
,, 10 ft., section 16 ins. round	20 to 27
,, 10 ft., section 21 ins. by 15 ins. dee	35 to 45
,, 10 ft., section 22 ins. by 16 ins. dee	

'THROUGH' RETORTS.

	Therms per diem.
Length 20 ft., section 24 ins. by 16 ins. dee	90 to 100
,, 20 ft., section 22 ins. by 18 ins. oval	90 to 105

A later development is the short 'through' retort, 12 to 16 ft. in length, while a 21-ft. retort is now sometimes employed.

VERTICAL RETORTS.

	Therms per diem.
Woodall-Duckham type	150 to 450
Glover-West type	120 to 300
Chamber ovens	500 to 600

The gas yield from vertical retorts is extremely flexible, very much depending upon the proportion of steam admitted and the class of coal carbonised.

COAL STORAGE.

In the present day, owing to uncertainty of delivery and such causes, it is advisable for gasworks to keep in hand much larger stocks than were thought necessary some years ago. No undertaking can now afford to risk three weeks' storage, although this is a usual and sufficient allowance for that kept under cover. When ground area is available large stocks may be arranged for out in the open. The calculation of the stock of coal in hand may be performed by assuming that one ton of average gas coal occupies from 42 to 43 cub. ft.

Coke Storage.

One ton of coke occupies 85 cub. ft. (average).

For the convenience of dealing with stocks of other materials used on gasworks the following figures are given :—

One ton of	broken coal occupies	40 cub. ft.
,, ,,	cannel coal occupies	35 to 45 cub. ft. (varies considerably).
,, ,,	anthracite coal occupies	35 to 39 ,,
,, ,,	breeze occupies	60 to 65 ,,
,, ,,	lime occupies	42 ,,
,, ,,	oxide of iron (Dutch)	45 ,,
,, ,,	ditto (prepared)	41 ,,
,, ,,	sulphate of ammonia	47 to 48 ,,
,, ,,	ashes	50 ,, (about).
,, ,,	Portland cement	23 to 26 ,,
,, ,,	loose earth	28 to 30 ,,

CONDENSERS.

Water condensers are now largely used in preference to atmospheric types. Many of the latter kind are, however, still in use, and are not without their recommendations. Rules for condenser capacity vary to some considerable extent, and there is by no means agreement on the subject. The following are given as representing the average practice :—

Atmospheric condensers.—Allow 5 sq. ft. of atmospheric condensing surface per 1,000 cub. ft. of gas made per diem.

Water condensers.—Allow 3 sq. ft. of surface per 1,000 cub. ft. per diem.

In using the first of these two rules it must be borne in mind that the figure arrived at includes (in addition to the areas exposed by the actual condenser) the area of all piping between the outlet of the hydraulic main and the inlet of the condenser. In making calculations the actual surface to be considered is that with which the gas is in contact. Thus, when the gas travels inside a tube the interior surface must be taken, and when outside the exterior surface is considered.

Water condensers are of two distinct types :—

(*a*) Multitubular condensers.

(*b*) Water-tube condensers.

In the first type the gas passes through the tubes, which are surrounded by a water jacket. In the second type the water is within the tubes and the gas around them. As to which type is chosen depends entirely upon the conditions of working. When any deposit is likely to take place it is preferable to have this within the tubes which may be readily cleaned. Thus, when muddy water alone is available there should be no hesitation about adopting the water-tube type. On the other hand, when the gas dealt with is likely to be particularly dirty or to contain a large quantity of heavy tar vesicles the multitubular type is to be preferred. Condensers for carburetted water-gas are invariably of the water-tube type. As regards general dimensions the height of the apparatus should be from two to five times the diameter ; 3-in. tubes are preferable for the larger condensers, but 2-in. pipes will suffice for those of smaller design. The ratio of the length of the tube to its diameter should be within the limits of 80 to 1, otherwise the tube loses in structural stability. In the direction of the number of tubes to be employed a good basis to work upon is that of arranging the tubes so that they occupy about 18 per cent. of the total area of the tube-plate. For water-gas condensers this may be increased to 25 per cent.

EXHAUSTERS.

In a works of from 4 to 6 million cub. ft. capacity per annum the saving to be effected by the installation of exhausters is problematical, after consideration has been given to interest on capital and running costs. Over six millions capacity the advantages of the machine are unquestionable. In the smaller works (from 15 to 20 million cub. ft. per annum) driving is nearly always carried out by means of a gas engine, the same engine providing power for operating tar, liquor, and other pumps. The effective hourly capacity of an exhauster is guaranteed by the makers. For the capacity of a four-blade machine, however, the following formula may be taken ; it is not to be recommended when dealing with very large or very small exhausters :—

$$Q = 65D^2LN ;$$

where,

Q = cub. ft. passed by the exhauster per hour ; D = inside diameter of outer drum in ft.; L = length of drum in ft. : N = number of revolutions per minute.

This gives the gross capacity. To arrive at the nett capacity, about 20 per cent. must be deducted (for 'slip') from the figure obtained.

On the larger works it is usual to maintain a vacuum of about 4 ins. of water at the exhauster inlet. At the outlet, the pressure to be overcome varies in accordance with the resistance offered by the apparatus following and the quantity of gas passing at the time. As a general rule the total back-pressure may vary between 8 and 10 ins. on a small country works to as much as

50 ins. of water on the largest plants, but under average conditions the following pressures will approximate to those found at the different portions of the apparatus :—

Retorts	Level gauge.
Hydraulic main	½ in. to 1 in. vacuum.
Exhauster inlet	4 ins. vacuum.
,, outlet	30 ins. pressure.
Tar extractor, outlet	26 ins. ,,
Washers, outlet	24 ins. ,,
Scrubbers, outlet	22 ins. ,,
Purifiers, outlet	9 ins. ,,
Station meter, outlet	8·5 ins. ,,
Holder, inlet and outlet	8·5 ins. ,,

It will be seen from the above that the forcing of the gas through the dry purification material and the raising of the holder bell account for by far the greatest portion of the work against back-pressure which the exhauster is called upon to perform.

Running Speed.

The speed at which the exhauster operates should be gauged, not by a consideration of the revolutions performed per minute, but by the peripheral speed of the tips of the blades. This speed should be approximately constant for all sizes of exhausters, and should lie within the limits of 650 to 850 ft. per minute.

Lubrication.

This is a point requiring the most careful attention. Much depends upon the type of lubricant made use of, the best being a mixture of refined creosote and a mineral oil. These should be admixed in the proportion of one part of creosote to three parts of mineral oil. A vegetable oil should not be used, as this will tend to thicken the tar inside the drum.

In modern practice there is a tendency for the ordinary rotary blade type of machine to give way to the newer high speed turbo-exhauster working on the fan principle and providing large clearances. An advantage attached to this type of machine is that it has some considerable volumetric capacity per unit of floor-space occupied. The construction consists of an outer case provided internally with two or more impellers which rotate on a common axis, but in distinct cells. The gas is passed from cell to cell in series until it is discharged from the machine at the requisite pressure, the pressure obtained being dependent upon the size and speed of the impellers.

WASHERS AND SCRUBBERS.

Washers.

The capacity of the wet purification plant depends very largely upon the type of apparatus employed, whether mechanical or merely static. Mechanical washer-scrubbers are now largely used, while of the static washers the well-known Livesey type has few rivals.

Rules for Capacity.—For washers of the Livesey and similar types allow one-seventh to one-fifth of a cubic foot capacity per 1,000 cub. ft. of gas passed per maximum diem.

For mechanical washer-scrubbers an allowance of one-half to three-quarters of a cubic foot capacity per 1,000 cub. ft. of gas per diem may be made.

Scrubbers.

Some works are provided with scrubbers of the tower type only, and have no separate washing vessels. In such cases the size of the scrubbers and their number may be based on the following rule :—

Allow 10 cub. ft. of capacity per 1,000 cub. ft. of gas dealt with per maximum diem. When the scrubbers are operated in conjunction with mechanical washer-scrubbers the above allowance may be reduced to from 5 to 6 cub. ft. When Livesey and such washers are employed prior to the scrubbers, the latter should have a capacity based on 6 cub. ft. of volume per 1,000 cub. ft. of gas per diem.

Washing and scrubbing capacity is greatly dependent upon the manner in which condensation is carried out. Extremely effective condensation will be the means towards reducing the usual wet purification allowances by nearly 50 per cent.

Horse-Power Required to Drive Washer-Scrubbers.

The following figures refer to the power necessary for the modern vertical type of machine. The horizontal machines of similar capacity will usually require one or two horse-power less :—

500,000 cub. ft. capacity per diem	4 H.P.
1,000,000 ,, ,, ,,	5 H.P.
2,000,000 ,, ,, ,,	7 H.P.
3,000,000 ,, ,,	10 H.P.

It is advisable to allow a small margin (about 20 per cent.) above these figures for emergencies.

If the power employed is electricity, and this is obtainable for a halfpenny per unit, the cost of driving amounts to about 0·033*d.* per 1,000 cub. ft.

The ratio of the height to the diameter of tower scrubbers varies between 2½ and 5 to 1. In exceptional instances, however, it may be so much as 7 to 1, particularly in the case of scrubbers of small capacity. When the diameter becomes greater than 30 ft. the flat cast-iron top is inclined to sag. In such cases it may be found advisable to provide a domed top having a rise equivalent to one-sixth of the diameter, and made from steel.

As regards the material employed for packing, Livesey has given the following figures relating to the area of wetted surface exposed to the gas :—

	Sq. ft. per cub. ft. of Scrubber Capacity.
Coke	8½
Drain pipes, 3 ins. diameter	17
,, 2 ins. diameter	21
Boards on edge	31

Boards on edge, although expensive in the first instance, are to be preferred to any other type of packing. They conform to no hard and fast rule as regards size, but the following will afford satisfactory results :—

6-in. boards, ¼ in. thick, laid ¾ in. apart.
11-in. boards, ⅛ in. thick, laid ⅛ in. to ¾ in. apart.

WATER REQUIRED.

The amount of water required to effect wet purification depends very largely on the type of apparatus, but very variable results are found. As an average it may be taken that the water admitted to the final scrubber will vary between 10 and 13 gallons per ton of coal carbonised. It has been found that with a modern form of vertical washer-scrubber the whole of the ammonia can be removed by admitting only 3¾ gallons of water per ton of coal carbonised.

DRY PURIFICATION PLANT.

Capacity of the dry purifiers depends upon the extent to which purification is carried. Nowadays it is customary to remove sulphuretted hydrogen alone, but if lime purification (for the removal of carbon disulphide) is resorted to it is advisable to employ rather larger vessels. It is always as well, however, that the vessels should be too large rather than too small, for the first cost increases but slowly as compared with the capacity, and purification charges undergo considerable reduction as the unit capacity becomes greater. For oxide boxes the following rule may be taken :—

For a set of four purifiers allow *for each box* an area of 0·5 sq. ft. per 1,000 cub. ft. of gas to be dealt with per maximum day. If lime is to be used this figure should be increased to 0·6 sq. ft., or 0·65 to 0·7 if no catch boxes are available.

Hunt's rule for the total amount of purification space required, i.e. the combined area of all boxes, says that 20 to 30 sq. ft. per ton of coal carbonised per maximum day should be allowed.

As regards the purifying capacity of oxide of iron it may be taken that one ton will purify about two million cubic feet of gas before it is finally spent.

In order that the oxide of iron in the dry purifiers may be retained in an alkaline condition it is not advisable to remove the whole of the ammonia from the gas. The usual practice is to permit 1 grain of ammonia per 100 cu. ft. of gas to remain as a minimum.

Purifiers are invariably square or rectangular in shape and are constructed from cast-iron plates bolted together. In one or two isolated instances reinforced concrete vessels have lately been experimented with.

As regards the necessary thickness of the cast-iron plates the following figures may be taken as indicative of the general practice :—

Purifiers up to 10 ft. square	⅜ in. plates.
,, ,, 20 ,, ,,	11/16 in. ,,
,, above 20 ,, ,,	½ in. ,,

The flanges are usually cast 1/16 to ⅛ in. thicker than the body. The smallest vessels are usually 3 ft. deep, while the largest sizes vary from 6 to 8 ft. in depth. The following rule is suggested for ascertaining the required depth :—

$$\text{Depth in feet} = \sqrt[4]{\text{Total superficial area}} \times 1{\cdot}1.$$

The depth as given may be taken to the nearest foot. For smaller purifiers, i.e. up to 300 sq. ft. in area, multiply by 1·3 instead of 1·1.

PURIFIER CONNECTIONS.

The diameter of the connecting mains is most readily and accurately computed from the following formula :—

$$\text{Diameter of pipe in ins.} = \sqrt{\text{area of each box in sq. ft.}}$$

For small purifiers (up to 60 sq. ft. area) the result can be taken as it stands, but for medium size boxes deduct 16 per cent., and for large vessels 25 per cent.

CONSTRUCTIONAL NOTES.

From the point of view of economy water-lute purifiers should be so constructed that the lute is portion of the side plate itself and not a distinct unit. This method of construction facilitates erection and is less costly in the first place. The depth of the lute is usually half the depth of the side plate, but the depth of water obtainable must in all events be sufficient to withstand the greatest pressure which is likely to prevail within the box. The covers of purifiers are invariably made from wrought iron or steel plates, usually about $\frac{1}{4}$ in. in thickness. They are either flat or slightly curved, but in either case some form of trussing or stiffening is necessary, and strong curbs should be provided when the vessel is of any size. In modern purifiers the water-lute principle is largely abandoned, and dry-luted covers are provided. These possess many advantages over the older method, chiefly in the direction of initial outlay, whilst they combine greater durability with increased safety. Moreover, owing to the lighter construction of the covers the lifting apparatus may be less cumbersome and costly. A gastight joint between cover and box is usually ensured by inserting a strip of rubber or tallowed hemp between the parallel flanges, the two flanges being afterwards pulled together by means of special fasteners or ordinary bolts.

For carburetted water gas purifiers the capacity allowed should be rather greater than is the case with purifiers used in connection with coal gas. A satisfactory allowance is 0·8 sq. ft. per 1,000 cub. ft. of water gas per maximum day.

STORAGE CAPACITY.

The holder capacity necessary is somewhat dependent upon whether or not the works is provided with a water gas plant. If such a plant is available the storage allowed for need not exceed 18 hours maximum make, but if there is no water gas to fall back upon provision should be made for 21 to 24 hours maximum production. In years gone by it was customary to provide considerably greater storage chiefly on account of the heavy fluctuations in output. The levelling up of the hourly load-curve has, however, had a marked effect in the direction of diminishing the quantity of gas kept in hand.

PROPORTIONS OF GASHOLDERS.

Single lift height = 0·3 to 0·4 of diameter.
Multiple lift height = 0·6 to 1·0 of diameter.

In computing the capacity of a holder the volume enclosed by the crown is neglected, as the gas contained therein is not available for distribution. Accordingly

$$\text{Capacity in cub. ft.} = 0.7854 \times \text{diameter in ft.}^2 \times \text{height in ft.}$$

With multiple lift holders the capacity of each lift should be estimated separately by applying the above formula to each section.

DEPTH OF LIFTS.

Each lift will be approximately of equal depth.

RISE OF CROWN.

The greater the rise the stronger will be the crown. The dome should conform to a segment of a sphere. Normally, the rise will range between $\frac{1}{15}$th to $\frac{1}{10}$th of the diameter, but when trussing is employed it may be less than when the plain crown only is used.

The cubic capacity of the crown space may be found from the following :—

$$\text{Volume in cub. ft.} = 0.5236\,R\left(R^2 + \frac{3D^2}{4}\right),$$

where,

R = rise of crown in ft.;
D = diameter of top lift in ft.

The depth of each lift should never be less than one-seventh of its diameter, otherwise locking or tilting may occur. In general, the proportion varies between one-fourth to one-fifth of the diameter.

The crown sheeting of gasholders varies from 14 gauge to 10 gauge (about $\frac{5}{64}$ in. to $\frac{1}{8}$ in.), but much depends upon the size of the holder.

The side sheeting varies from 12 gauge to 10 gauge, but curb or cup and grip rows are thicker, $\frac{1}{4}$ in. to $\frac{3}{8}$ in. Top lift sheets are usually thicker than those of succeeding lifts, often about 8 gauge.

The thinner sheets of the bell are generally riveted up cold with $\frac{1}{4}$ in. rivets at a pitch of 1 in. to $1\frac{1}{8}$ in. All rivets above $\frac{1}{4}$ in. must be driven hot.

In the gas holder recently built for the Gartson station of the Liverpool Gas Co., wrought-iron plates are used, as these are less liable to corrode than plates of mild steel. The gasholder, which is of the spirally guided type, is 150 ft. in diameter and has a total height of 148 ft. The iron plates have a tensile strength of 21 tons per sq. in. and an area reduction of 18 per cent. with the fibre, and 18 tons per sq. in. with an area reduction of 8 per cent. across the fibre.

(*Machinery*, *April* 2, 1925.)

GASHOLDER TANKS.

Steel tanks have many advantages over the masonry variety, and cast-iron as a material for this purpose may now be looked upon as obsolete.

The thickness of plate required may be calculated as follows:—

$$T = \frac{PD}{2fe},$$

where,

T = thickness of the plate in ins.;

D = diameter of the tank in ins.;

f = allowable working stress (usually $5\frac{1}{2}$ tons per sq. in.);

e = the efficiency of the vertical riveted seams. This will range up to 90 per cent. for large holders. For small holders it will vary between 75 and 85 per cent.;

P = the pressure due to the water in lbs. per sq. in.

The latter may readily be found from the following:—

$$P = WD,$$

where,

W = the weight of a cub. ft. of water = 62·4 lbs.;

D = depth below the surface of the section under consideration.

As regards the apportionment of the cost of gasholders, the following figures represent normal conditions:—

	Per Cent. of Total Outlay.
Bell, complete	35 to 45
Guide framing	18 to 23
Tank (steel)	35 to 45

Single lift holders (up to about 50,000 cub. ft.) cost in pre-war days from 25*l.* to 28*l.* per 1,000 cub. ft. If of the spiral type the outlay would be reduced by 25 per cent. Two lift holders (about 250,000 cub. ft. capacity) ranged from 16*l.* to 20*l.*; or, if spirally guided, about 10*l.* per 1,000 cub. ft. capacity. Holders varying from 2 to 3 million cub. ft. capacity cost from 9*l.* to 12*l.* per 1,000 cub. ft. The large 12-million holder at the East Greenwich Works cost five guineas per 1,000 cub. ft. capacity, whilst a $10\frac{1}{2}$-million holder at Manchester worked out at 5*l.* per 1,000 cub. ft.

CALCULATION OF PRESSURE THROWN.

The pressure thrown is dependent upon the weight of the floating portion and its diameter. It may be found as follows:—

$$\text{Maximum pressure (ins. of water)} = \frac{549W}{D^2},$$

where,

W = weight of bell and water in lutes, in tons;

D = diameter of holder in ft.

When dealing with a multiple lift holder take the mean diameter.

Size of Works Mains.

No hard and fast rules are adhered to, but the following will form a guide as to the average conditions :—

Size of Works.	Suitable Size for Mains. Ins. Diam.
3 to 4 million cub. ft. per annum	5
6 to 10 " "	6
15 to 25 " "	8
30 to 45 " "	10
55 to 90 " "	12
100 to 150 " "	15
200 to 300 " "	18
350 to 450 " "	20 to 21
500 to 600 " "	24
600 to 900 " "	30

Composition of Various Gases.

Per Cent. by Volume.	Coal Gas.	Carburetted Water Gas.	'Blue' Water Gas.	Mond Gas.	Suction Gas.	Dowson Gas.
Hydrogen	49·0	35·0	52·0	26·0	16·0	20·0
Carbon Monoxide	9·0	32·0	38·0	15·0	34·0	24·0
Carbon Dioxide	2·5	4·5	4·5	12·0	3·0	6·0
Methane	27·0	13·0	1·0	3·0	nil	1·0
Heavy Hydrocarbons	4·0	10·0	nil	nil	nil	nil
Nitrogen	8·5	5·5	4·5	44·0	47·0	49·0
Candle Power	14·0	18·0	nil	nil	nil	nil
Calorific Power, B.Th.U. gross	550	580	300	165	160	155

Calorific Value of Various Fuels and their Cost per Therm.

The following table (compiled by G. Evetts) gives the calorific value of various fuels, and the lost per therm (100,000 B.Th.U.). The cost must only be regarded as the prime cost of a therm used in such a manner that the heating power can be developed :—

	Calorific Value. B.Th.U.	Cost.	Cost per Therm Pence.
Coal	13,000–15,000 per lb.	36*s.* per ton	1·4
Coke	11,500–13,500 per lb.	30*s.* per ton	1·35
Coal Gas	400–560 per cu. ft.	10*d.* per therm	10·0
Electricity	3,440 per unit	2*d.* per unit	58·2
Petrol	19,500 per lb.	2*s.* per gall.	16·6
Fuel Oil	18,000 "	5*l.* per ton	3·0
Motor benzole	19,000 "	2*s.* per gall.	14·2
Alcohol	12,000 "	5*s.* "	62·0

Composition of Coal and Coke.

Per Cent.	Anthracite Coal.	Average Gas Coal.	Average Gas Coke.
Carbon	94·0	80·0	88·0
Hydrogen	2·5	5·5	0·2
Oxygen	0·25	8·8	traces to 3·0 (varies considerably)
Nitrogen	0·5	1·5	2·0
Sulphur	0·5	0·8	1·0
Ash	2·25	3·4	5·8
Calorific Power, B.Th.U.	15,500 per lb.	14,800 per lb.	13,500 per lb.
Volatile Matter	8 per cent.	30 per cent.	1 per cent.

Products of Distillation.

One ton of average gas coal will yield (approximately) the following products :—

Gas	14,000 cub. ft., or approximately 70 therms.
Coke	12 to 13 cwts., excluding breeze.
Breeze	1 cwt.
Tar	9 to 11 gallons.
Ammoniacal liquor	32 to 40 gallons at 8 ozs.
Sulphate of ammonia	24 to 28 lbs.
Sulphur	5 to 7 lbs.
Cyanogen (HCN)	4 lbs.
Virgin liquor	10 to 12 gallons.

The yield of gas as given above is the normal quantity of straight coal gas obtained, but it should be borne in mind that the modern vertical retort in which 'steaming' is employed will give a yield of from 85 to over 100 therms per ton of coal.

(The sulphate of ammonia is obtained from the ammoniacal liquor, and not in addition to it. The virgin liquor is included in the figure given for total yield of ammoniacal liquor. The figure given for sulphur is that which may be recovered during purification of the gas, and does not include the quantity remaining behind the coke.)

The approximate distribution of the elements of the original coal, and the manner in which each exists after the process of carbonisation, is illustrated in the following table :—

One ton of coal, consisting of :—

	Lbs.
Carbon, 1,792 lbs., distributed as—	
Coke	1,385
Breeze	107
In gas, as CO and CO_2	30
In gas, as hydrocarbons	130
In tar	122
As scurf, cyanide, etc.	18
Hydrogen, 123 lbs., distributed—	
In gas and tar	98·5
As ammonia	1·0
As water	18·5
In coke	5
Oxygen, 197 lbs., distributed—	
In gas, as CO, CO_2, and combined in tar	49
As water	148
Nitrogen, 34 lbs., distributed—	
In gas (free)	11·8
In coke	14·6
In tar (combined)	1·0
As ammonia	5·8
As cyanogen	0·8
Sulphur, 18 lbs., distributed—	
As gaseous impurities and in liquor	6
In coke	12
Ash remaining in coke and breeze	76
Total	2,240

Amount of Coke Used as Fuel.

The quantity of coke used for heating the retort benches varies in accordance with the system of firing adopted. There are three types of firing now in common use, namely :—

(*a*) Direct-fired settings.
(*b*) Semi-gaseous settings.
(*c*) Gaseous-fired settings.

In addition, some works employ external producers, in which the producer gas is generated in a producer of special design situated away from the retorts, and forming a central source from which all the settings are supplied. At the Fuel Research Station at East Greenwich blue water gas is employed for heating a setting of vertical retorts.

The following shows the amount used :—

	Per cent. of the original weight of coal carbonised.
Direct-fired settings	28
Generator settings	15 to 18
Regenerator settings	11 to 14
Vertical retorts :—	
(*a*) Intermittent types	16
(*b*) Continuous types	11½
Outside producers	13 to 16

With modern systems it should be possible actually to sell 10 cwts. of coke per ton of coal.

See also ' Coke and Coking,' p. 2096, and ' Coke as Boiler Fuel,' p. 2101.

Composition of the Producer Gas.

The following is the average composition under good conditions :—

	Per cent. by volume.
Carbon monoxide	25
Carbon dioxide	5
Hydrogen	6
Methane	1
Nitrogen	63

(Oxygen should be absent, for its presence indicates an excess of primary air.)

The analysis of the waste gases emitted from the retort setting should approximate to the following :—

	Per cent. by volume.
Carbon dioxide	19
Oxygen	0·4
Nitrogen	80·6

(The presence of carbon monoxide in the waste gases is indicative of a deficiency of secondary air, and is wasteful in firing. The oxygen, if above 0·5 per cent., denotes an excess of secondary air.)

Gasworks Temperatures.

	F.°
Retorts	1800 to 2100
Ascension pipes	200 to 300
Foul main (inlet)	140
Condensers (inlet)	125
,, (outlet)	75 to 85
Washers and scrubbers (outlet)	60
Purifiers (inlet)	60
,, (outlet)	65
Holders	60

The modern combustion chamber temperature rarely, if ever, exceeds 2800 F.° The prevailing temperature of the fuel-bed is in the neighbourhood of 1800 to 1900 F.°

Before the introduction of the regenerative system, one of the chief causes of the loss of heat arose from the escape of the waste gases of the producer at unnecessarily high temperatures. In such cases the normal temperature at which the gases are allowed to leave the settings is in the neighbourhood of 1700 to 1800 F.°, but by the transference of the sensible heat from these gases to the inflowing secondary air the temperature of the waste gases has, in the modern regenerator, been reduced to 600–800 F.° before their escape is permitted. In the ordinary way, the secondary air approaches a temperature of 1800 F.° before combustion.

Grate and Chimney Area.

The grate area of the retort bench producer must in all cases be ample, so as to ensure a steady travel for the air passing through the fuel. When the ordinary horizontal fire-bar grate is employed the recognised modern rule for grate area is as follows :

Allow one-tenth square foot of grate area for every lineal foot of retort in the setting. Thus, for a through setting of ten 20-ft. retorts, this gives a total grate area of 20 sq. ft.. Another,

but less common rule, is that which gives the allowance as 1 sq. ft. of area for every 8 lbs. of coke consumed by the furnace per hour. As the actual consumption of coke (which is shot into the producer hot) is somewhat difficult to compute, the rule is not readily applied.

The ordinary horizontal form of bar grate is now rapidly giving way to the sloping form of grate. The original sloping arrangement consisted of a number of flat plates placed progressively in the manner of a stairway, cooling being effected by a small stream of water which was permitted to drop from step to step. The latest development is the Grille grate, which is composed of a number of independent components set together so as to form an interlocking grille. The grate is made entirely from special cast iron, and embraces a series of hanger bars, which are hung from specially shaped cross-bars. When in the working position each hanger is automatically locked, so that it cannot be displaced during the process of cleaning the fire, while at the same time, should it be necessary to remove any one of the hangers, this may readily be done by applying a slight forward movement to the lower end. The grate is employed in conjunction with a supply of steam, and the formation of clinker is practically avoided, the inert matter coming down in the form of a fine dust.

The rule given above for grate area does not apply when grates of the sloping type are employed, for, owing to the more favourable conditions of the base of the fuel bed, the circulation of primary air is uninterrupted by layers of dead matter. With the Grille type of grate the following rule may be employed :—Allow 0·6 sq. ft. of sloping superficial area per 10 lineal ft. of retort in the setting.

Flue and chimney area is calculated by allowing $1\frac{1}{2}$ sq. ins. of area per lineal foot of retort in all those settings which depend upon the flues and chimney under question. Thus, if a retort bench consists of eight settings, each containing ten 20-ft. retorts, the area required would be $16\frac{1}{2}$ sq. ft.

In large retort houses the height of the chimneys varies from 50 to 70 ft. The chief considerations to bear in mind are the heights of adjoining buildings, also the avoidance of down draughts and the effect of shifting winds. It is not advisable to connect a chimney to a greater number of retort beds than ten, for above this number its dimensions become unwieldy. Circular chimneys, except for vertical retort installations, are now almost things of the past. The rectangular chimney with an external batter is most commonly employed. The batter usually varies between the limits of 1 in 36 to 1 in 40. Retort house chimneys are usually braced for their entire height; the general methods being to run angle-iron up each corner, the angles being held in position by tie bands placed at intervals of about six feet. An inspection door should be left at the base of the shaft for cleaning purposes. As regards material of construction, stock bricks may be employed for the external courses, but a lining of fire bricks in the interior is essential. Very frequently the whole chimney is constructed from fire bricks, in which case no lining is, of course, necessary. The volume of gas drawn up a chimney increases in proportion to the square root of its height; thus any increase in height produces only a comparatively small change in this respect. On the Continent it is occasionally found that a separate chimney is installed for each retort setting, but the idea is confined almost wholly to stop-ended settings. The construction of retort bench shafts should be such that the cross sectional area, in spite of the batter, is constant throughout the whole height. This may readily be arranged for by reducing the thickness of the brickwork from the bottom upwards.

Proportions of Horizontal Retort Benches.

The following normal dimensions are given as exemplifying the usual proportions of various types of retort houses and benches :—

(*a*) Single retort bench, 10-ft. retorts :—	ft.	ins.
Width of bench	12	6
At back of bench	1	6
In front of bench	18	0
Total width inside houses	32	0

The height of the retort house to the eaves would be 20 ft., and the height of the retort bench from ground level 11 ft.

(*b*) Through retort bench, hand charging and discharging—	ft.	ins.
Width of bench	20	0
Each side of bench, 20 ft.	40	0
Total width of house	60	0

The height of the retort houses to eaves, if house of the stage type, would be about 35 ft.; if of the subway type 8 to 10 ft. less. The height of the retort bench from base of producers to top of brickwork about 20 ft., if retorts set in three tiers.

(*c*) Through bench, mechanical charging and discharging—	ft.	ins.
Width of bench	20	0
Charging side of bench	23	0
Discharging side	17	0
Total width of house	60	0

Retort House Governors.

The retort house governor is a more or less essential auxiliary of the modern retort house. It differs from the station governor in that, whilst the latter is employed with the object of reducing pressure, the retort house governor is interposed for the purpose of reducing the intensity of vacuum created by the exhauster. Thus the governor ensures a constant vacuum in the hydraulic main, whatever the volume of gas coming away from the coal charges may be. The intensity of vacuum required is obtained by loading the bell on similar lines to those employed with the station governor. The best place for the governor is on the top of the retort bench, as close up to the end of each section of the foul main as possible, for it is not so sensitive when interposed at the inlet or outlet of the condenser as is occasionally found. By-passes should be fitted to the governor, for it will require cleaning out about every four months.

Cost of Manufacturing Coal Gas.

The cost of manufacturing towns' gas depends primarily upon the capacity of the works, its geographical position relative to suitable coalfields, and the character of the plant in use. It must be borne in mind, too, that the actual cost of production (*i.e.* cost into gasholder) represents only about one-half of the ultimate selling price, the remainder being accounted for by the cost of distribution, overhead charges, dividends, etc. In considering a normal case of an undertaking supplying about 1,000 million cu. ft. of 500 B.Th.U. gas per annum, the manufacturing costs would be approximately as follows, assuming that coal gas only was produced :—

	Cost per 1,000 cu. ft.	Cost per Therm.
Coal	26*d.*	5·2*d.*
Less Residuals	17*d.*	3·4*d.*
Net cost of coal	9*d.*	1·8*d.*
Purification	0·5*d.*	0·1*d.*
Salaries and wages	3·5*d.*	0·7*d.*
Wear and tear	7·5*d.*	1·5*d.*
Net cost into gasholder	20·5*d.*	4·1*d.*

Gasworks Conveyors and Elevators.

The formula given below may be taken as giving a useful guide as to the capacity of bucket conveyors :

$$\text{Capacity} = \frac{S \times B \times W}{96{,}768 \times P} \text{ tons per hour,}$$

where,

B = capacity of buckets in cub. ins. ;
S = speed of conveyor in ft. per minute ;
W = weight per cub. ft. of substance carried (see page 2452) ;
P = pitch of buckets in ft.

The horse-power required to operate elevators and conveyors may be readily arrived at by adopting a coefficient of friction in accordance with the conditions under which the machine is working.

Let M = the weight of material carried in lbs.
W = the weight of the moving parts in lbs.
K = the coefficient of friction.
S = the speed of the conveyor or elevator in ft. per minute,

then, for

(*a*) Vertical elevator :

$$\text{H.P.} = \frac{M \times S}{33{,}000} + \frac{K \times S(M+W)}{33{,}000};$$

(*b*) Inclined elevator :

Let α° = the angle of inclination with the horizontal, then,

$$\text{H.P.} = \frac{M \times S \times \sin\alpha^\circ}{33{,}000} + \frac{K \times S(M+W)\cos\alpha^\circ}{33{,}000};$$

(*c*) Horizontal conveyor :

$$\text{H.P.} = \frac{K \times S(M+W)}{33{,}000}.$$

As regards the value of K, the following figures may be taken :

0·15 for metal sliding on metal ;
0·07 to 0·8 ,, ,, (well lubricated) ;
0·25 for wood sliding on wood.

Purification of Coal Gas.

The purification of coal gas is carried out in two stages, namely, by means of wet purification in the washers and scrubbers and afterwards in the dry purifiers. During the wet purification of the gas the alkaline ammonia is made use of for removing a portion of the acidic impurities, sulphuretted hydrogen and carbon dioxide. The two last-named are, therefore, absorbed with the formation of certain salts, which are themselves soluble in water. The resultant solution consists of water containing a certain proportion of these salts, and is known as ammoniacal liquor. In crude coal gas the ammonia content is usually in the neighbourhood of 1·5 per cent. by volume, and of this amount from about one-third to one-half will have been deposited prior to the gas reaching the wet purification plant. Hunt has given the following figures for the distribution of ammonia :

	Per cent. of total.
Ammonia removed by condensation . . .	42·7
„ „ first scrubber . . .	43·3
„ „ second scrubber . . .	**14·0**

When gas containing carbon dioxide and sulphuretted hydrogen comes in contact with a solution of ammonia both acid and normal salts are formed. Thus we have :

(*a*) $2NH_3+H_2O+CO_2=(NH_4)_2CO_3$ (normal) (*c*) $2NH_4OH+SH_2=(NH_4)_2S$ (normal) $+2H_2O$.
(*b*) $NH_3+H_2O+CO_2=NH_4HCO_3$ (acid) (*d*) $NH_4OH+SH_2=NH_4HS$ (acid) $+H_2O$.

Composition of Gas Liquor.

The ammonia present in gas liquor is combined in two distinct ways. In the first place it is present as easily decomposable compounds, such as carbonates and sulphides, and secondly, as more stable compounds which will only undergo decomposition by heating in the presence of a caustic alkali. In general, the final mixture of gas liquor obtained consists of from 75 to 80 per cent. of the more unstable salts, i.e. 'free' ammonia, whereas the remaining 20 to 25 per cent. is made up of the more stable salts, i.e. 'fixed' ammonia. The possible constituents of gas liquor are enumerated below, although it must be borne in mind that any one sample of liquor will seldom contain all of the compounds given. In fact, some of those included are only met with on rare occasions.

Water, containing in solution:

Ammonium carbonate „ bicarbonate „ carbamate „ sulphide „ hydrosulphide „ cyanide „ polysulphide	'Free' ammonia.	Ammonium chloride „ sulphocyanide „ sulphite „ thiosulphate „ sulphate „ ferrocyanide „ acetate	'Fixed' ammonia.

Also phenols, amines, and other nitrogenous bodies.

The amount of ammonia in gas liquor is in reality quite small, and varies between 1·5 and 2 per cent. In general, it will be apportioned as follows :

	Per cent.
'Free' ammonia	1·2 to 1·6
'Fixed' ammonia	0·3 to 0·4

The following figures relate to sulphuretted hydrogen and carbon dioxide :

	Per cent.
Carbon dioxide in gas liquor .	1·3 to 2
Sulphuretted hydrogen . .	0·1 to 0·6

The distribution of the total ammonia in gas liquor varies, of course, to some considerable extent. The following table, however, refers to the average solution :

	Per cent. of total ammonia.
Ammonium sulphides	6
„ carbonates	74
„ chloride	15
„ sulphocyanide	1·75
„ thiosulphate, sulphite, etc. . . .	3
„ sulphate	0·25

The most effective manner of operating the washing and scrubbing plant is to ensure that the gas on first entering the apparatus is treated with the strongest liquor available. In each succeeding vessel the washing liquor employed becomes gradually weaker and weaker until, in the final scrubber, clean water should be employed. Where circumstances permit, it is preferable that the first washer should be operated with the liquor from the hydraulic main, for in this way both CO_2 and SH_2 may be considerably reduced.

The amount of water which must be added for the purpose of wet purification seems to vary to some considerable extent in accordance with the conditions prevailing. The writer has

found with Durham coal that the ammonia may be completely removed in ordinary coke-filled tower scrubbers by adding from 10 to 13 gallons per ton of coal carbonised. When mechanical washer-scrubbers are in use the quantity of water required will be considerably less, probably no more than 4 gallons per ton of coal.

Mr. Thos. Glover states that the liquor distributed per sq. ft. of cross sectional area of the scrubber should be 0·145 gallon per minute. This is less the quantity of clean water added to the final scrubber.

Ammonia Lost.

The quantity of ammonia lost in the direction of that permitted to go forward from the final scrubber may be conveniently calculated as so many gallons of 10 oz. liquor.

$$\text{Quantity of 10-oz. liquor lost per week (in gallons)} = \frac{\text{Total grains of ammonia passing forward from scrubber per week.}}{1{,}522}$$

Impurities in the Gas at various stages.

	Grains per 100 cub. ft.
Outlet of condensers—	
Ammonia	200 to 300

Carbon dioxide	750 to 1,150
Sulphur compounds	35 „ 45
Hydrocyanic acid	nil „ 10

(The last three named above may all be removed, or partially removed, by the employment of special processes, but in the majority of gasworks such processes are not resorted to.)

Removal of Sulphuretted Hydrogen.

Sulphuretted hydrogen is now almost universally removed by means of oxide of iron in one of its forms. Natural ferric oxide (bog-ore) is still largely employed for the purpose, although in recent years various artificial preparations have found a good deal of favour, chiefly owing to their lower cost. The natural bog-ore is chiefly obtained from deposits in Holland, Belgium, and Ireland. In the dried state its composition varies between the following limits :

	Per cent.
Hydrated ferric oxide (Fe_2O_3, H_2O)	60 to 65
Organic matter	15 „ 25
Silica	3 „ 6
Alumina	1

The active material in bog-ore and artificial preparations is not actually the iron oxide, but the oxide plus a certain quantity of water of combination, i.e. a hydrated ferric oxide. In addition to this moisture the material as used should contain a further quantity of water, usually from 20 to 30 per cent. The artificial oxides are employed with a similar degree of moisture. The made-up or artificial material, if of good quality, is usually rather more active than the natural product, owing to a rather higher content of ferric hydrate, which may reach so much as 70 to 75 per cent.

Reactions during the Removal of Sulphuretted Hydrogen.

The absorption of SH_2 by the active oxide occurs in two distinct ways :

(*a*) Fe_2O_3, $H_2O + 3H_2S = Fe_2S_3 + 4H_2O$.

(*b*) Fe_2O_3, $H_2O + 3H_2S = 2FeS + S + 4H_2O$.

In the first instance ferric sulphide is formed, whilst secondly the result is ferrous sulphide and some free sulphur.

When spent and inactive the material is removed from the purifier and subjected to the process of revivification, or exposure to the air, when the sulphides are oxidised to oxides and the material is ready for further use. The following are the revivification reactions:

$$(a)\ 2Fe_2S_3 + 3O_2 + 2H_2O = 2Fe_2O_3,\ H_2O + 3S_2.$$
$$(b)\ 4FeS + 3O_2 + 2H_2O = 2Fe_2O_3,\ H_2O + 2S_2.$$

Oxide is generally laid in the purifiers on grids to a depth of from 8 to 10 ins. In some works, however, it is still customary to employ deep layers of as much as 30 ins. This is particularly the case in those purifiers in which hurdle grids are made use of.

A space of at least two inches should be left between the top of one layer and the base of the sieves or grids of the layer immediately above. Oxide as it becomes fouled increases in bulk, hence this precaution. Partial revivification *in situ* is nearly always arranged for in present-day systems. This is effected by admitting a small measured quantity of air to the purifiers along with the gas. The air may be taken from a small compressor and forced into the box, or may be injected by means of steam. In other cases, it is sucked in with the gas through a pipe attached to the main on the inlet side of the exhausters. When air is admitted at some point prior to the washers and scrubbers it should not be overlooked that undesirable reactions may be set up in the wet purification plant.

It is generally understood that the material in any one purifier cannot simultaneously extract sulphuretted hydrogen and undergo revivification. The assumption is not entirely accurate, but the process of sulphiding takes place at a very much more rapid rate than does the oxidation effect.

If the capacity of the purification plant is not ample the full effect of the admitted air will not be realised. For the most effective results a slight excess of air above that theoretically required (as determined from the SH_2 present) should be admitted.

When air is admitted to a purifier a rise in temperature of about 5 degrees Fahr. will usually be found as the gas passes from inlet to outlet. The air acts, of course, as a diluent, and therefore a careful check must be kept on the quantity admitted with the gas. As regards the effect of the air in this direction the following may be quoted:

Audouin and Berard found that 1 per cent. of air reduces illuminating power by 6 per cent.

	Per cent.
2 per cent. of air reduces illuminating power by . .	11
3 " " " " . .	18
4 " " " " . .	26

Würtz has stated that

3 per cent. of air causes 15·69 per cent. loss in light.
5 " " 24·0 " "

Dr. W. B. Davidson, in more recent experiments, has found the following results:

				Per cent.
1 per cent. of	oxygen	reduces	candle power by .	3
1 "	"	"	calorific power by .	1
1 "	nitrogen	"	candle power by .	2·8
1 "	"	"	calorific power by .	1
1 "	carbon dioxide	"	candle power by .	3·5

Lime Purification.

Prior to the year 1905 lime purification for the removal of carbon dioxide and sulphur compounds other than sulphuretted hydrogen was in almost universal use. To-day, purification by this method is met with only in isolated instances.

Lime in the slaked condition is an active absorbent of sulphuretted hydrogen and carbon dioxide, and—after special treatment—is capable of removing carbon disulphide. The following reactions occur during the process of purifying by means of lime:

(*a*) **Removal of carbon dioxide—**

$$Ca(OH)_2 + CO_2 = CaCO_3 + H_2O.$$

(*b*) **Removal of sulphuretted hydrogen—**

$$Ca(OH)_2 + 2SH_2 = Ca(SH)_2 + 2H_2O.$$

(*c*) **Removal of CS_2.**

It must be borne in mind that slaked lime in itself has no action upon carbon disulphide. The active medium which accounts for the removal of the CS_2 is now generally supposed to be calcium hydroxyhydrosulphide. This is prepared by sulphiding the slaked lime, in other words by admitting gas containing sulphuretted hydrogen to the vessels which are destined to

remove the CS_2. Carbon disulphide certainly cannot be absorbed according to the following equation, which has been so often set down as illustrating the reaction:

$$CaS + CS_2 = CaCS_3.$$

Veley has laid down the following theory as to the actual reactions which occur:

(1) Calcium hydrosulphide is formed in the first place—

$$Ca(OH)_2 + 2H_2S = Ca(SH)_2 + 2H_2O.$$

(2) By the addition of water or oxygen the hydrosulphide is converted into hydroxyhydrosulphide—

(*a*) $Ca(SH)_2 + H_2O = CaOH,SH + SH_2$

or

(*b*) $2Ca(SH)_2 + O_2 = 2CaOH,SH + 2S.$

(3) The carbon disulphide and hydroxyhydrosulphide then react as follows:

(*a*) $2CaOH,SH + CS_2 = SH_2 + Ca(OH)_2,CaCS_3$

or

(*b*) $3CaOH,SH + CS_2 + H_2O = 2SH_2 + (Ca(OH)_2)_2,CaCS_3.$

When gas is manufactured and is to be freed from the whole of its impurities it is usual to instal a system in which oxide of iron and lime are used in conjunction. Many methods of operating for this purpose are employed, but one of the most common systems is that generally known as the 'Beckton' method. It consists in the main of four sets of purifiers operated in rotation:

First Set, Lime.—These remove the whole of the CO_2 and some SH_2, which is afterwards displaced by CO_2. Some CS_2 is also absorbed.

Second Set, Oxide.—These remove the whole of the SH_2, including any which may be displaced from the lime in the previous set.

Third Set, Lime.—This lime has been previously 'sulphided' and removes the bulk of the CS_2. It will not remove the whole of this impurity.

Fourth Set, Oxide.—These vessels remove any SH_2 which is disengaged from the third set.

Cost of Purifiers.

It is difficult to give any reliable figure, based on each 1,000 cub. ft. capacity, for the cost of purifiers, for everything is dependent upon the size of the vessel. The larger the box, the lower the cost per unit of capacity. As regards the distribution of the cost, the following is illustrative of normal conditions with a medium size installation:

	Per cent. of total expenditure.
Purifying boxes	50
Covers (dry lute)	15
Lifting apparatus	4 to 6
Grids	6 to 10
Connections and valves	20 to 30

Castings for the boxes, in normal times, cost from 10*l.* to 11*l.* per ton. The covers cost from 17*l.* to 19*l.* per ton. As regards valves, it is usual to base these per inch of diameter. The following figures are approximate pre-war costs:

	Per inch of diameter.
Ordinary rack and pinion valve	1*l.*
Centre valves	9*l.*
Weck's valves, and such types	10*l.* 10*s.*

Removal of CS_2 by Hot Purification.

Owing to the uncertainty and expense of lime purification for the removal of sulphur compounds other methods of effecting the same end have recently been introduced. The most important of these is the Carpenter-Evans system of hot purification, which is now in everyday use at some works. The principle of the process consists in converting the CS_2 into sulphuretted hydrogen, and then removing the latter by means of ordinary oxide of iron purification. The gas, after being purified from SH_2 in the usual way, is passed into special chambers containing a catalyst heated to a temperature of about 800°F. The CS_2 is thereby decomposed according to the following reaction:

$$CS_2 + 2H_2 = 2H_2S + C.$$

The catalytic agent employed consists of fireclay balls about 1 in. in diameter impregnated with nickel reduced from the chloride. The free carbon resulting from the reaction is left behind in the catalysing apparatus, and after about thirty days' run it is necessary to remove it. This is carried out by the process known as 'aeration.' Air is pumped through the catalyser tubes at a definite rate, thus burning out the carbon and disposing of it as carbon dioxide. The aeration

process on the larger plants usually occupies about one week, after which the apparatus is again ready for work. When starting and stopping special precautions have to be taken to ensure immunity from explosion. The effect of the process on the general composition of the gas seems to be but slight; as an instance the following figures, given by Dr. Carpenter, are quoted:

Analysis of Gas.	Before Treatment.	After Treatment.
CO_2, per cent. by volume	1·44	1·45
Heavy hydrocarbons	3·55	3·63
Oxygen	0·33	0·06
Carbon monoxide	8·16	8·03
Methane	26·85	27·26
Hydrogen	54·19	54·25
Nitrogen	5·48	5·32
Illuminating power	14·70	14·70
Calorific power (Gross, B.Th.U.)	590·0	594·40

Cost of Purification.

The present-day cost of operating the Carpenter-Evans system of purification is shown in the following table:—

	Pence per 1,000 cubic feet.
Fuel (coke @ 42*s.* 6*d.* per ton)	0·2550
Conveying coke and cleaning producer	0·0240
Power	0·0129
Labour and chemical supervision	0·1180
Repairs and maintenance	0·1649
Capital charges	0·1967
Total	0·7715*d.*

Purification by means of Charcoal.

Mr. W. Gordon Adam has introduced a method for removing carbon disulphide and thiophen by passing the gas, after washing and scrubbing, through animal or wood charcoal in a granulated state. The impurities (including naphthalene) are afterwards removed from the charcoal in an unchanged condition by the application of heat, a temperature of about 300° C. being sufficient. After this treatment the charcoal is ready for further use, and is employed in a purifying vessel of ordinary construction. The prevention of ethylene absorption is effected by curtailing the quantity of charcoal used—in other words, by increasing the space-velocity above that at which ethylene is extracted.

Removal of Naphthalene.

During recent years it has become usual to employ special naphthalene solvents, to the action of which the gas is subjected before travelling to the district mains. Paraffin, water-gas, tar, and anthracene oil have all proved effective, particularly the latter. In general the gas will contain, if no special treatment is accorded it, from 6 to 12 grains of naphthalene as it leaves the works. Butterfield has pointed out that a million cubic feet of gas cooled from 68° to 50°F. may deposit about 14 lbs. of naphthalene. The introduction of carburetted water gas has to a certain extent lessened the naphthalene evil, although its effect in this direction is somewhat erratic. As regards the methods of washing with solvents, the most ready plan to adopt is that of treating the gas in a Livesey or mechanical washer just prior to its entering the holders.

Carburation with the aid of solvents was introduced by Botley, who injected, by means of a special spray, about 4 gallons of thoroughly atomised paraffin oil per million cubic feet of gas. Botley found that petroleum oil was more suitable for the purpose than spirits such as benzol. Leather made use of a creosote oil for washing the gas, but owing to the 'stripping' properties of this oil he took the precaution to pre-benzolise it first. The practice of Ferguson Bell is somewhat uncommon. The gas whilst in a warm state is washed with warm tar, and at the outlet of the wet purification plant it is further treated with a naphtha oil.

Recovery of Cyanogen on Gasworks.

Cyanogen is a subsidiary by-product which is only recovered on the largest of works. The maximum amount which can be obtained from a ton of coal is about 1½ lbs. of hydrocyanic acids or about 10,000 grains. The processes now employed recover the hydrocyanic acid either as ammonium sulphocyanide or as sodium ferrocyanide (prussiate of soda). The most readily applied method is that operating on the polysulphide principle. In this system the gas, prior to washing and scrubbing, is passed through a special vessel (of the nature of a small purifier)

containing a layer of spent oxide of iron about 2 ft. in depth. Above the oxide material sprays are arranged around the box, and the oxide is periodically sprayed with water or weak cyanide liquor. The gas, containing hydrocyanic acid, passes upwards through the layer of oxide and comes in contact with the polysulphide solution trickling through the mass. The hydrocyanic acid combines with the ammonium polysulphide and yields ammonium sulphocyanide according to the following equation :

$$(NH_4)_2S_2+HCN=NH_4SCN+NH_4SH.$$

The spent oxide used in the process should contain about 50 per cent. of sulphur, and it is a surprising fact that although sulphur is required for the completion of the reaction the spent oxide, when removed from the vessel after working for about three months shows little or no loss in sulphur, while occasionally some slight increase may be found. Accordingly, the process would be of a continuous nature were it not for the fact that the physical nature of the oxide gives rise, after a time, to excessive back-pressure, when the only remedy is the substitution of a fresh layer. Figures obtained in practice show that one ton of spent oxide is capable of removing the cyanide evolved from 350 tons of coal.

The Recovery of Crude Benzol.

While the 'stripping' of gas for the recovery of the aromatic series of hydrocarbons has been carried out in the case of coal gas produced on coke-oven works for some years, the practice has only recently been introduced in gasworks, primarily as a means of meeting the demand for certain essential war products. The coal gas, either in the semi-crude state (*i.e.* after the wet purification plant) or when completely purified, is subjected to washing with a solvent which absorbs the benzene hydrocarbons but which has no effect on the remainder of the constituents. The solvent employed consists usually of a coal-tar distillate known as 'green oil,' although other substances, such as creosote, blast-furnace oil, or crude petroleum, may also be employed. The oil, after having been in contact with the gas, is said to be benzolised, when it may contain up to 5 per cent. of benzene hydrocarbons, according to the extent to which 'stripping' is carried. The benzolised oil is then passed through a series of vessels comprising the distilling plant in which the benzene hydrocarbons, with some light naphthas and a small proportion of naphthalene, are driven off and separated from the wash-oil. The benzene vapours thus obtained are condensed and collected as a crude spirit, while the wash-oil, having been 'debenzolised,' is cooled and once more employed for treating the gas. In general, it is customary to recover from normal coal gas from 1¼ to 2½ gallons per ton of coal carbonised, depending upon the amount of aromatic hydrocarbons contained in the original gas and the proportion of these which it is deemed advisable to extract. The crude spirit will vary in composition, but in general about 65 to 70 per cent. will distil over up to 120° C., and 80 per cent. up to 160° C. The portion which distils over will consist of about 80 per cent. of benzol and 15 per cent. of toluol, the remainder being xylol. The amount of wash-oil employed for extraction per ton of coal carbonised undergoes considerable variation in accordance with the taste of the responsible engineer. It may be said, however, that it should never be less than 60 gallons per ton of coal, while it may be so much as 100 gallons. Water in the wash-oil is strongly to be guarded against, and should never exceed 1 per cent. by volume if effective results are to be obtained. Temperatures play an important rôle in the process, and it may be said that the scrubber should never exceed about 70° F., and as regards the temperature of the debenzolised oil a good rule to observe is that of maintaining the oil about 5° F. above the temperature of the gas. Now that the demand for explosives has ceased many gas undertakings have discontinued the recovery of benzol.

There can be no question, however, that experience with benzol stripping has shown that a valuable effect results so far as naphthalene is concerned. On quite a number of works it has, therefore, become a common practice to wash the gas with oil, the primary object being, not the recovery of benzol, but the reduction of naphthalene. Green oil of the usual kind may be utilised for the purpose, but gas oil has in many cases been found to be superior.

Tar Distillation.

(Contributed by Harold Moore, M.Sc., A.I.C., F.C.S.)

The yield of coal tar depends very largely upon the volatile content of the coal : but, in addition, it is considerably affected by the design of the retort. Retorts in which heating is conducted gradually, and which ensure the rapid removal of the volatile products from the heat zone, yield the largest quantities of tar. The nature of the tar depends, to a slight extent, upon the type of coal used, but is much more seriously affected by the carbonising conditions. A rapid rise in temperature, with a high maximum temperature, tends to produce tar high in specific gravity, high in viscosity, rich in free carbon, and mainly consisting of aromatic hydrocarbons. Gradual heating, low maximum temperature, and rapid removal of the volatile products result in brown mobile tars, comparatively devoid of free carbon and rich in aliphatic hydrocarbons.

Horizontal retorts subject the coal to a very rapid heating with a high maximum temperature, whilst the volatile products have to pass along the heated retort walls, whereby they undergo cracking. The result is a viscous tar, rich in free carbon. Horizontal retort tars frequently

contain over 20 per cent. They possess a specific gravity of about 1·2. In continuous vertical retorts the coal is slowly passed from the cool zone into a hotter zone, undergoing gradual heating, whilst the volatiles are removed from the cooler end of the retort, and, therefore, are not so liable to undergo cracking. The resulting tar possesses a specific gravity of about 1·08, and about 1 to 8 per cent. of free carbon. Inclined retorts give products of intermediate composition; whilst coke ovens yield tars of very varied composition, depending upon the design of the ovens.

Special processes for the low-temperature carbonisation of coal, such as the Coalite and Premier Tarless systems, yield brown low-gravity tars in which free carbon is almost entirely absent. Gas works and coke ovens supply nearly all the tar produced in this country. Tar produced in gas works is accompanied by ammoniacal liquor, and requires settling out previously to distillation. The tar in distillation is usually divided into the following fractions in English distilleries:—

	Temperature.	Approx. Yield.
1. Crude naphtha	Up to 110° C.	3 per cent.
2. Light oil	110° to 200° C.	7 ,,
3. Crude carbolic oil . . .	200° to 240° C.	7 ,,
4. Creosote oil	240° to 270° C.	15 ,,
5. Anthracene oil	270° to finish	10 ,,
6. Residuum of pitch . . .	—	58 ,,

The finishing-point of the distillation is decided by the quality of pitch desired. The yields of the above products vary, of course, with the nature of the tars, horizontal retort tars yielding a residue of about 65 per cent. of pitch, whilst vertical retort tars give only about 50 per cent. of pitch. The benzene and toluene are mostly present in the crude naphtha fraction, the yield of benzene being about 2 gallons to the ton of tar. They are separated by distillation combined with washing with dilute alkali, which removes phenols, cresols, and other acidic bodies, followed by washing with dilute acid, which removes pyridine, quinoline, and other basic substances, and are finally refined by treatment with strong sulphuric acid, which removes certain sulphur-containing compounds and a portion of the unsaturated hydrocarbons originally present in the tar. Similar processes of refining are adopted for other fractions, though the strong acid treatment is usually applied only to the benzene, toluene, and solvent naphtha-containing fractions. The most common grades of these three distillates are sold under the names of 90*s.* benzol, 90*s.* toluol, and 90*s.* xylol. The 90*s.* benzol distils 90 per cent. of its volume at 100° C. by the tar distillers' retort test; 90*s.* toluol yields 90 per cent. at 120° C. by the same test; whilst 90*s.* solvent yields 90 per cent. at 160° C. The solvent fraction consists mainly of the three isomeric xylols. Naphthalene and anthracene are removed from the higher boiling fractions (naphthalene mainly from the carbolic oil fraction, anthracene from anthracene oil) by cooling and decantation, or by cooling and filtration.

The limiting temperatures of the fractions are liable to alteration, depending upon market conditions, whilst the distillation is frequently stopped at an earlier stage than that indicated in the above table, in order to yield a soft residue known as treated or refined tar, which is used for tar spraying on the roads. A soft finished residue is also frequently sold as pitch-creosote mixture, and used for the fuel market.

Benzol is mainly used for motor fuel, together with a considerable quantity of the toluol, though smaller amounts are employed in the synthetic chemical industry. Carbolic acid (phenol) and cresylic acid (cresols), obtained by alkali washing, both find their main market for the manufacture of disinfectants. Creosote oil is used for timber preservation and as fuel. The use of creosote as fuel is somewhat intermittent, depending upon the price of petroleum. Pitch is mainly used for road repairing, but also for many other purposes, a considerable amount being consumed for electric insulation.

WATER GAS.

Manufacture of Water Gas.

Water gas, which is employed as an auxiliary to coal gas in gasworks, is now usually of the 'blue' type, although in some instances oil enrichment has again been resorted to owing to the very considerable drop in the price of oil. The composition of these two gases has already been given on pp. 2189, 2458. The reactions occurring in the generator of the water gas plant are as follows:

$$(a)\ C + 2H_2O = CO_2 + 2H_2.$$
$$(b)\ C + H_2O = CO + H_2.$$

The carbon dioxide produced in the lower portion of the fuel bed according to equation (*a*) is then reduced to carbon monoxide on passing through the remainder of the fuel bed :

$$(c)\ CO_2 + C = 2CO.$$

The extent to which the reaction (*b*) takes place depends largely upon the temperature prevailing in the lower part of the fuel bed.

As the above reactions are of an endothermic nature the heat of the fuel bed is gradually absorbed, accordingly this is replaced at intervals by the process of blowing. The reaction occurring during the 'blow' is of an exothermic nature, being simply as follows :

$$C + O_2 = CO_2.$$

All practical water gas plants are now operated on the intermittent principle of providing for short periods of a gasmaking 'run' and a 'blow.' In the more common carburetting plants the 'run' continues for 5 or 6 minutes, and is followed by a 'blow' extending for 3 or 4 minutes. In certain forms of plant intended entirely for the production of 'blue' gas the blowing period is generally of much shorter duration, lasting for about 70 to 90 seconds. The primary object of the 'blow' is to convert the coke direct into CO_2, thereby liberating the maximum quantity of heat, but this condition is never attained in practice, some CO being always present. This CO, in the enriching plants, is made use of for heating up the subsequent apparatus in which enriching takes place. In some of the later forms of 'blue' plants (in which no enriching vessels are required) the CO is employed for the purpose of raising the steam required during the 'run.' The average composition of the 'blow' gases issuing from the top of the generator is as follows :

Carbon monoxide	17 per cent. by volume.
Carbon dioxide	10 „ „ „
Nitrogen	73 „ „ „

Traces of hydrogen, methane and sulphuretted hydrogen may also be found. The CO is at a maximum, and the CO_2 at a minimum, during the first minute of the 'blow,' and as the period proceeds the CO undergoes reduction while the CO_2 increases in quantity.

As regards temperatures the generator should, at the commencement of the 'run,' be worked up to 2,000F.° By the time that the 'run' is completed the temperature will have dropped by from 300° to 500°. Owing to this fact the quality of the water gas undergoes gradual deterioration from the commencement of the 'run' onwards ; thus at the end of the first minute of the 'run' the CO_2 content will only amount to some 2 per cent., whilst at the end of the fifth minute it may amount to from 7 to 8 per cent. The temperature of the carburettor and superheater varies in accordance with the type and quantity of oil in use at the time. Under normal conditions the following will apply :

Carburettor	1350 to 1400 F.°
Superheater	1400 to 1450 F.°

For the manufacture of carburetted water gas the materials required are as follows :

Coke . .	35 to 41 lbs. per 1,000 cub. ft. of gas ;
Oil . . .	about 2½ gallons per 1,000 cub. ft. of 18 candle gas ;
Steam . .	27 to 30 lbs. per 1,000 cub. ft. of gas.

The cost of carburetted water gas is mainly influenced by the current value of the enriching oil utilised. To-day, blue water gas is a far more common and important product, so that many plants formerly utilised for producing carburetted gas are now employed for the production of blue gas only. The present-day cost of manufacturing blue gas is as follows :—

BLUE WATER GAS : COST OF MANUFACTURE (1925).

	Per 1,000 cubic feet. *d.*	Per therm. *d.*
Coke, generator	6·0	2·0
Coke, for steam	3·0	1·0
Water, for steam	0·15	0·05
Wages	3·5	1·16
Maintenance	2·5	0·84
Purification	0·5	0·16
Establishment charges . . .	0·75	0·25
Total	16·40	5·46

The impurities in water gas consist of carbon disulphide and sulphuretted hydrogen, which are present in the following quantities:

	Grains per 1,000 cub. ft.
Sulphuretted hydrogen	110 to 120
Carbon disulphide	10 to 15

As regards water gas tar, S. Carter has given the following analysis:

Specific gravity	1·0665
	Per cent.
Benzol	1·11
Naphtha	2·33
Creosote oil	21·35
Naphthalene	4·09
Anthracene oil	15·91
Pitch	56·70

The Complete Gasification of Coal.

Now that the choice of the quality of gas to be distributed rests with the gas engineer instead of being stipulated by Parliament, a certain amount of interest has been displayed in the process known as the complete gasification of coal. By this is meant the treatment of the coal under such conditions that no solid residue other than ash remains. Complete gasification may, of course, be carried out in two ways, namely, by treating the coal in two stages for the production, firstly, of straight coal gas, and secondly, of blue water gas in distinct plants, the two gases being subsequently mixed either in the crude or purified state. The alternative is to employ plant of special design in which the above two processes are carried out simultaneously.

From the standpoint of gas production, the two methods may be contrasted as follows:—

A. Dual Process.

	B.Th.U.
1 ton of coal yields—	
13,000 cubic feet of straight coal gas @ 520 B.Th.U and 11 cwts. surplus coke.	= 6,760,000
11 cwts. coke yields—	
20,500 cubic feet of blue gas @ 300 B.Th.U.	= 6,150,000
Total yield in gaseous form from 1 ton of coal.	= 12,910,000

B. Single Process.

	B.Th.U.
1 ton of coal yields—	
50,000 cubic feet of mixed gas @ 370 B.Th.U.	= 18,500,000

The composition of the gas obtained from the modern single-stage complete gasification plant is as follows:

	Per Cent.
Hydrogen	51·0
Carbon monoxide	30·0
Methane	8·0

Yield per ton of coal (cubic feet)	50,000
Calculated calorific power (gross)	370
Therms per ton of coal	185

SULPHATE OF AMMONIA.

Average commercial salt contains:

Ammonia	from 24½ to 25½ per cent.
Equal to	
Nitrogen	20·2 to 20·8 per cent.
Free acid	0·4 per cent.
Moisture	2 to 3 per cent.

Materials required for the manufacture of 1 ton of sulphate of ammonia:

Liquor, approximately	3,400 gallons of 8 oz. strength.
Acid ,,	18 cwts. at 80 per cent. strength.
Lime ,,	3 cwts.

The sulphate of ammonia recovered per ton of coal varies in this country between 24 and 28 lbs.

Equation for formation :

$$2NH_3 + H_2SO_4 = (NH_4)_2SO_4.$$

Gallons of liquor × ounce strength × 0·0823 = lbs. of sulphate.

The total quantity of ammonia products (mainly sulphate of ammonia) produced in England, Scotland, and Wales in 1923, was 425,590 tons.

CONCENTRATED LIQUOR.

The exigencies of the war were responsible for a new gasworks product in the form of concentrated and purified ammoniacal liquor. This product contains about 25 per cent. of ammonia, while the sulphuretted hydrogen is reduced to 0·5 per cent. by volume. The concentrated liquor is prepared by passing the ordinary liquor from the storage well through a desulphurising column in which the carbon dioxide and sulphuretted hydrogen are removed, the purified liquor being afterwards concentrated in a special still. With the war ended the majority of these plants have been shut down. During 1923 the quantity of concentrated liquor, made in Great Britain was equivalent to 39,071 tons of sulphate of ammonia.

USEFUL MEMORANDA.

1 in. of mercury = 0·490 lbs. per sq. in. ; 1 in. of water = 0·0361 lbs. per sq. in.; 1 lb. per sq. in. = 27·7 ins. of water.

A British Thermal Unit is the amount of heat required to raise 1 lb. of pure water 1° Fahr. correctly, from 39·1° Fahr. to 40·1° Fahr.

A Calorie is the amount of heat required to raise 1 kilogramme of water 1° Cent. ; correctly from 0° to 1° Cent. This is the *large* calorie, which is the unit employed on gasworks.

1 British Thermal Unit	= 0·252 calories.
1 Calorie	= 3·968 B.Th.U.
1 Therm	= 100,000 B.Th.U.
Therms	= cu. ft. × calorific value per cu. ft. ÷ 100,000.
Cu. ft.	= therms × 100,000 ÷ calorific value per cu. ft.

CALORIFIC VALUE OF VARIOUS GASES.

South Met. Co. . . .	560 B.Th.U. per cu. ft.
Gas Light & Coke Co. .	500 „ „
Commercial Gas Co. . .	500 „ „

200 cu. ft. of Gas Light and Coke Co.'s gas = 1 therm.

High Pressure Lighting.

For high-pressure lighting the cost of compressing the gas only amounts to from 2½ per cent. to 4 per cent. of the total cost of the gas consumed, which is very small when it is compared with the extra light obtained.

With a water-driven compressor, from 250 to 300 gals. water are required per 1,000 cubic feet gas compressed to, say, 9 ins. pressure; with a gas-driven plant, 12·4 to 13·4 cubic feet per 1,000 cubic feet compressed to same pressure.

Compressing coal gas reduces the illuminating value until, with a pressure of 200 lbs. per sq. in., the loss is 16 per cent.

(See also 'LIGHTING,' Section XXXVIII., Part III., p. 2525.)

AUTOMATIC CONTROL OF INDUSTRIAL GAS BURNERS.

When gas is used for industrial heating processes, in many cases automatic control is desirable; this can be effected efficiently by a 'Thermo-gas Regulator' such as is made by The Drayton Regulator and Instrument Co., Ltd., of West Drayton.

Incandescent Burners.

The Bunsen burners used for incandescent lighting should give a flame with a green inner cone and not a violet one, so as to show that the proportion of air used for primary combustion is as large as possible. This ensures an intense heat in the flame, which intensity adds greatly to the light emitted by the burner. This intensity of flame is obtained in the high pressure systems, which are now becoming so general for street and shop lighting, by increasing the pressure of this gas to about 2 lbs. per sq. in., and when this is used with an inverted mantle of a much longer shape than the ordinary low pressure ones, the rush of gas at this high pressure at the nipple causes the full quantity of air required for combustion to be drawn in at the base of the burner mixing tube and so give a flame of the highest intensity. This flame only gives off the same heat per cubic ft. of gas as an ordinary Bunsen burner, but the heat is concentrated and the flame is much smaller. If the quantity of air induced by the current of gas into the mixing tube is 2½ times that of the gas there will be a lilac inner cone, and the hottest part of the flame will be about 2,800°F., and the mantle will then show about 20 candles per cubic ft. of gas consumed. If 3½ times of air are induced, a green inner cone will be noticed, and then the flame will be about 3,000°F., and 30 candle power per cubic ft. of gas obtained.

Products of combustion must be conveyed away and not allowed to enter at the primary air hole of the Bunsen burner. The air used there should contain the full proportion of oxygen to ensure proper combustion. Mantles must fit the flame, or, inversely, the flame must fit the mantle, as then it will be in the hottest part of the flame which is at the outside where the C in the gas is combining with the O_2 of the air to form CO_2 with the evolution of the heat. As the flame is hollow, if the mantle is smaller than the flame it will be in the cooler region of the flame where the gas is not being fully burned. Upright burners give their greatest light horizontally, inverted burners downwards. Shades for gas lights should be at 45° with the horizontal, not 60° or 70° as usually adopted, when very little light is reflected.

The best effects are obtained with burners which permit of the adjustment of both air and gas. These burners should be adjusted from time to time. The burner should be thoroughly cleaned out each time a mantle is fixed.

Incandescent Mantles.

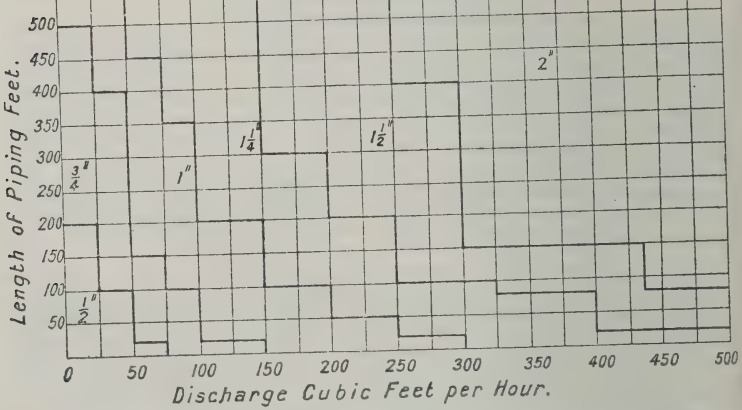
Mantles are made from cotton, ramie, or artificial silk knitted into a 'stocking' or hose about 2 ins. in diameter. This stocking is thoroughly washed and dried. Then it is saturated with a solution of nitrate of thorium and 1 per cent. of nitrate of cerium. After the stocking has been washed and dried, it is either cut to proper size and impregnated with the thorium solution, or is first impregnated and then cut to the required lengths. The impregnated stockings, after being cut and dried, are sewed at one end with asbestos thread so as to form a head provided with a loop, which serves to hold the mantle in process of manufacturing and when in use on the burner. Then the impregnated stocking is hung on a wire by the asbestos loop, and heated in a gas flame of the Bunsen type. This is done in order to burn out the thread. The next process is called the shaping. The mantle now consists only of ashes of thorium (oxide of thorium), and is carefully held over a high pressure Bunsen flame, and gradually given the right shape, at the same time being hardened. As soon as the mantle is shaped and hardened it is practically completed, but in order to protect it from breakage it is 'dipped' in a stiffening solution. There are many forms of 'dip,' but the one most used is made of soluble cotton (gun cotton) dissolved in good alcohol and acetone. To this mixture castor oil and shellac are added.

Gas versus Electricity.

The inverted incandescent gas lamp requires 47 B.Th.U. per candle-power hour obtained. The one-watt electric lamp requires 5·4 B.Th.U., and the ½-watt lamp 3·1 B.Th.U. A considerable proportion of gas burners consist of the upright type, which are less efficient, requiring 82 B.Th.U. per candle-power hour. The average may be taken at 64 B.Th.U. per candle-power hour. High-pressure incandescent burners reduced the heat consumption to 23 B.Th.U. per candle-power hour and flame arcs in electric lighting use only 1·5 B.Th.U. At about 75 per cent. of full load a gas engine of the ordinary type would deliver to the consumer as actual or brake horse-power 11 per cent. of the heat used at the gasworks, while an electric motor would deliver, also as brake horse-power, only 6·8 per cent. of the heat used at the electricity generating station. The efficiency of the gas power production and distribution was thus over 1·6 times that of the electricity system. (*Sir Dugald Clerk.*)

Gas Piping.

In the following diagram the point of intersection of consumption in cub. ft. per hour and length of pipe falls into an area indicating size of pipe for the work.



The diagram shows the size of pipe for the conveyance of a given quantity of gas. It is based on a fall of pressure between the extreme ends of the pipe of $\frac{3}{10}$-inch water gauge, and for

ordinary low-pressure gas supply it would not be desirable to have a drop greater than this. The diagram does not provide for piping smaller than ¼ in. because generally sizes smaller than this are only used for the branches to pendants or other apparatus consuming less than 25 cub. ft. per hour. Up to 10 cub. ft. per hour ¼ in. pipe is sufficient and for 10 to 25 cub. ft. ⅜ in.

Flow of Gas in Mains.

Pole's Formula.

Let Q = the discharge of gas in cub. ft. per hour.
d = the diameter of pipe in inches.
p = pressure of gas in inches of water,
s = specific gravity of gas, air being 1.
l = length of pipe in yards.

then,

$$Q = 1350d^2\sqrt{\frac{p\,d}{s\,l}};\quad d = \sqrt[5]{\frac{Q^2 s\,l}{(1350)^2 P}};\quad p = \frac{Q^2 s\,l}{(1350)^2 d^5};\quad l = \frac{(1350)^2 d^5 p}{Q^2 s}.$$

Unwin's Formula for High Pressure Gas Mains.

Let D = diameter of pipe in ft.
S = specific gravity of gas (air being 1).
L = Length of pipe in ft.
P_1 = initial pressure in lbs. per sq. inch absolute.
P_2 = final pressure in lbs. per sq. inch absolute.
C = coefficient of friction $= 0{\cdot}0044\left(1+\frac{1}{7D}\right)$.
U_1 = initial velocity of gas in feet per second.
U_2 = final velocity of gas in feet per second.
W = area of pipe in sq. ft.
Q = discharge in cub. ft. per hour,

then,

$$Q = 1{,}323{,}250\sqrt{\frac{P_1^2 - P_2^2}{P_1^2}\cdot\frac{P_1^2}{P_2^2}\cdot\frac{D^5}{CSL}};\quad U_1 = 468\sqrt{\frac{D}{CSL}\cdot\frac{P_1^2 - P_2^2}{P_1^2}};\quad U_2 = \frac{P_1}{P_2}U_1.$$

Cement Joints for Gas Mains.

An excellent method of making cement joints for gas mains is as follows :—

The inside of the bell and spigot end of the pipes should be thoroughly cleaned with a wire brush before being placed in the trench, and the open joint kept covered with sacking to keep out earth and dirt.

In making the cement joint, two caulkers work on the joint, one on each side. Air is first blown into the open joint at 50-lb. pressure through an air hose to clean out all particles that may have accumulated there.

Eight strands of untarred yarn are next saturated in neat cement-grout and tamped home with a hand tool. About 1 in. of common paste is then tamped in with a hand tool and the joint allowed to set at least 12 hours. This backing of cement keeps the moisture from being forced into the pipe and drying out the mixture by caulking too much.

The joint is then filled with the cement mixture (two cement to one sand), which is carefully and thoroughly mixed to a stiff paste.

The packing yarn, consisting of 25 strands of untarred yarn, is coiled and tamped into the joint with pneumatic caulking hammers working at 46–60-lb. pressure, commencing at the bottom and working around to the top.

The packing yarn is then pulled out and the joint again filled with cement paste, and another coil of 25 strands of yarn is caulked in and allowed to remain.

The joint is finished off smooth with a collar of cement.

Careful supervision must be exercised on the caulkers, and careless habits corrected at once.

Each caulker should mark his own joint with a distinguishing letter, so as to facilitate correcting carelessness in any of the men.

After the joint has been made, the sacking covering the joint should be watered daily until backfilled. All joints should be tested with soapy water at 75 lb. per sq.i n. air pressure. A joint that leaks at the first test should be cut back 4 in. and remade.

A 4-in. cement joint should cost less than 1*l.*, including all labour and material.

TABLE OF CONSTANTS FOR FRICTION IN GAS MAINS.

Diameter of Main in Ins.	Diameter of Main in Ft. = D.	Area of Main in Sq. Ft. = W.	Value of C = Coefficient of Friction $= 0{\cdot}0044\left(1+\frac{1}{7D}\right)$

(*Professor Unwin.*)

EVERITE GAS PIPING.

(*Asbestos Cement Building Products, Ltd., Trafford Park Manchester.*)

Everite piping is specially manufactured for the gas industry, and all the usual accessories can be obtained, including flue pipes, bends, baffiers, cone caps, etc., etc.

Gas Pressures.

Generally, gas pressures (in a factory, for example) are sufficiently constant for the correct working of gas consuming apparatus, but occasionally owing to piping being of insufficient size a variation in the consumption will cause a variation of pressure. The best remedy is to relay or supplement the piping in the building, but, as a temporary measure, governors can be installed on any apparatus which needs a fairly constant supply of gas. The Stott, Peebles, Tilley, Sugg, and Williams governors are typical of this appliance. They maintain a constant pressure on their outlet regardless of wide variation at the inlet.

Gas Meters.

Size of Meter.	Normal Capacity.	Safe Maximum Capacity.
Lights.	Cub. ft. per hour.	Cub. ft. per hour.
5	30	60
10	60	100
20	120	200
30	180	300
50	300	450
60	360	480
80	480	600
100	600	750
150	900	1,100
200	1,200	1,500
250	1,500	1,900
300	1,800	2,300
400	2,400	3,000
500	3,000	3,700
600	3,600	4,500
800	4,400	6,000
1,000	5,000	7,500

It is desirable that the normal capacity should not be exceeded for continuous working, as there will be some risk of the meter breaking down and the supply of gas temporarily stopped. If additional gas-consuming apparatus is installed a larger meter should, if necessary, be used.

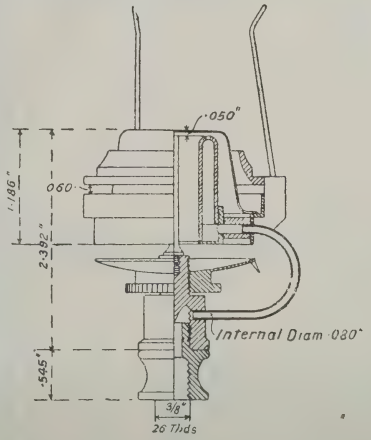

FIG. 1.

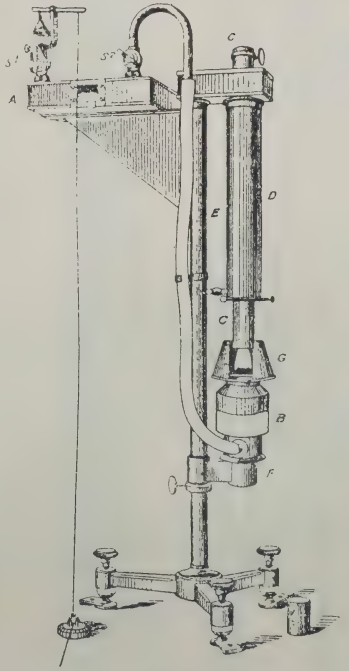

FIG. 2.

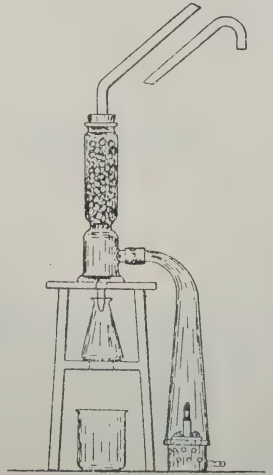

FIG. 3.

Gas Tests.

Gas Tests as Prescribed by the Gas Referees.

As gas is now sold on the 'Therm' basis, the determination of calorific power is the most important of the official tests. Illuminating power, however, is frequently required as a matter of interest rather than importance, and for this reason the test is given below.

(1) *Illuminating Power.*

Although calorific power is taking the place of illuminating power as a standard of quality, the latter test is still carried out in many instances.

This test is made by a photometric comparison between (*a*) a standard Argand burner called the Metropolitan Argand Burner No. 2, of which a part section drawing is given in fig. 1; (*b*) a standard flat-flame wing burner $\left(\text{Bray's } \frac{G}{L} \text{ 5 ft. } \frac{15}{10}\right)$ having a slit 0·028 in. wide, and a 10-candle power standard lamp burning a mixture of pentane and air. The standard lamp is shown in fig. 2. A is a receptacle subdivided by seven alternate partitions which do not extend the full width of the chamber; so that air, drawn in through the cock S', by means of which the supply is regulated, is caused to traverse the surface of the liquid, with which the chamber is filled to about two-thirds of its height, eight times. The mixture of gas and air passes through the cock S^2 to a burner B, consisting of a steatite ring pierced with thirty holes between 1·5 and 1·25 mm. in diameter. The flame is viewed through a mica window in G. Careful adjustments are made to regulate the height of the flame and the concentricity of the chimney D.

The pentane for the lamp is prepared and tested in the following manner:—Light American petroleum, such as is used for making air-gas, is rectified by three successive distillations, at 55° C., 50°, and 45°. The distillate is shaken up from time to time, during two periods of not less than three hours each, with one-tenth its bulk of (1) strong sulphuric acid, (2) solution of caustic soda. After this it is again distilled, and that portion which comes over between the temperatures of 25° and 40° is collected. This consists chiefly of pentane, with small quantities of other homologues the presence of which does not affect the light of the lamp.

The density of the liquid pentane at 15° C. should lie between 0·6235 and 0·626 compared with water of maximum density.

Any admixture with pentane of hydrocarbons having a higher photogenic value, such as benzene or amylene, must be avoided. The presence of these may be detected by the following test:—Pour into a stoppered 4-oz. bottle of white glass 10 c.c. of dilute nitric acid, specific gravity 1·32; add 1 c.c. of a dilute solution of potassium permanganate (1 gr. in 200 c.c.). Pour into the bottle 50 c.c. of the sample of pentane, and shake strongly during five successive periods of 20 seconds. If there is an admixture of as much as $\frac{1}{2}$ per cent. of amylene or benzene, the pink colour will disappear.

The photometric comparison is made by producing equality in the illumination of a white paper screen by shifting the test burner nearer to or further from the screen; the result, after applying barometric and temperature corrections, is expressed to the nearest hundredth of a candle.

(2) *Test for Sulphuretted Hydrogen.*

The gas is passed through a glass vessel in which are suspended six strips of bibulous paper moistened with a solution of 6·5 grams acetate of lead crystals in 100 c.c. water. The gas having been turned on full for three minutes, one of the slips is compared with a slip similarly moistened but not exposed to the gas. The gas is taken as exhibiting a trace of H_2S if the exposed is unmistakably darker than the unexposed slip.

(3) *Tests for other Sulphur Compounds.*

Ten cubic feet of gas is burned in a Bunsen burner at the rate of ·5 cubic foot of gas per hour. The stem of the burner is surrounded with about 2 ounces of sesquicarbonate of ammonia, and the combined products of combustion and volatilisation are collected by means of a trumpet glass fitted over the burner and salt, an air-way being provided for the burner in the stand upon which it is placed (see fig. 3). The products are condensed as far as possible in the upper glass vessel, which, to aid the condensation, is filled with a number of glass balls about 15 mm. in diameter. The distillate, collected in a beaker placed beneath the bottom orifice of the condenser as shown, is poured, together with the washings of the trumpet and condenser, into a measure glass. A sample $\left(\frac{1}{n}\text{th part}\right)$ of the liquid is treated with hydrochloric acid in a covered beaker until there is an excess of acid, and then raised to boiling point; an excess of a barium

chloride solution is added, and the boiling continued for five minutes. After standing for a time, barium sulphate settles; the latter is filtered off and washed with hot distilled water, in order to remove all traces of ammonium and barium chlorides. (A sample of the washings is tested for this in a test tube with silver nitrate, the washing being continued until no cloudiness is produced by the nitrate.) The filter paper with the barium sulphate is heated in a weighed platinum

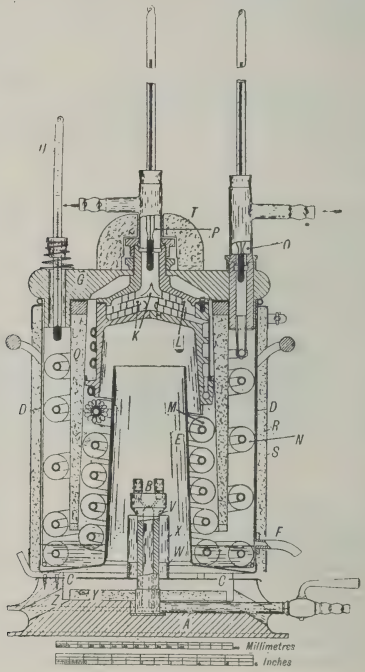

FIG. 4.

crucible until the paper is removed. When cool the crucible is placed in a desiccator over strong sulphuric acid and again weighed. The number of grains of barium sulphate thus obtained, multiplied by $\frac{11n}{8}$ (n being the quantity of liquid under test as above), gives the grains of sulphur per 100 cub. ft. of gas. This figure is corrected for barometric and temperature variations as in the case of the illuminating power test.

(4) *Tests for Calorific Power.*

These are carried out by observations taken by means of a calorimeter illustrated in fig. 4, in which water flowing is heated by a double burner consuming about $\frac{1}{10}$ cu. ft. per minute. The calorimeter having been set up, the burners are lighted and the water flow is so adjusted that the difference between the inlet and outlet temperatures is about 20° C. The heating of the calorimeter is allowed to proceed for not less than 45 mins. While the hand of the meter is making four revolutions, four readings of the inlet thermometer and fifteen readings of the outlet thermometer are taken at intervals, during which period the discharged water is collected in a measuring vessel. The temperature of the surrounding air, of the gas in the meter, and of the effluent gas are also observed. The mean of the four readings of the inlet temperature is subtracted from the mean of the fifteen readings of the outlet temperature, and the difference is multiplied by 11·976 and by the number of litres of water collected. The product is divided by the tabular

number.* The difference in degrees Fahrenheit of the temperature of the effluent gas and the surrounding air is multiplied by $\frac{2}{5}$, and this is added to the result previously found if the effluent gas is the warmer of the two, or subtracted if the effluent gas is cooler. The result is the gross calorific power of the gas in British thermal units per cu. ft. (*c*).

In addition to the foregoing, the amount of condensed water resulting from the combustion of the gas is measured. For this purpose the condensation water is led into a measuring vessel not less than 20 mins. after the calorimeter has been set up. The amount collected in not less than 30 mins. is measured, and the time of collection accurately noted. The number of cubic centimetres collected is multiplied by the number of seconds taken for four revolutions of the meter and by the constants 1·86 and 3·968 (*a*). The number of seconds during which the water is collected is multiplied by the tabular number (*b*). The first product (*a*) divided by the second (*b*) and subtracted from the gross calorific power (*c*) gives the net calorific power in British thermal units per cubic foot.

The meters used for these tests are of the 'wet' type, having a calibrated capacity of $\frac{1}{10}$ cu. ft. per revolution of the drum. The drum carries an index hand moving over a dial divided into 100 divisions, and the meters are provided with a thermometer for measuring the gas temperature.

ACETYLENE.

(Contributed by the late Professor Vivian B. Lewes, F.C.S., F.I.C.) Revised by Charles Bingham, C.E.

Acetylene, which is a gaseous compound of hydrogen and carbon, represented by the formula C_2H_2, is a colourless gas with a density of 0·92. As ordinarily prepared, it has a strong and very penetrating odour, but when purified from minute traces of other gases, invariably present with it in its crude state, has a not unpleasant ethereal odour. It can be converted into a liquid at a pressure of 21·53 atmospheres, at a temperature of 0° C., and liquefies under ordinary atmospheric pressure when cooled to a temperature of −82° C. The critical point of the gas is 37° C., and at this temperature the pressure has to be raised to 68 atmospheres for its liquefaction.

Acetylene is readily soluble in water, which at normal temperature and pressure takes up about its own volume of the gas; its solubility in other liquids is given in the following table:

100 Volumes of		Volumes of Acetylene.	100 Volumes of		Volumes of Acetylene.
Brine	absorb	5	Fusel oil	absorb	100
Water	,,	110	Benzene	,,	400
Alcohol	,,	600	Chloroform	,,	400
Paraffin	,,	150	Acetic acid	,,	600
Carbon disulphide	,,	100	Acetone	,,	2,500

Extended researches by Bistrow and Liebreich upon the toxic properties of acetylene show that it acts upon the blood in much the same way as carbon monoxide, but exhaustive experiments show that it is less poisonous than ordinary coal gas.

Acetylene forms compounds of an explosive character with copper and silver, and at first this was thought to be a great drawback to its general use; but experience has shown that these fears were unfounded, and that brass gas fittings, when gas-tight, can be used with perfect safety.

Acetylene, when heated, polymerises, like most hydrocarbons, i.e. it is partly or wholly split up, and the resulting gas is usually a mixture of acetylene itself and poorer gases, such as hydrogen, methane, etc., while tarry compounds and even solid carbon are formed, if the heating is carried far enough.

This is a matter of the utmost importance to acetylene users. For lighting purposes, it means that a poor light is given; for oxy-acetylene welders it means that the temperature at the blow-pipe is reduced considerably, indeed in some cases it has proved impossible to make satisfactory welds, owing to the poor quality of the gas.

These troubles arise almost exclusively with water-to-carbide generators, which are often faultily designed, so that overheating is bound to occur.

Experiments lately carried out by the French Acetylene Office have shown that polymerisation starts in an ordinary commercial generator at about 130° C., *i.e.* at a much lower temperature than was originally believed to be the case. Unfortunately many generators sold in this country act by driving the water away from the carbide container, when a certain amount of gas has been generated, leaving the live carbide surrounded by a mass of moist lime sludge, which is again surrounded by a blanket of acetylene. Acetylene, however, is a far poorer conductor of heat than water. At the instance of the writer, the heat conductivity of acetylene was ascertained by the National Physical Laboratory, we believe for the first time. It was found to be 0·000043 c.g.s., or only about one thirty-second of that of water. If, therefore, decomposing carbide is

* The tabular number depends upon the barometer reading and the temperature of the gas passing through the meter.

surrounded by acetylene instead of by water, only about 3 per cent. of the heat is carried off in a given time, which could be carried off by water, and the writer has seen sludge become actually visibly red under such conditions.

It is therefore of the utmost importance that acetylene users should be careful to see that they select acetylene generators in which there is always an ample supply of water in constant contact with the carbide, or constantly surrounding the carbide containers. It may also be pointed out that the better the carbide is, the more quickly it is attacked by water and, in consequence, the greater the quantity of heat liberated in a given time by its decomposition.

A new type of acetylene generator which differs radically in its generating chamber from anything previously used, although of extremely simple construction, has been put on the market in this country. The system has been in considerable use for about two years, and has given complete satisfaction.

In contact with air acetylene inflames at a temperature of 480° C. and burns with a flame which, when properly spread out so as to obtain a large quantity of oxygen, emits more light than any other gaseous compound of carbon and hydrogen.

Gas.	Candle hours per 5 cub. ft.	Carcel hours per cub. metre.	Gas.	Candle hours per 5 cub. ft.	Carcel hours per cub. metre.
Methane	5·2	3·5	Propane	56·2	40·0
Paris gas	13·2	9·6	Ethylene	70·0	49·0
London gas	16	11·5	Butylene	123·0	86·0
Ethane	35·7	25·0	Acetylene	240·0	168·0

Professor Clowes has shown that acetylene has a wider range of explosibility when mixed with air than any other combustible gas, the limits in percentages being as follows:

	Per cent.		Per cent.		Per cent.
Acetylene	3 to 82	Carbon monoxide	13 to 75	Methane	5 to 13
Hydrogen	5 to 72	Ethylene	4 to 22		

Acetylene is made commercially by acting upon a compound known as calcium carbide (CaC_2) with water, when acetylene gas is liberated and calcium hydrate (slaked lime, $Ca(HO)_2$) is formed.

Calcium carbide is made by fusing together very pure coke (or high-carbon anthracite coal) and very pure lime by the intense heat of the electric furnace. No other way of heating the mixture to the required temperature has yet been discovered, although many attempts have been made; for instance, by the use of the oxy-acetylene blowpipe.

Acetylene generators, in which the interaction of the calcium carbide and water to generate the gas takes place, may be either automatic or non-automatic. In the former class, devices are used to stop the generation of the gas automatically, by cutting off the supply of water or the supply of carbide, thus doing away with the need of a large store-holder for the gas, whilst in the non-automatic class the action is allowed to continue until all the carbide is decomposed, the gas being stored in a holder from which it is used as required.

In making acetylene, water may be brought in contact with the carbide either by adding it to the carbide, or by adding the carbide to water.

The overwhelming majority of acetylene generators in practically all countries are now constructed on the water-to-carbide system.

Of late years the automatic type of apparatus for the generation of acetylene has almost entirely superseded the non-automatic type, owing to the very large quantity of acetylene now being required for the oxy-acetylene welding process.

Experience has shown that automatic generators can be constructed with a high factor of efficiency, while the capital outlay per unit of gas generated is considerably less than in the case of non-automatic apparatus.

Owing also to the much smaller space occupied by the automatic type, it has also been found much more convenient for private use.

Until comparatively recent times, the pressure customary in acetylene generators was from 4 to 8 inches water-column, these limits having been found to give the most satisfactory results for lighting purposes. The advent of the oxy-acetylene welding blowpipe, however, soon caused experiments to be made with higher pressures, with the most favourable results. To-day the general tendency in most countries is to have the acetylene under slightly higher pressure than the oxygen in the welding blowpipe, it being claimed that less oxidation of the metal took place under these conditions and that there was less chance of the right proportion of the two gases being interfered with by accidental obstruction in the blowpipe, and, lastly, there was less tendency for the flame to flash back.

In consequence of this movement, the Governments of the United States, Canada, Switzerland, and Denmark now allow a maximum pressure of 1 atm. in acetylene generators for welding, and Germany is on the point of adopting this maximum pressure also. Very interesting details of tests have been published by the Government Bureau of Standards in the United States.

The oxy-acetylene blowpipe has been most successfully used for a considerable time for case-hardening various parts of machinery, and in particular the gear-wheels and other parts of motor cars. Lately a most important development has taken place in this direction, the

blowpipe having come into the most extensive use, not only for cutting and repairing rails, but for applying an exceedingly hard surface, to a depth reaching even the high figure of ¼ inch and more, to the entire rail system of electric tramways.

The improvement shown in the wearing properties of rails is shown by the following figures:

	Wear of rails in 12 months. Untreated.	Treated.	No. of cars carried.
Bristol	0·045	0·0157	300,000
Liverpool	0·030	0·0125	200,000

The rails are hardened *in situ*, without otherwise interfering with the track in any way.

When acetylene first made its appearance, its use was confined almost entirely to lighting detached buildings, motor-cars, and cycles.

The advent of electric sets materially reduced the field for acetylene for lighting purposes, but recently there has been a decided revival in this direction, owing to the enormously increased construction of houses of the bungalow type, large numbers of which are situated so far from a centre of supply of coal-gas or electric current that the cost of laying the necessary supply pipes or cables makes the capital outlay too great, in view of the modest requirements per bungalow.

In such cases the very low capital outlay required for an acetylene outfit, its extreme simplicity, and the beautiful light it gives, have made this form of lighting extremely popular.

The use of the oxy-acetylene blowpipe has continued to increase during the past year; indeed these and other applications have so greatly extended the use of acetylene that whereas the consumption of carbide before the war amounted to about 28,000 tons, it rose in 1925 to 40,000 tons per annum. There was a set-back, owing to the difficulties in the coal industry, but at the time of writing a consumption of approximately 40,000 tons a year has again been reached.

The use of acetylene in other directions than as a combustible again made great strides in the past year. One of the most interesting new derivatives is the 'Meta' block, which has been placed on the market by a Swiss firm. This block resembles in appearance solidified methylated spirit, but in its properties it is greatly superior, inasmuch as the block does not liquefy when burning, nor evaporate even if exposed to the air for many months.

Acetylene as obtained from ordinary generators contains a certain amount of impurities. The use of the acetylene blowpipe for welding high-class steels has shown more and more clearly the necessity for removing these impurities from the gas, a purification which can easily be effected by the use of such purifying materials as catalysol, heratol, etc.

One pound of commercial calcium carbide, when acted upon by water, yields on an average about 4·5 cub. ft. of the gas.

Before the war the price of carbide was about £12 10*s.* per ton, packages included. The price is now about £16 to £18 in the United Kingdom, while it is still higher in many of the countries producing it.

Dissolved Acetylene.

By an Order in Council issued in 1897 the compression of free acetylene was made illegal, but further orders were issued in 1901 and 1912 exempting the process now known as 'dissolved acetylene.' This is acetylene thoroughly purified and washed, and compressed into steel cylinders previously filled with a porous mass and having a fixed quantity of acetone added. Acetone is a liquid hydrocarbon, having the property of absorbing 25 times its own volume of acetylene at one atmosphere and 15° C.

For each additional atmosphere of pressure, the same proportion of gas is absorbed, but an allowance has, of course, to be made not only for the volume occupied by the porous filling of the cylinder, but, in addition, in order to allow for expansion, so that it is customary to charge these cylinders with only 43 per cent. of acetone.

A cylinder will therefore in actual practice contain about 100 times its own volume at 10 atmospheres pressure and about 150 times at 15 atmospheres pressure.

In order to show the enormous capacity for storing light obtained in this manner, it may be mentioned that the standard oil-gas cylinder in use on railways has a capacity of 14 cub. ft. at atmospheric pressure. As the oil-gas is usually compressed to 12 atmospheres, this gives a gas volume of 168 cub. ft., which, if filled with oil-gas, will supply eight burners using 2 ft. per hour and burning eight hours per day, for about a day and a half. If this cylinder were filled with porous material and acetone in the manner described above, and charged with acetylene at 15 atmospheres, its capacity would be 2,100 cub. ft., or sufficient to supply eight acetylene burners of 1 cub. ft. each (giving a most brilliant light), for about thirty-three days (basing on eight hours' lighting per day), before the cylinders would require to be re-charged.

The possibility of obtaining acetylene in compressed form opens up a very wide field for the expansion of its utility.

The tests carried out by the Home Office Authorities before issuing the exemption order of 1901 were exhaustive, and furnished satisfactory proof of the safety attending the process of manufacture and the use of the cylinders.

Storage of Dissolved Acetylene

Acetylene dissolved in acetone and stored, under a pressure not exceeding 225 lbs. per sq. in. in a vessel filled as completely as possible with some porous substance is not deemed an explosive, and can therefore be manufactured, stored, and used without risk of infringing the Explosives Act.

(See also 1919 Order in Council, 'Dissolved Acetylene.')

Porous Material.—Various types of filling are in use and appear to give satisfaction. In this country the Kapok filling, patented by *Allen-Liversidge, Ltd.*, is chiefly in use. The porosity of the material should not exceed 80 per cent. The material should completely fill the receptacle, and should contain no pockets or cavities.

The Solvent.—Acetone is the most suitable commercial solvent, but substitutes for acetone could be permitted. The solvent should not completely fill the porosity of the material under any rise of temperature likely to be met with in practice.

Pressure Allowed.—The pressure can be 225 lbs., provided the cylinders used are of the solid drawn type, the pressure to be measured at 60° F.

The Cylinders.—The cylinders should be made of mild steel containing not more than 0·25 per cent. of carbon and not more than 0·05 per cent. each of phosphorus and sulphur. The test pressure should be four times the working pressure, and should be maintained for not less than fifteen minutes. All cylinders should be annealed, but the use of fusible plugs, at present compulsory on acetylene cylinders, should be discontinued, as they are apt to become loose and, further, in the event of fire occurring, may actually lead to the fire being augmented.

It is not considered necessary to impose any conditions as regards the retesting of acetylene cylinders beyond requiring them to be thoroughly examined visually at intervals. The form of retesting to which oxygen and other cylinders are subjected cannot readily be applied to acetylene cylinders with their content of porous material and solvent.

Acetylene Lighting.

For the illumination of buildings, towns, and large areas by acetylene, generators of some suitable type are in general use.

Dissolved acetylene is used successfully from an economical and efficient point of view for many purposes where a constant supply of acetylene is required, and is particularly adaptable where space available for the apparatus is strictly limited.

In the matter of motor vehicle lighting it has been very extensively adopted. A cylinder containing acetylene absorbed in acetone under pressure and of convenient size is attached to the footboard or other suitable position on the car. Such a cylinder contains a sufficient supply of acetylene to meet the requirements for the lighting of the necessary lamps. The time for which the supply is available is variable according to the rate of consumption; the pressure of gas in the cylinder is reduced by an automatic governor or regulating valve, and the supply in the service pipes is maintained at a constant pressure to the lamps.

The standard automobile cylinders contain 20 cub. ft. and 40 cub. ft. of dissolved acetylene, and by the exchange system originated by the manufacturers it is possible for users to obtain refills at practically all important garages throughout the country.

Larger vehicles, such as motor omnibuses, mail vans, motor lorries, etc., may be equipped with outfits of larger capacity to meet the requirements of any particular case.

Another recent departure is the manufacture and circulation of cylinders containing dissolved acetylene of such capacity to meet the demands of motor cyclists. These cylinders are standardised and contain 5 and 10 cub. ft. of acetylene and, as with the standard cylinders for automobile work, they may be exchanged throughout the country.

For buoy and coast lighting dissolved acetylene has many advantages. The purity of the gas in this form, which is assured before compressing, gives the light increased brilliance and greater penetrating power, hence a shorter light period can be employed than with any other illuminant. Various special apparatus are in use, in which flashes of long or short duration are obtained by automatic means, the light being extinguished between the flashes instead of obscured (a small bypass burner remaining alight), thus economising gas. In some cases a flash of as short duration as one-tenth of a second is obtained, with perfect accuracy and flame. By means of this economical consumption and the great storage capacity of a comparatively small cylinder, a gas supply for periods as long as 12 months can be easily carried on a buoy, no attention being required until the gas is exhausted, when the cylinder is disconnected and replaced by a full one. The cylinders may be arranged in the form of a battery where larger consumption is involved.

Owing to the smallness of space required for acetylene in this form it is particularly adaptable for lighting railway coaches, yachts, and small craft. The effect of atmospheric temperature on the gas in this form is almost negligible, and other advantages are obtained by reason of the purity of gas and the elimination of handling carbide, water, waste and residue, and by the fact that the gas in this form can be stored indefinitely without deterioration.

The applications of this form of acetylene are ever increasing, and it has been recently applied with success to cinematographs, searchlight, signalling and projection work, where a small and compact plant consistent with efficiency is required.

The most recent application for illuminating purposes is that of its adoption for portable hand-lamps for mining and other similar purposes.

Lately acetylene buoys have commenced to displace other forms of coast-lighting to a very considerable extent. Such buoys take a very large charge of calcium carbide, usually one to two tons. They are entirely automatic, require practically no attention, and as they run for six to twelve months before requiring recharging, they form an exceedingly economical means of coast and harbour-lighting. Another great advantage is the fact that the light can be recognised at a much greater distance than that of the oil, or oil-gas, buoys previously used.

(See also pp. **1490, 1497.**)

PETROL AIR GAS.

(Contributed by E. Scott-Snell, A.M.S.E.)

Petrol gas is made by impregnating air with the vapour of petroleum spirit, this mixture being sent through pipes in the usual way for combustion with incandescent mantles. The essential features of an apparatus for producing this gas are an air compressor, a carburettor—in which the air and petrol are brought into contact—and a gas-holder from which the pipe service is fed. In automatic apparatus, *i.e.* machines in which gas is made according to the demand, the holder is also used as a governor for controlling the supply of air and petrol to the carburettor. The relative proportions of air to petrol are very important: in fact, upon the relation of these ingredients, and the constancy of this relation under varying load and climatic conditions, the success or failure of any apparatus must depend. As a mantle is used for light-giving, a flame is required at the burner which shall give the highest possible temperature, *i.e.* the amount of air mixed with the petrol vapour must be such as to completely combust it. With the more volatile spirit, mainly hexane (C_6H_{14}), used for making this gas, complete combustion is assured when approximately two volumes of vapour are mixed with 98 volumes of air. This is calculated from the typical equation $2C_6H_{14}+19O_2=12CO_2+14H_2O$ representing the combustion of the chief constituent of light spirit. At present, opinion seems to be divided as to the advisability of sending such a mixture—which from its composition is obviously an explosive one in a confined space such as a gas-holder—through the system. It is found, however, that when the percentage of vapour in the mixture exceeds 4½ per cent., e.g., a 5 per cent. or 6 per cent. mixture, the gas is incombustible without the addition of further air, and in the better class machines advantage is taken of this fact to make a slightly richer gas than 4½ per cent., diluting it with the extra air required for complete combustion by the aid of Bunsen burners.

The air-compressing apparatus of a petrol gas machine may be actuated by any motive power, but as the work of forcing the gas through the pipes is comparatively light, nothing more powerful than a hot-air motor or wound-up weights is usually required. In a good apparatus, the relative amounts of air and petrol are mechanically measured before passing to the carburettor, so that constancy of mixture is obtained under all conditions of temperature within wide limits. When other means are adopted, such as leading the air across a bath of petrol, selective evaporation takes place, producing erratic results, the make of gas varying with every change of temperature. In fact, attempts to make apparatus of this sort automatic almost inevitably end in failure.

Petrol gas is probably one of the safest lighting mediums known, by reason of the small compass over which mixtures of petrol vapour and air are explosive (1½ per cent. to 4½ per cent., c.f. acetylene 3·3 per cent. to 52·3 per cent., coal-gas 7·9 per cent. to 19·1 per cent.) and the fact that over 90 per cent. of the escaping gas from any leak is air. It is also non-asphyxiating.

The gas varies in calorific value according to the proportions of the mixture and the spirit used, but a 6 per cent. mixture from 0·680 sp. gr. petrol has a gross calorific value of nearly 300 B.Th.U. per cubic foot. Although this is a comparatively low figure, cooking and heating can be efficiently performed with suitably proportioned burners.

One gallon of light spirit gives 5,000 candle-power hours (Lewes). With petrol at 1*s.* a gallon this is equivalent to 2·4*d.* per 1,000 candle-power hours. The Government tax of 3*d.* per gallon is remitted when petrol is used for purposes other than propelling road vehicles.

Petrol gas can be stored almost indefinitely over water, but since a small 'Bijou' mantle requires anything from 4 to 12 cub. ft. per hour (according to whether a 6 per cent. or 2 per cent. mixture is used) the storage of any reasonable quantity of the gas entails the use of very large holders. Hence the advantage of the weight-driven type of automatic generator.

Attempts are being made to effect economy by using the less volatile petrols of 0·720 to 0·760 sp. gr. for lighting purposes, such as are in general use for motor cars. The physical characteristics of these spirits, however, are such that they do not lend themselves readily to cold carburation, for either considerable quantities will pass through the carburettor unvaporised, or if heat is used to evaporate them, heavy condensation is unavoidable in the pipe service, which must necessarily be very carefully laid to provide for it.

An explosive (or 'weak') mixture in the pipes and holder is unavoidable if heavy spirits are used, since they are not sufficiently volatile to allow of the use of a 'rich' mixture. See also Scott-Snell on 'Petrol Air Gas,' Soc. of Eng. Journal and Trans., March 1911; Illuminating Engineers' Soc. Journal and Trans., February 1913.

Heating Value and Candle-Power of Petrol-Air Gas.

According to *The Snercold Engineering Co.*, as the result of tests of a variety of different brands and grades of petrol, the fair average heating value of a gallon of petrol is 143,500 B.Th.U., and the maximum candle-power hours that can be obtained under the best conditions is 6,025. The following table shows different mixtures in percentages of petrol vapour used; for calculation purposes the heating value has been taken as 143,000 B.Th.U., and the candle-power hours as 6,000 per gallon.

TABLE SHOWING VARIOUS MIXTURES OF PETROL-AIR GAS.

Mixture Percentage of Petrol Vapour.	Gallons per 1,000 Cubic Feet of Gas.	Heating Value B.Th.U. per Cubic Foot.	Cubic Feet of Gas to the Gallon.	Candle-power Hours per Cubic Foot.
6	2·184	312	458·3	13·104
5½	2·0	286	500	12·0
5	1·82	260	555	10·92
4½	1·638	234	612	9·828
4	1·4638	208	687·5	8·7828
3½	1·274	182	785·7	7·644
3	1·092	156	916·6	6·552
2½	0·91	130	1100	5·46
2	0·728	104	1375	4·368
1½	0·546	78	1833·2	3·276

The heating value of coal-gas varies from 420 to 550 B.Th.U. per cubic foot according to the source of supply.

THE SNERCOLD PETROL-AIR GAS PLANT.

In this plant a 5½ per cent. mixture is generated. The carburettor will vaporise petrol in very cold weather without the application of warmth; in it, the temperature of evaporation falls as low as 49° of frost (− 17° F.), which is well below the lowest winter temperature in this country; for this reason condensation is impossible with the apparatus. The arrangement extracts the moisture from the air, which is carefully kept from contact with water, and thus the air on carburation is dry; hence it always absorbs the correct proportion of petrol, and a uniform gas is produced without possibility of variation. The air cannot obtain more than the predetermined quantity of petrol, while from the design of the carburettor it must take all that is supplied. When no gas is being consumed the apparatus is entirely inactive.

HEAT TREATMENT OF GAS CYLINDERS.

(Second Report.)*

In view of experiments made by the Gas Cylinders Research Committee the Committee agree that the periodical re-heat treatment of carbon steel gas cylinders which have not been obviously damaged, serves no useful purpose, and they recommend that the practice be discontinued.

ADDENDA.

GAS MADE IN GREAT BRITAIN. (See p. 2451.)

The quantity of gas made in Great Britain is now 330,000,000 cu. ft. per annum. The total number of consumers is now yearly 10,000,000, of which nearly 6,000,000 are slot consumers.

VERTICAL RETORTS. (See pp. 2452 and 2462.)

WOODALL-DUCKHAM SYSTEM.—The retorts are now built in five standard sizes which vary only in the dimensions of the major axis, the minor axis being the same in all cases. The coal carbonised and the average gas output per day of the different sizes of retorts are as follows:

Mean Major Axis.	Coal Carbonised, tons.	Gas Output, cu. ft.
44 ins.	3 to 5½	51,000 to 79,000
53 ins.	3½ to 6½	59,000 to 94,000
62 ins.	4½ to 7½	72,000 to 109,000
80 ins.	5½ to 9½	90,000 to 142,000
103 ins.	6½ to 12	115,000 to 180,000

* 'Periodical Heat Treatment of Gas Cylinders.' Published for the Department of Scientific and Industrial Research by H.M. Stationery Office. Price 2s. 6d. net.

GLOVER-WEST SYSTEM.—The retorts on this design are now standardised in three sizes, as follows:

	Type I.	Type II.	Type III.
Major and minor axis of ellipse, at top	33″ × 10″	40″ × 10″	50″ × 10″
Major and minor axis of ellipse 21 ft. from top	39″ × 18½″	46″ × 18½″	56″ × 18½″
Total length of retort	25 ft.	25 ft.	25 ft.
Capacity per day in cubic feet of gas	60,000	75,000	90,000

HEATING.

(Revised by J. Roger Preston, M.I.Mech.E., M.R.S.I., Past-President of the Institution of Heating and Ventilating Engineers.)

General.

The unit of heat or British Thermal Unit (B.Th.U.) is the heat required to raise the temperature of 1 lb. of water 1° F.; the unit of surface is the square foot; the unit of pressure is the pound per square inch; the unit of temperature is the degree Fah. Air may be expressed in cubic feet or in pounds weight, and Table A shows how these are convertible.

TABLE A.

Air Temperatures.	12°	22°	32°	42°	52°	62°	72°
Relative Volume of dry air at given temperatures (Volume at 32° F. = 1) . . .	·960	·980	1·00	1·02	1·04	1·06	1·08
Weight per cubic foot in pounds	·0842	·0824	·0807	·0791	·0776	·0761	·0747

NOTE.—The volume of 1 lb. of dry air at 32° F. = 12·38 cub. ft. For any other of the above temperatures, multiply by the relative volume.

OPEN FIRE GRATES.

It would seem that the open fireplace is not the criminally wasteful contrivance that it is commonly supposed to be, and that the 'well' type of fireplace is open to criticism. 'The pleasant British practice of sitting round the open fire,' says the Fuel Research Board Report, 1918-19, 'is amply justified from the scientific point of view, when we know that so much as one-fifth of the total heat of the coal is immediately available for absorption by the sitters if they constitute themselves into a sufficiently close screen around the fire.' In addition to the directly measured radiant heat, the open fire, it seems, is to be credited with heat conducted, radiated, and convected from the fireplace, chimney, and walls to an extent which is such that all together some 60 to 70 per cent. of the heat of the coal is utilised in warming the room and the general fabric of the building.

The following hints as to the best method of altering ordinary house fire-grates, so that they will be more effective and economical, have been circulated by the Royal Institute of British Architects: 'Line your grates with fire-bricks. See that the fire-bricks are high enough to stand up above the fire. Take care that the back brick leans forward and is not more than 4 ins. from the front bars. Fill in the space at the back with fire-clay. See that your register is open not more than one-fourth of its full capacity. If you have no register, partially close the chimney opening with another fire-brick. Fill in the front space beneath the grate with a movable piece of metal. If you cannot do this, put a small fire-tile in the bottom of the grate.'

It must be remembered, however, that the above efficiencies are only obtainable under the most favourable conditions ensuring the proper combustion of the fuel.

Heat Losses.

When a room is maintained at a higher temperature than the surrounding air, there is always a loss of heat through the windows, walls, air-change, etc. Modern practice demands that these losses shall be estimated as accurately as possible; a few of the most useful factors concerned are given below:—

Brick wall 12″ thick	0·30	B.Th.U. loss per	F. deg. diff.	per sq. ft. per hour
Brick wall 18″ thick	0·24	,,	,,	,, ,,
Without plaster 12″ thick	0·34	,,	,,	,, ,,
Without plaster 18″ thick	0·26	,,	,,	,, ,,
Concrete wall 4″ thick	0·53	,,	,,	,, ,,
Concrete wall 8″ thick	0·40	,,	,,	,, ,,
Single window	1·06	,,	,,	,, ,,
Double window	0·76	,,	,,	,, ,,
Air	0·019	,,	,,	,, cu. ft. ,,

Thus with an inside temperature of 70° F. and an outside temperature of 30° F., the loss per sq. ft. per hour in the case of a single window would be

$$1{\cdot}06 \times (70 - 32) = 40 \text{B.Th.U.}$$

The following are some of the channels through which heat may be lost:—

Gases of high calorific value escaping to the chimney unburnt.
Flue gases passing away at high temperatures.
By radiation and convection from uncovered pipes and fittings in Boiler House.
,, ,, ,, ,, ,, in Trenches.
,, ,, ,, ,, ,, in Basements.
,, ,, ,, ,, ,, on Roof.
Steam blowing away into atmosphere.
Condense water cooling in collecting well, etc.
Leakage from, and the cooling of air in, ducts where heated at intake.
Heated air passing away without doing any useful work.
Excessive heating of rooms.
Normal heating of rooms where not in use.
Leakage from air flues.

Reliable comparison of existing work can only be made after exhaustive tests, as owing to conditions varying so much, comparison can easily be misleading, a careful theoretical test balance would be more reliable than an incomplete one of existing conditions.

Care in design at every point to prevent waste, makes a very important whole in large buildings.

Economy.

The most economical system is that which wastes the least heat and costs the least in attendance and upkeep, providing the initial cost is reasonable.

Direct radiation plants are the most economical. Systems where the air is fully heated at the intake and distributed by ducts throughout the building will obviously have a rather high fuel consumption.

As a distributing medium, hot water comes the first, except where exhaust steam is available; there is not a great deal of difference between water and steam, providing that each is the best of its kind.

Cost of Heating.

The warming of the air costs much more than moving it; where it would take 2*d.* to move 1,000,000 cubic feet, it would cost 12·5*d.* to heat it from 30° to 60° F.

Heating Systems.

The heating medium may be either water, steam, or gas. In the case of water and steam these may be distributed in various ways, as follows:—

Water	Low pressure gravity circulation. Forced or induced circulation by accelerators. Various automatic induced.
Low-pressure steam.	Condense through traps (live-steam or exhaust-steam). Vacuum systems. Automatic vapour systems.

Heating by Hot Water.

Gravity Circulation.

For installations not exceeding, say, 5,000 sq. ft. of radiating surface, where upkeep and attention are serious items, and the building is suitable, this system is very satisfactory, and, if no exhaust steam is available, for economy it cannot be beaten.

Arrangements of Circulation.

The two-pipe method was at one time nearly universal. The single pipe has taken its place to a great extent, but a combination of the two is most general. The 'drop' system gives a very rapid circulation.

The following points require to be borne in mind :—Short circuits, dips and air-pockets, size and lengths of mains.

Size of Mains.

The first thing to decide is the maximum drop in temperature to be allowed between the flow and return ; a small drop is desirable, but not always practicable, 20° may be taken as a standard. The following formula agrees very well with practice :—

$$U = \left[\left(16{\cdot}353 \frac{\left(H - \frac{S_1 H}{S_2}\right) 12D}{L} + 0{\cdot}00665 \right)^{\frac{1}{2}} - 0{\cdot}0816 \right] D^2 1224F,$$

where,

H = height of circulation in feet; S_1 = specific gravity of water in flow pipe ; S_2 = specific gravity of water in return pipe ; L = equivalent length of pipe in feet (bend, say, 12 diameters) ; D = diameter of pipe in inches ; F = drop between flow and return in degrees ; U = British Thermal Units per hour.

The rapidity of circulation in vertical pipes often increases at a greater rate, owing to bubbles of steam forming.

The above formula gives B.Th.U., but the curves on the following diagram, fig. 1, are in sq. ft. of radiation, calculated on an average of 160 B.Th.U. per ft. of radiating surface.

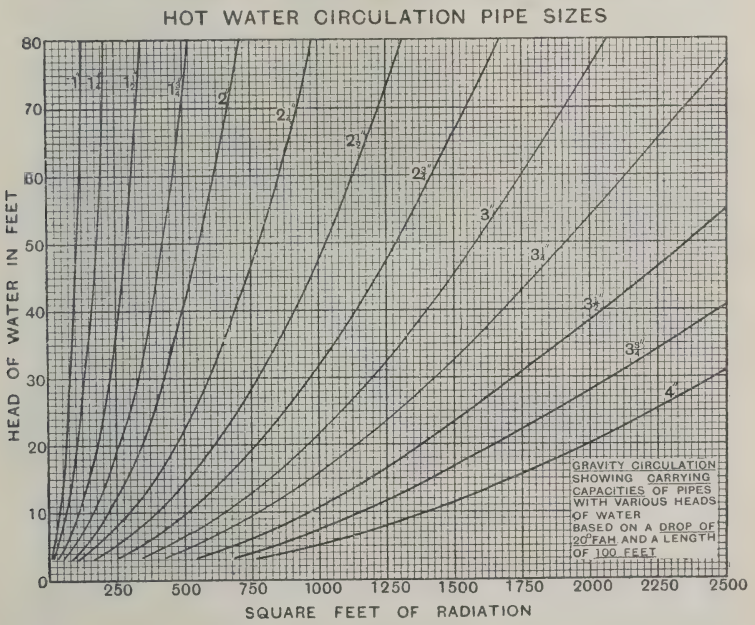

FIG. 1.

For short pipes, such as connections to radiators, a liberal allowance should be made to make up for velocity loss at entry and through connections; these have a considerable effect, so that apart from having a well-designed scheme, it is necessary to have an intelligent fitter.

TABLE OF FACTORS FOR DIFFERENT LENGTHS OF MAINS.

Length of Main. Ft.	Factor.
50	1·5000
100	1·0000
150	0·8125
200	0·7000
250	0·6125
300	0·5375
350	0·4875
400	0·4500
450	0·4375
500	0·3875

For different lengths of mains, multiply the heating surface from fig. 1 by the factor given.

CIRCULATION BY ACCELERATORS.

In large buildings where the radiation is extensive and at many different levels, pumps may be employed to circulate the water; this allows of smaller mains, owing to the higher velocities obtained. The piping may be arranged either on the one-pipe or two-pipe system. With the one-pipe, practically only the mains are under the influence of the pump, though there is a little pull on the branches, due to the loss of head on the main between the point where the flow is taken off and the return back.

The number of gallons of water required to supply the heat can be ascertained as follows:—

$$G = \frac{U}{10D},$$

where,

G = number of gallons per hour; U = heat loss in B.Th.U.; D = drop in temperature (F.°) allowed between flow and return.

The size of mains depends upon their length, the number of gallons, and the maximum loss of head due to friction to be allowed. A fair velocity in the mains is from 60 to 200 ft. per min., according to the size and length, arranging for the frictional head not to exceed about 20 ft.; this is a point that should be carefully watched, as a contractor may cut down the size of mains to save initial cost, but, as a result, increasing the cost of upkeep.

The friction head and power required may be calculated in the usual manner for cold water.

There are several special types of accelerators on the market, though most centrifugal pumps are suitable, also drum or other pumps may be used if desired.

AUTOMATIC INDUCED CIRCULATION.

Where power is available, a simple accelerator is to be preferred; but there are conditions where an automatic arrangement is an advantage. These utilise the power of steam in some form, either by condensation, a partial vacuum being formed, which exerts a powerful pull on the water in the returns, or by the pressure being utilised to lift water from one tank to another at a higher level, the water returning through the circuits by gravity; a separate steam boiler is not always needed, steam being formed in connection with the water boiler.

Apart from the particular apparatus for producing the motive power, the heating system is the same as any other low-pressure system.

Low Pressure Steam Heating.

GRAVITY RETURN.

In this system the condense water finds its way back to the boiler by gravity. The steam may be distributed to the radiators by either the one- or the two-pipe system.

In single-pipe work the steam in the mains travels in the direction of the condense water, but in the risers and branches they meet (except in the drop system), and when starting the heat, noise is created. Where absence of noise is essential at all times, the two-pipe system is preferable; with this arrangement there are two pipes to each radiator, the condense pipes are carried down into a wet return or fitted with an automatic water-seal at the outlet to the radiator.

Size of Pipe.

The size of pipe to supply a given amount of heat at a given point depends upon the length initial pressure, and the maximum loss of pressure to be allowed.

Taking the known formula for steam, and modifying the exponent and value of P, we get the following:—

$$U = \left(\frac{WDP^5}{L\left(1 + \frac{3\,6}{D}\right)} \right)^{\frac{1}{2}} 10^6,$$

where,

U = British Thermal Units per hour; W = weight of a cubic foot of steam; P = loss of pressure in inches of water; D = diameter of pipe in inches; L = length of pipe in feet.

The results shown in Fig. 2 have been worked out for about 1·3 lb. initial gauge pressure and 3 ins. water gauge drop.

For one-pipe work, multiply B.Th.U. by 0·5.

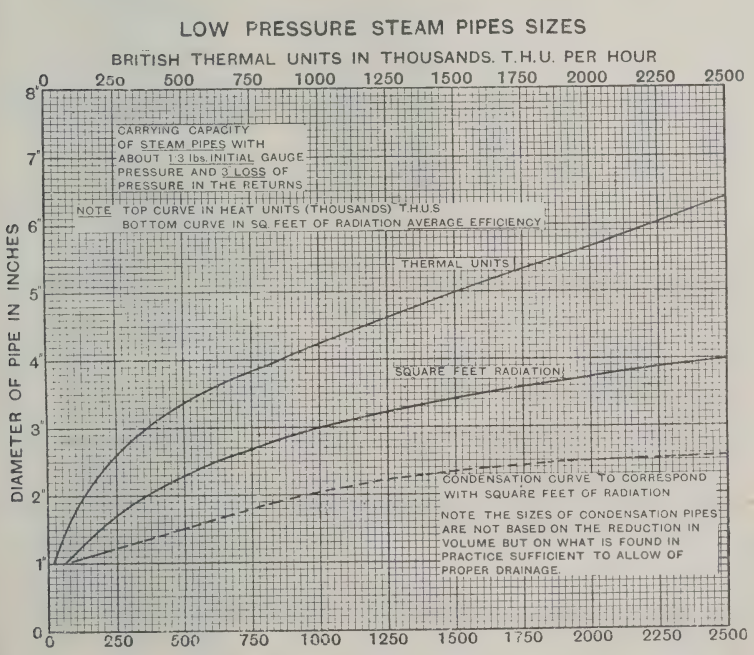

Fig. 2.

Pipe Sizes for Vapour or Low Pressure Steam Systems.

For small work, and ready reference, the following tables may be used; they are based on a conservative drop in pressure in all piping; care should be exercised in ascertaining length of runs:—

Example.—To find size of main required under the following conditions:—Length of run, 150 ft., with six 90° elbows, and carrying 250 sq. ft. of radiation. From Table I a 2 in. main approx. is required. Under 2 in. on Table II it is found that each 90° elbow has the equivalent resistance of 5 ft. of pipe, or 30 ft. for the six elbows. This makes the total length of pipe equivalent to 180 ft. Checking back under 200 ft. of run (the nearest length to the run desired), it is found that a 2 in. pipe will carry 325 sq. ft. of radiation.

Riser sizes are determined in the same way. All lengths to be measured from the boiler.

TABLE I.—MAIN AND RISER SIZES.

Main Sizes.						Riser Sizes.				
Pipe Size in ins.	Length of Run in feet.					Pipe Size in ins.	Length of Run in feet.			
	200	300	400	500	600		100	200	400	600

Minimum Weights of Pipes (fig. 4).

Overall Length. Feet.	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.
3	15	24	32	50	67	86	108	130
6	27	45	61	94	125	160	201	243
9	—	66	90	138	182	234	294	356

All sizes of low-pressure heating-pipes and fittings shall be tested by an internal hydraulic pressure of 100 lbs. per square inch, applied for at least 2 minutes. While under pressure each pipe and fitting shall be struck all over with a hand hammer weighing $\frac{1}{4}$ lb.

* By permission of the British Engineering Standards Association.

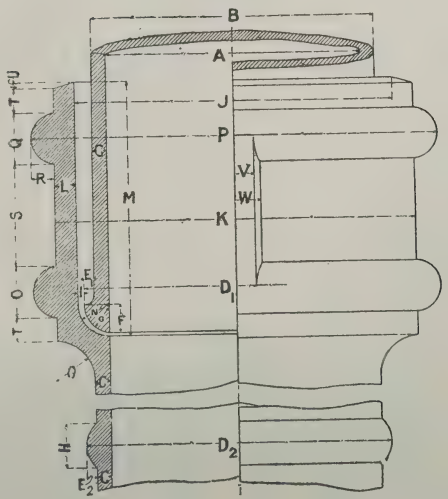

FIG. 3.

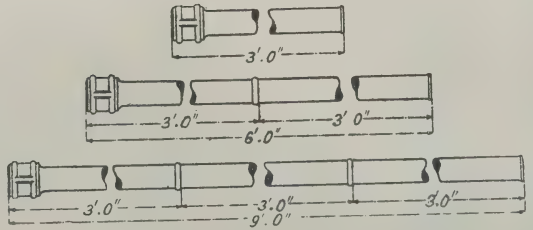

FIG. 4.

Vacuum System.

One of the objections to the ordinary gravity steam work is the difficulty of displacing the air in the radiators, and controlling the heat; this may be overcome by attaching a system of piping to the air valves connected to a small exhausting pump, which draws away the air and forms a partial vacuum; another way is to attach all the condense mains to a pump which will exhaust the air and draw away the condense water, this method is known as the 'Vacuum System.'

The piping is much the same as an ordinary gravity arrangement, except that the mains are rather smaller, and the condense pipes much smaller.

Owing to the thorough circulation of steam, the radiating surface has a high efficiency per sq. ft. per degree difference. It should be noted, however, that this does not materially affect the fuel efficiency.

The success of a vacuum system depends to a large extent on the proper working of the valves which are fixed on the radiators, or wherever condense water is likely to collect.

Plenum System.

'Plenum' is the name given to the system where the air is dealt with at the intake, tempered, washed, heated, and blown into the various rooms in such a quantity as to provide ventilation and make good the heat losses, the size of outlets being so proportioned as to allow of a slight pressure in the building, hence the name 'Plenum.'

The inlets may be from 8 to 10 ft. above the floor level, outlets at floor level on the same side of the room, the initial velocity of the air carrying it across the room, some of it cooling and gradually falling on the way—an extra outlet at ceiling level is advisable, especially if gas is the illuminant. Two ducts are necessary, one for hot and one for tempered or cold air.

NOTE.—Any system where the air is propelled into a building and maintained at a higher pressure than the atmosphere is a Plenum system, though the name is usually associated with downward methods of ventilation only.

Centrifugal fans are the most suitable, as the resistance of the heaters is considerable, apart from the ducts.

There are several special makes, including the multivane types, for which a much higher efficiency is claimed.

For economy a fan should be chosen that will pass the amount of air just running at a suitable speed to overcome the resistance, as the power rises as the cube of the speed, while the output is only directly as the speed.

Heating by Exhaust Steam.

The use of exhaust steam for heating and other purposes such as drying, hot-water supplies, etc., is to be recommended wherever possible, as the adoption of this system enables the latent heat in the steam to be used, whereas this cannot possibly be used for the production of power, and the extension of this system would render many small and inefficient power plants at present in existence more efficient.

For instance, the Technical Advisor to the Coal Controller states that the average thermal efficiency of steam-driven electric power plants at the present time is only 8½ per cent., whereas, if sufficient demand for heat can be found to enable the exhaust steam to be used for heating purposes, etc., the thermal efficiency of these plants might be increased to something like 60 per cent.

The exhaust steam can be either taken direct from the engines and conveyed without back pressure, for considerable distances, by the adoption of a modern vacuum system, or alternatively it can be used to heat water in calorifiers and the water pumped round to the various points where heat is required.

In many institutions, hotels, etc., it is found that there is practically no difference in the coal consumption whether the power is purchased from outside or generated on the premises, as there is a demand for heat all the year round which can be met by the exhaust steam from the power plant, so that the extension of this system to general domestic heating from the existing small power plants would enable these small power plants to run at a greater efficiency than any large condensing plant.

The utilisation of exhaust steam for heating when, as is too frequently the case, there is a back pressure on the engine—does not always result in economy. For assume that at a large works offices are to be warmed, requiring 800 sq. ft. of radiation, which offices are at such a distance from the main engine that a back pressure of 8 to 10 lbs. is required to force the circulation, the engine being 200 h.p. cutting off automatically at one-third of its stroke; the effect of the back pressure in this case would be to decrease the range of expansion to approximately one-half stroke, and presuming the initial pressure to be 80 lbs., and the consumption at one-third stroke to be 25·7 lbs. weight of steam per h.p. per hour, the consumption would be increased to 29 lbs. per h.p. hour, or a total for the 200 h.p., of 200 × 3·3 (the latter figure being the difference in the con-

sumption without and with back pressure) = 660 lbs. of steam per hour. Now as the amount of radiation mentioned would require, at 8 to 10 lbs. pressure, less than 300 lbs. per hour, there is, so far from being an economy, a loss of over 360 lbs. of steam per hour as the result of using the exhaust steam under such conditions of back pressure. Only when it is used without back pressure will the full economy be derivable from the utilisation of exhaust steam for heating.

One square foot of radiation will give off about 250 heat units an hour. One pound of steam an hour will supply about 4 square feet of radiation. A rough-and-ready rule for finding the radiation that may be supplied by an engine is to multiply the horse-power of the engine by 131.

When estimating on exhaust-steam heating, with non-condensing engines, the steam consumption for each indicated horse-power an hour will be about as follows :—

Engine.	Total.	Available for Heating.
Compound automatic	20 lbs.	18 lbs.
Simple Corliss	30 lbs.	27 lbs.
Simple throttling	40 lbs.	36 lbs.
Simple automatic, single valve . . .	35 lbs.	31 lbs.

When exhaust steam is employed as the heating medium it is necessary to extract the grease by means of a separator, so placed as to intercept the grease before the steam enters the heating main. It is also necessary to have an outlet to the atmosphere which should be closed by a valve weighted to open at a pressure of ½ lb. above the atmosphere, so as not to cause any back pressure. So low a pressure can, however, only be used for circulation when a vacuum return line is maintained, as in the vacuum system, for unless the air is first exhausted from the apparatus, a definite pressure is required to force it out through the air valves. With a vacuum return line no air valves are required on the radiation, and no foul air from the radiators is discharged into the rooms.

In steam heating, the temperature depends on the pressure of steam in accordance with the figures given in the following table :—

TABLE OF THE PROPERTIES OF SATURATED STEAM.

Absolute Pressure per Square inch.	Tempera-tures.	Total Heat of One Pound of Steam from Water at 32 deg. F.	Latent Heat of One Pound of Steam from Water at 32 deg. F.	Weight of One Cubic Foot of Steam.	Volume of One Pound of Steam.	Pressure as shown by Gauge.

Boilers.

If plenty of draught is available, a boiler with a liberal amount of secondary flues and small grate area may be chosen; if the draught is small, one with less flue resistance would be more suitable. It should be of such a design as to allow of proper combustion in the fire-pot, free circulation in the waterways, the lighting, feeding, and ash doors to be well fitted, so as to stop an inrush of air at undesirable points; the general design to allow of clinkering and flue cleaning to be carried out with a minimum of trouble. The catalogue rating should give the number of B.Th.U. given off with a *six hours' firing interval*; *this should be taken from test, not based upon square feet of boiler heating surface, the value of which varies very much with different makes.* The *fuel efficiency* should be stated, and should *not be less than* 60 *per cent.* On testing a well-known sectional boiler, the highest efficiency was found to be at seven hours' firing interval (78 per cent. evaporative test), with a slight drop to four hours (due to loss from high flue temperature) and a quick drop to ten hours (due to incomplete combustion). While in power boilers combustion has received a deal of attention, heating boilers have been neglected in this respect.

The Cochran Hot-Water Boiler.

This boiler (*Cochran & Co., Annan, Limited*) is manufactured in twenty-two sizes corresponding to the range of standard boilers, the essential difference being the considerably reduced height, diameter for diameter, as compared with the steam units.

The 8 ft. 6 in. diameter boiler can be limited in height to 14 ft. should headroom considerations necessitate this.

The range of duties vary from 390,000 to 6,500,000 B.Th.U. per hour reckoned on a two-hourly stoking interval in the case of boilers with two fireholes.

These boilers retain all the constructional advantages of the standard Cochran boiler.* They can be supplied for a working pressure of 100 lbs. per sq. in. (*i.e.* for use with a head of 230 feet of water), and, with reasonable care, will last indefinitely. The Cochran boiler manufacturers claim that as a hot-water unit the arrangement occupies less floor space than any other type of boiler. As compared with cast-iron sectional types, the high efficiency and durability of this boiler are important considerations, while the prices are below those of steel sectional and wrought welded boilers. Also, owing to the entire absence of brickwork setting, etc., they are cheaper than the built-in types of boiler, a feature of importance in large heating schemes.

A fire-box of any capacity can be supplied, but the standard sizes are fully equal to all normal requirements, and to meet 'banked' conditions two fire-doors can be provided.

With regard to the outlet connection at the top of the boiler, it is necessary to submit details of the available head-room and size of flow-pipe in the system, to enable a suitable flanged bend to be supplied. The diameter of the return pipe must also be indicated, in order that a suitable flange connection may be provided. In the absence of this information standard flow and return connections would be supplied; these are made with flanges to B.S. Table No. 1.

The smoke-box of the Cochran hot-water boiler enables the funnel to be taken off in any desired direction relative to an existing system of flues in the building, thus keeping within the height of the boiler, in cases where headroom is limited.

* See p. 1582.

Fuel.

The average calorific value per pound of fuel may be calculated at 12,000 B.Th.U., but of this it is only possible to obtain in the boiler an actual efficiency of 70 to 75 per cent. In other words, 8,000 B.Th.U. would represent the heat available from the boiler per pound of fuel burnt, the coal being of an average quality.

SIZE OF MINIMUM FUEL SPACE REQUIRED FOR VARIOUS SIZES OF HEATING INSTALLATIONS ON A BASIS OF ONE MONTH'S SUPPLY.

Radiation in feet super . . .	1,000	2,500	5,000	10,000	20,000	50,000
Fuel space in cubic feet . . .	500	1,000	2,000	3,800	7,600	19,000

FUEL SPACE REQUIRED FOR GENERAL OFFICE BUILDINGS.

Cubic feet of fuel space = cubic contents of building $\times \frac{6 \cdot 45}{1\,000}$.

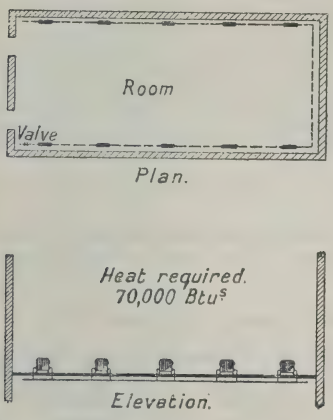
Radiators.

RADIATING SURFACE.

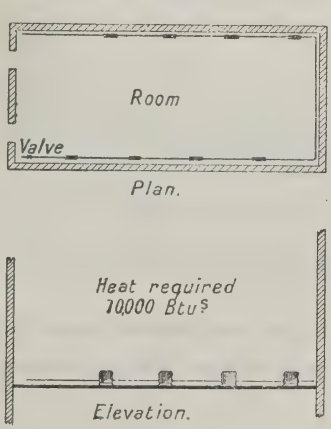
Vertical Loop Radiators are mostly used. Their efficiency varies with the design and size. They should be plain, smooth, and the loops so spaced as to allow of every part being easily cleaned.

Where it is permissible for the pipe supplying the radiators to be above the floor, the initial cost is considerably reduced, as will be seen from fig. 6; this is an important point often lost sight of in considering the cost of a heating installation.

The amount of radiating surface will vary according to the class of surface and its temperature.



Pipes below floor: cost £98.
FIG. 5.



Pipes above floor: cost £73.
FIG. 6.

A recent test carried out by the Research Committee of the Institution of Heating and Ventilating Engineers has shown that a safe figure for modern radiation is 150 B.Th.U. per sq. ft., with a difference of 100° F. between the temperature of the water and surrounding air.

The above figures show the advantage of having the pipe above the floor where permissible. Note.—Prices fair competitive basis (January 1929).

It has also been proved that the emission varies as the 1·3 power of the temperature difference between the heating medium and surrounding air. This is a very useful factor, as within reasonable limits obtained in general heating the transmission can be found at any given temperature difference.

It will be seen, therefore, that the amount of radiation in any room will vary considerably according to the temperature of the heating medium; for instance, if a room has a heat loss of 100,000 B.ThU., the amount of surface required for providing a temperature of 60° F. would be:—

| | | |

RADIATING SURFACE REQUIRED FOR DIFFERENT CLASSES OF BUILDINGS, AND COST OF HEATING.

Type of Building. (Taking the total cube.)	Average Heating Surface in Feet Super. per 1,000.	Approximate Cost of Heating per 1,000 Cubic Feet.
Churches	12	75 shillings
Hospitals	20	140 "
Block of offices	15	98 "
Public buildings	12	84 "
Factories	7 to 10	47 "
Residences	12	84 "
Small detached residences	15	105 "
Retail shops, etc.	8	52 "

The amounts given include the surface in mains for average work.

These costs, which are based upon present-day prices (January 1929), do not include builders' work, cutting away, making good, etc.

For country work, add 10 per cent. to cover additional allowance to workmen, travelling, and incidental expenses.

Where all pipes are concealed, add 25 per cent.

APPROXIMATE HEATING SURFACE REQUIRED FOR HORTICULTURAL HEATING.

Type of House.	Approx. surface in feet super per 1,000 cubic feet.
Houses requiring to be kept at a temperature above 35° in order to prevent frost entering	16
Peach and similar Houses	27
Greenhouses	40
Tomatoes, Vines, etc.	60
Forcing Pits	130

TABLE OF RADIATION.

Height of Radiator in Ins.		46	38	36	32	30	26	24	23	20	18
Type.	Length of One Section. Ins.	Heating Surface per Section in Ft. Super.									
Single Column	3	—	3	—	$2\frac{1}{2}$	—	2	—	$1\frac{3}{4}$	—	—
Two Columns	3	5	4	—	$3\frac{1}{2}$	—	$2\frac{3}{4}$	—	—	—	—
Three Columns	$2\frac{3}{4}$	6	5	—	$4\frac{1}{4}$	—	$3\frac{1}{2}$	—	—	—	$2\frac{1}{4}$
Four Columns	3	—	8	—	$6\frac{1}{2}$	—	5	—	—	—	3
Classic 4 Column	2	—	—	3	—	$2\frac{1}{2}$	—	2	—	—	$1\frac{1}{2}$
Classic 6 Column	2	—	—	$4\frac{1}{2}$	—	$3\frac{3}{4}$	—	3	—	—	$2\frac{1}{4}$

To find the space necessary for radiators, multiply the above figures by the number of sections required, adding 8 ins. in length for valve, elbow, union, and bushing.

WIDTH OF RADIATORS AT FEET.

	Ins.		Ins.
Single column	5½	Three columns	10½
Two columns	8⅝	Four „	11

The kind of metal, and the thickness of the latter, of which the radiator is made, has little effect upon the heat transmission, provided the radiator is not painted.

Experiments have proved that painting affects the heat emission of a radiator. Taking the heat emission from a bare radiator as 100, the painted radiators compare as follows:—Flat-tone brown, 104·8; flat-tone cream, 104; white-gloss enamel, 102·2; ordinary white paint, 100; ordinary green, 96; aluminium, 93·7; liquid gold, 92·6; copper and aluminium bronze, 72.

The *thickness of the coat* makes very little difference, *i.e.* it is only the final coat that influences the heat emission.

THE WESTINGHOUSE PATENT STEAM RADIATOR.

The Westinghouse Patent Radiator shown in fig. 8 was designed to overcome the disadvantages formerly attendant on the use of steam for heating purposes. Steam enters the radiator at A and passes through the opening in the valve seat into a distribution pipe D, in the upper side of which a small hole is drilled opposite each column. It then passes up each column as shown

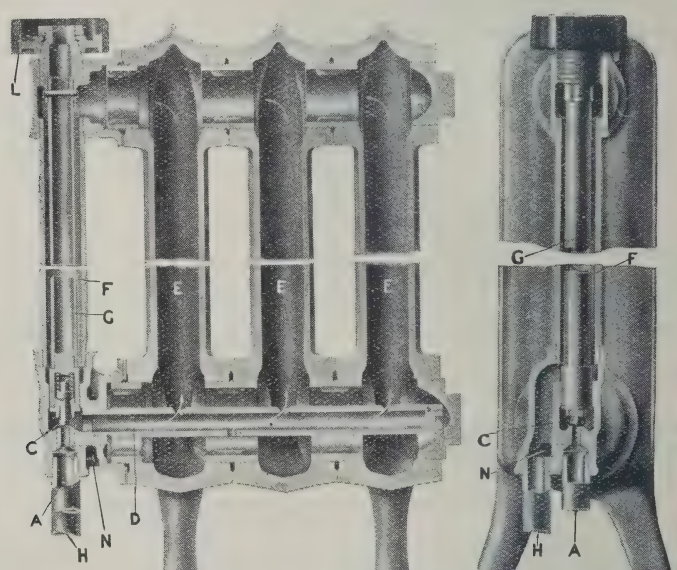


FIG. 8.—The Westinghouse Patent Radiator.

by the arrows and into tube F. This tube contains another tube G of metal with a high coefficient of expansion, which, when it reaches a temperature of about 210° F. or any other lower temperature to which it is set, expands and closes the valve C, thus shutting off steam until the temperature is slightly reduced, when the valve again opens.

FIG. 10.

The temperature of the radiator can be varied as desired up to the maximum by turning the handwheel L which, owing to its screwed socket, moves the tube F and valve C nearer to, or farther from its seat B, and thus causes the valve to close at a lower or higher temperature as desired. The temperature of the radiator can never exceed 212° F., as the steam inlet is restricted by the valve while the outlet is fully open to the exhaust, and the steam is therefore entirely condensed in the radiator, only water escaping to the atmosphere. It will therefore be seen that the temperature of the radiator does not depend on the pressure of the steam supply, nor is it affected by the distance of the radiator from the source of supply.

Contract Temperatures and their Equivalents.

(Direct Radiation.)

These, which are of considerable interest to architects and engineers, have been the subject of considerable controversy. Some years ago a Committee of the American Institute of Heating and Ventilating Engineers reported on the subject; in 1903 Mr. Walter Jones gave a paper before the English Institute. Professor Allen's paper on 'The Coefficient of Heat Transmission in Cast Iron Radiation,' June 1908, is one of the most modern.

The expression $$\frac{t_2 - t_3}{t_2 - t} = \frac{t_3 - t_5}{t_5 - t_4}$$

is considerably in error, *even taking into consideration the different coefficients of transmission, extra losses due to increased air changes, etc.* In the discussion on Professor Allan's paper, Mr. C. B. Thompson said he had recently made some tests, but could not get more than 105° F. inside, with an outside temperature of 85° F. and surface that gave 70° inside when 0° outside.

The following empirical formula is found to agree closely with *actual tests* :—

$$t = [t_1^{12} - t_2^{12} + t_3^{12}]^{\frac{1}{12}}$$

where,

t_1 = contract inside absolute temperature F.;
t_2 = contract outside " "
t_3 = existing " "
t_4 = estimated inside " "

The curves shown in fig. 9 are worked out from the above formula for reference under different contract conditions.

The time factor is an important one, as will be seen from fig. 10, which is from an actual test of a large public building warmed by steam-heated accelerated hot water. The upper curve shows the inside temperature and the lower curve the outside temperature.

Automatic Regulation of Heating Apparatus.

It is very desirable that with hot water or steam installations some arrangement should be made for automatic regulation of the room temperatures independent as far as possible of the human element. The chief drawbacks to regulation of this description have been—firstly, expense; secondly, complicated apparatus requiring skilled attention to ensure the proper efficiency of same. Recently, however, the tendency has been for each room to have its independent automatic regulation instead of being part of a complete system of automatic apparatus, and this tendency has gradually evolved a simpler form of apparatus, some of which are being used with great success at the present time.

In addition to the independent room regulation it is also desirable to have further regulation of the boiler independently, not based on the water temperature of the boiler, but on the variation of the outside temperature; and experience proves that in this country it is preferable to regulate the boiler by means of the outside temperature than by the temperature inside the building.

The Thermutator automatic boiler damper regulator combined with outdoor thermostat, made by *The Drayton Regulator and Instrument Co., Ltd., West Drayton*, for hot-water boilers, operates the draught door in accordance with variation of outdoor temperature. The boiler thermostat is arranged above the boiler in a tube, and can be isolated by closing a cock.

The 'Drayton' A.M. Regulator.

(*The Drayton Regulator and Instrument Co., Ltd., West Drayton.*)

This regulator, fig. 11, is operated by water pressure. The pilot valve is actuated by metal expansion.

The fig. shows the regulator applied to the control of a water heater, but in place of the diaphragm operated valve, diaphragm operated dampers or other devices may be substituted.

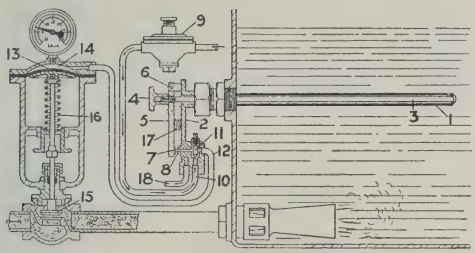

FIG. 11.—'Drayton' A.M. Regulator.

A modified form of this type of regulator is also made for the control of room temperatures.

The great power obtained by the 'Drayton' pilot valve system enables the largest valves or dampers to be operated without loss of accuracy.

HOT WATER SUPPLY.

Hot water supply can be divided into three classes:—

1. Domestic hot water supply suitable for ordinary houses.
2. Hot water supply for institutions, hotels, etc.
3. For industrial work.

Domestic Hot Water Supply.

The general apparatus for this purpose in an ordinary house is a boiler behind the range, a cylinder in a convenient position, and a supply tank. Points which should have attention are as follows:—

Boiler and its flues should be so fixed in the range as to be easily cleaned; also it should have an emptying tap.
Cylinder should be as near the boiler as possible, so as to ensure an easy circulation.
Feed tank should be in an accessible position, and protected from frost.

The fuel efficiency of a range boiler is low, and experience proves that even in quite small houses an independent boiler is more economical. It will be found that the major portion of the fuel used in a range is taken by the boiler, and not by the ovens required for cooking.

Institutions and Hotels Hot Water Supply.

For this class of work where steam is not required for other purposes, independent hot water boilers are the most economical. The type of boiler will depend on the nature of the water; where the water is hard it is desirable to have the boiler of as simple a form as possible, with ample provision for cleaning out, a bolted top being very desirable in this connection. In some cases it may be found necessary to either soften the water or put in a system of secondary heating, in which case the water in the boiler is circulated through a coil which heats the water in a secondary manner. Where the water is not hard, the sectional boilers 'Bower-Barffed' have proved very successful and highly efficient. In domestic supply it is desirable that the cylinder, which would usually be of a horizontal type with dome ends, should be as near the boiler as

possible ; from this cylinder, secondary circulations of considerable length may be taken to the various parts of the building, to supply the different fitments. In arranging hot water supply circulations and draw-offs, it must always be remembered that where there is a branch off the circulation, and the tap on the end of that branch is open, water will flow both ways, both from the flow direction and from the return direction, the return, therefore, should connect to the cylinder at a high point. This is most important, and many failures have been due to neglect of this necessary arrangement.

In many cases steam is required, especially in institutions and hotels, for different purposes, such as cooking, etc. ; in such cases, instead of having a separate hot water supply boiler, it is desirable to heat the water by steam. This is done by means of a calorifier · in principle it is simply a coil of steam pipe enclosed in a vessel of water, the steam being condensed and the latent heat of the same being conveyed through the coil to the water outside. This system also lends itself to thermostatic control. For this class of work it is very necessary that the pipe from the supply tank to the storage cylinder be of ample size. In some installations of a large size it is desirable to do away with the supply tank and simply keep the installation full by means of a pump, the pump automatically starting on a tap being opened. This system has many advantages, but is not so well known as the usual one of having a supply tank.

Westinghouse Lavatory Water Heater.

Where a supply of steam is available this heater affords a convenient means of obtaining hot water instantly without the use of hot-water tanks.

Referring to fig. 12. steam enters by a pipe connection B, which is in direct communication with chamber D. Cold water enters by pipe connection A which communicates directly with chamber C. Valves E and F are kept closed by springs G and H, when the handle J is in the ' OFF ' position.

When the handle is moved to position ' COLD,' the bell crank K pushes open valve F, and cold water only flows through the passage L to the space between the tubes N and M, and thence by pipe connection O to the lavatory basin.

On moving the handle further over to the position 'HOT,' the steam valve E is also opened by the bell crank K pushing against its stem, and steam then flows by passage P to the interior of tube N, and thence to the atmosphere by pipe connection R.

The heat of the steam being transmitted through the walls of the tube N to the water as it flows down the narrow space between the tubes M and N, the water is hot by the time it reaches the outlet O, while the steam in tube N is partially condensed before issuing from outlet R. The spring S returns the handle to the ' OFF ' position.

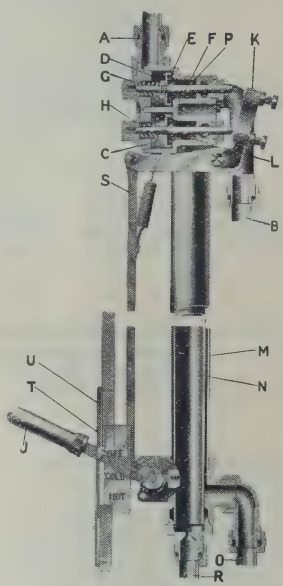

Fig. 12.

Method of ascertaining Heat necessary for a given Supply of Hot Water.

The basis of the calculations is that one British Thermal Unit will raise the temperature of 1 lb. of water 1° F. This figure varies a little according to the temperature of the water, but the variation is so small that for the purpose of hot water supply calculation, it may be neglected.

On the above basis we get the following simple formula—

$$B = \frac{G \times 10 \times T}{H} + R,$$

where,

B = British Thermal Units per hour ;
G = gallons of water ;
T = degrees it is required to raise the temperature of water ;
H = time in hours allowed for obtaining the required temperature ;
R = radiation losses from pipes and cylinder, per hour.

Example.

It is required to raise 100 gallons of water from 40° to 150° F. in 2 hours; then

$$B = \frac{100 \times 10 \times 110}{2} = 55{,}000.$$

With regard to radiation losses, we may assume the cylinder and pipes loss to be, say, a mean of 10,000 B.Th.U. per hour; the total B.Th.U. per hour would then be

$$55{,}000 + 10{,}000 = 65{,}000.$$

It is assumed that the circulating pipes and cylinder would be covered with non-conducting material to conserve the heat.

A boiler will transmit on an average from 2,500 to 7,000 B.Th.U. per hour per foot of boiler surface, 2,500 being for secondary flue surface, and 7,000 for fume firepot surface. An average of 5,000 may be taken for an ordinary independent boiler with normal firing. A tube in a well-designed calorifier will transmit from, say, 8,000 B.Th.U. per foot at 1 lb. pressure to 37,000 B.Th.U. at 50 lbs. pressure. The pressure of the water surrounding the tubes has quite an appreciable effect on transmission, apart from the temperature of the steam.

Apart from the usual hot water supply in a hospital, a special sterilised supply is required for surgical work in the operating theatres; steam is generally used for this purpose, and the water is heated to sterilised temperature, or generally boiled, and the apparatus so arranged that the sterilised water does not come into contact with unsterilised water or air before it is delivered at the taps for the use of the surgeon.

Hot Water by Gas.

Gas is often used for the purpose of heating water, especially in small installations, and a very usual application of this, in an ordinary size house, is to connect up the gas-heating boiler to the circulating pipes, so that during the summer when the range is not required (the gas-cooker being used for cooking) the gas-heater boiler can be used when desired. Apart from the geysers, etc., the systems of heating the water are arranged in a general manner, as regards arrangements of circulation, etc. The amount of gas necessary is on the basis of the calorific value per cubic foot. The average calorific value of town gas is, say, about 500 B.Th.U. per cubic foot. Assuming the boilers of the heaters to have an efficiency of 80 per cent., this would mean that 400 B.Th.U. of the 500 should be actually transmitted to the water, so that, taking the amount of water to be heated as mentioned above, namely, 100 gals., to be raised 110°, which requires 65,000 B.Th.U, this divided by 400 will give 162·50 cub. ft. of gas necessary.

Heating Water by Electricity.

For domestic uses surgical work, industrial, and other purposes, a method of heating water by electricity is very handy; but there is a disadvantage, it is very expensive if a very large quantity of water is required; this will be seen from the following:—

The electrical Board of Trade Unit contains 3,411 B.Th.U., and as the efficiency of electrical heating apparatus is very high, it may be considered that 3,000 B.Th.U. of the 3,411 would be transmitted to the water. Again, taking the quantity mentioned above, the amount of electricity required would be 65,000 B.Th.U. divided by 3,000, which gives us 21·7 units of electricity required. With regard to the type of heater, one very handy form, and one easily replaced, is the 'Immersion Heater.'

Industrial Hot Water Supply.

Hot water is required in a great many industries, and the method of heating the same is generally similar to the foregoing methods, although, very often waste heat of the furnaces in various industrial processes can be utilised for heating the boiler. For some requirements such as bottling, washing, etc., where it is desirable to have the water under considerable pressure the closed pump system lends itself to this class of work. (*J. Roger Preston.*)

Heating and Drying.

Not infrequently rooms and chambers are found provided only with steam pipes, which have to do duty at night and in the day time in order to keep pace with requirements Such rooms

are very bad drying places, and very slow into the bargain because the essential air current is lacking, and failure attends the introduction of a fan under these circumstances, owing to the influx of cold air following its use and lowering the temperature. To be effective the air must be raised to the required temperature before distribution and should act as a vehicle for the conveyance of the heat to and about the drying rooms or chambers.

To derive the maximum benefit from the use of exhaust steam, drying rooms of considerable size should have two or more divisions, as by this means operations may commence in one section soon after starting the engine, and conveniently proceed so that the operators may work in the cool part and finish up within a period of time to coincide with shutting off steam.

The proper temperature to effect rapid and perfect drying varies considerably, and depends upon the nature and texture of the material to be treated. Provided, however, the warm air current is fairly proportioned, then mechanical drying will considerably enhance the value and quality of the work, and vastly expedite and cheapen the process.

Drying Room Temperatures.

SECTION XXXVIII

PART II

VENTILATION.

(Revised by J. Roger Preston, M.I.Mech.E., M.R.S.I., Past President of the Institution of Heating and Ventilating Engineers.)

Amount of Air necessary for Ventilation.

Whenever possible, it is desirable to provide 3,000 cubic feet of air per hour per person for halls, theatres, etc. Owing to the restrictions of cost and building construction, the sizes of the ducts necessary for this amount are rarely attainable, so a more usual figure is 1,800 cubic feet of air per hour per person. The L.C.C. regulations give 1,000 cubic feet of air per hour per person as the minimum amount of air required in buildings licensed by them.

Assuming a building in which there are, say, 3,000 people, and taking the L.C.C. requirements of 1,000 cubic feet per hour, this means about 830 cubic feet of air per second. The velocity permissible in the ducts will depend to some extent on their length, but 15 to 20 feet per second may be taken as a good maximum average. This means that the inlet and distributing ducts should have an area of not less than 50 square feet. As a streamline section must be maintained, it follows that where a change of direction in a duct of this size takes place, considerable space is taken up, and unless provision has been made for same, difficulties may be encountered. Steelwork is often a very important factor, especially in connection with the vertical subsidiary ducts, and is very difficult to modify; this trouble can only be avoided by close collaboration between the various parties concerned in the early stages of the building.

A very important point to bear in mind in the general planning is to allow plenty of room for the engineering equipment and to arrange that every part shall be easily accessible to the engineer in control of the plant. Experience proves that this is most essential, but is often overlooked or sidetracked to make room for something else.

The aim should be to make a system of ventilation as noiseless as possible, though this may not be necessary in industrial work. A good deal can be done by attention to details, but the fundamental factor is to keep low velocities, enabling the fans to run at slow speed, thus saving power. The space required and the initial cost will probably be more than for a system having high velocities, but it cannot be too strongly emphasised that in good class work *low air velocities and slow-running fans are essential to successful ventilation.*

The foregoing statement applies whatever system is adopted, and it must be remembered that *high air velocities and high-speed fans are a source of trouble and expense*, however attractive it may appear at the time to install small trunks that are easily adapted to the building.

Distribution of Air.

Convection currents are a most important factor in ventilation, and should be closely studied. This can conveniently be done either by balanced mica vanes or by blowing air through HCl and NH_4OH, the vapours so formed causing, when mixed, a dense white smoke (not heated). When these convection currents are known it can then be decided whether natural or mechanical methods will be required to give satisfactory ventilation and the best positions for the introduction of the air.

If natural ventilation is utilised, the air should be introduced at low level, preferably behind radiators, and allowed to find its way out at ceiling level.

Three methods of mechanical ventilation are employed, the particular method to be used depending on circumstances.

(*a*) *Mechanical extract* only. Inlets are provided at a low level, preferably behind radiators, the air being extracted by means of a fan at high level. This method is commonly employed in halls seating under 1,000 people, and similar buildings.

(*b*) *Mechanical inlet* only. Inlets are provided at a low level or about 6 feet above floor level. A common distribution is one-third of the total area of gratings at low level and two-thirds at 6 feet up. Outlets are provided through the walls at high level or through the ceiling. This method is employed when fresh air from outside is not otherwise obtainable.

(*c*) *Both mechanical inlet and extract.* The extracts should be as (*a*) and the inlets as (*b*). This method is used for large halls and particularly difficult problems, such as basements and enclosed rooms. The amount of air extracted mechanically is usually 75 per cent. of the air introduced by the inlet fan.

Where circumstances will allow, it is often found an advantage to arrange the distributing ducts, inlets, and outlets in such a way that the direction of air currents in the room can be reversed for different atmospheric conditions and temperatures.

Air-Filtering, Washing and Conditioning.

It is always desirable and frequently essential that the air should be as free from dust and impurities as possible. This dust can be removed by filters and air washers. There are several types of air filters obtainable, but they can be divided into two main groups:

(*a*) *Dry filters.*—These consist of a series of perforated plates arranged so that the perforations are staggered, the plates being covered with a sheet of wadding on the up-stream side for the better collection of the dust. The filtering effect is dependent on the number of plates. To clean, the filter unit is detached from its frame and shaken.

(*b*) *Viscous fluid filters.*—In these, the air passes over a series of plates or troughs coated with a viscous fluid to which the dust adheres. To clean, the filter unit is washed in strong soda water, dried, and then dipped in the viscous fluid and allowed to drain before replacing.

Air washers commonly used consist of a series of fine sprays through which water is pumped, the air mixing thoroughly with this finely divided spray, afterwards passing over a series of eliminator plates which collect the surplus water together with the dust.

The use of dry or viscous filters removes the dust without altering the temperature or humidity of the air, while the air washer varies both the temperature and humidity, thus making it unsuitable for certain purposes although it is frequently advantageous, especially when applied to the ventilation of halls and theatres.

The endeavour to produce a pleasant and healthy atmosphere inside at all times of the year whatever the outside conditions may be, has received a good deal of attention of late years, and in this connection a term *Effective Temperature* has been brought into use. The 'Effective Temperature' is influenced by three factors: (1) Dry bulb temperature; (2) Wet bulb temperature; and (3) Velocity of the air. The most suitable 'Effective Temperature' may vary, according to circumstances, from 60° to 70° F. If, however, it were 90° F. outside, it would be very unwise and actually uncomfortable for people to go into a temperature of, say, 60° F. or even 70° F. In this case, the reduction of the dry bulb temperature by about 10° F., together with a perceptible air movement, would probably give rise to a marked degree of comfort.

Air Cooling.

Air can be cooled by an air washer, but the relative humidity will always rise. In a washer using recirculated water, the heat content will not be substantially changed although a certain cooling effect can be obtained with a consequent rise in relative humidity. The wet bulb temperature is unaffected by this method, so that the cooling is limited by the initial wet bulb temperature and will in practice always be a few degrees above this. Actually it will be found that the dry bulb temperature can be reduced to, say, 75 per cent. of the difference between the wet and dry bulb temperatures.

When artesian well water or some other water having a temperature of 52° F. is obtainable, the air can be cooled to about 57° F. with a consequent reduction in the vapour contents of the air should the initial dew-point be above 57° F., which is most probable in hot weather. The air will then be saturated.

When air is required with a lower temperature than can be obtained by the air washer, refrigeration will have to be employed. Cooling air is far more expensive than heating, owing to the condensation of the moisture in the air. For general ventilation, the air may be cooled from 10° F. to 15° F., but for industrial purposes, when it is required to have complete control over the relative humidity and temperature, it is usual to cool the air to 35° F. The amount of brine to be circulated should be calculated on a drop of 3° F. The specific heat of brine may be taken as 0·82° F., and in calculating the heat required for the reduction in temperature the condensation of the vapour must not be forgotten. The heat in British thermal units required, divided by 12,000, will give the size of plant required in tons of refrigeration per day of 24 hours.

The heat exchange in cooling or heating air over a given range of temperature is not materially different, provided the dew-point is not reached. Should, however, the initial humidity be such that the dew-point is reached in the cooling, another very important factor is introduced, a portion

of the aqueous vapour being condensed and giving up its latent heat in the process. The British thermal units involved in the heat exchange may be ascertained by the following, which is accurate enough for all practical purposes and shows the various points involved :

$$U = \overbrace{L_c (W_1 - W_2)}^{\text{SECTION A.}} + \overbrace{S_v(T_1 - T_2) W_1}^{\text{SECTION B.}} + \overbrace{S_a (T_1 - T_2)}^{\text{SECTION C.}},$$

where,

T_1 = Initial dry bulb temperature;
T_2 = final ,, ,, ,,
W_1 = weight of aqueous vapour per lb. of air at initial temperature T_1;
W_2 = ,, ,, ,, ,, final ,, T_2;
L_c = mean latent heat of vaporisation or condensation at initial dew-point, and T_2;
S_v = specific heat of vapour;
S_a = specific heat of air;
U = B.Th.U.'s to cool 1 lb. of air from T_1 to T_2;

Basic figures to be taken for this and other equations :

S_v = specific heat of aqueous vapour = 0·44;
S_a = ,, ,, air = 0·2415 *;
L_c = latent heat of vaporisation varies from 1073·4 B.Th.U.'s per lb. ar 32° F. to 1052·3 B.Th.U.'s per lb. at 70° F.

Section A is the heat required to be extracted to condense the water vapour.

Section B is the heat required to be extracted to reduce the temperature of the water-vapour contents of the air and is so small that it can usually be neglected.

Section C is the heat required to be extracted to cool the air from T_1 to T_2.

Velocities of Air Flow for Mechanical Ventilation and Flow of Air Through Ducts.

Where silence is essential, the velocities of flow of air in ducts must be kept low, the ideal velocity being from 10 to 15 feet per second, and on no account exceeding 20 feet per second. For factory work speeds up to 30 feet per second are allowable, but this velocity should not be exceeded. In general, the outlets to the rooms (if at low level) should be of such an area that the air issues at a velocity of from 3 to 5 feet per second, as such velocities do not give rise to a sensation of draught. In certain circumstances, however, such as during hot weather, it may be found desirable to direct a flow of air across a room at a velocity of 10 to 15 feet per second, this movement giving a feeling of coolness. (See 'Effective Temperature' p. 2618.) The following table gives the permissible velocities for different parts of the ventilation system. The lower figure refers to ventilation where silence is desired, and the higher gives the maximum permissible for factories, etc.

Fresh air intake	500 to 800 ft. per min.	Main ducts	800 to 1,200 ft. per min.
Heating battery	800 ,, 1,500 ,, ,,	Branch ducts	600 ,, 900 ,, ,,
Filter	150 ,, 350 ,, ,,	Registers	180 ,, 300 ,, ,,
Washer	300 ,, 500 ,, ,,		

The flow of air through a building resembles an electrical circuit, the inlets, outlets, and ducts acting as the resistance, and absorbing some of the aeromotive force. *To ensure an even flow in various ducts requires considerable care*; the resistance must be low, as the initial force in ventilation is small, usually equal to about 0·25 ins. of water, or 17 pneumatic units. In natural ventilation it is much less than this.

In order to obtain an even distribution of air throughout the system, the design of the ducts is very important. Changes in direction and section should be as gradual as possible, particular care being taken to avoid sudden changes. The finish of the ducts should always be of the best, as roughness and irregularities increase immensely the resistance to the flow of air. The ducts are usually made of galvanised iron or in builders' work. When made by the builders the ducts should be lined with glazed bricks, or, if this is too expensive, finished with Keene's cement or some similar hard, smooth finish. It is always advisable to whitewash the latter, as the presence of dust is then easily noticed and more likely to be removed. The importance of the foregoing will be appreciated when it is realised that in mechanical ventilation where silence is essential the fan should not work against a resistance exceeding 1in. W.G. and in other general work it is advisable not to exceed 2in. W.G., except for dust extraction and similar industrial processes.

* 0·238 was at one time the accepted figure for specific heat of air and will be found in many textbooks, but 0·2415, or sometimes 0·2400, is now accepted as the more correct value.

RESISTANCE OF FLOW OF AIR PER 100 LINEAL FEET OF CIRCULAR GALVANIZED IRON TRUNKING.

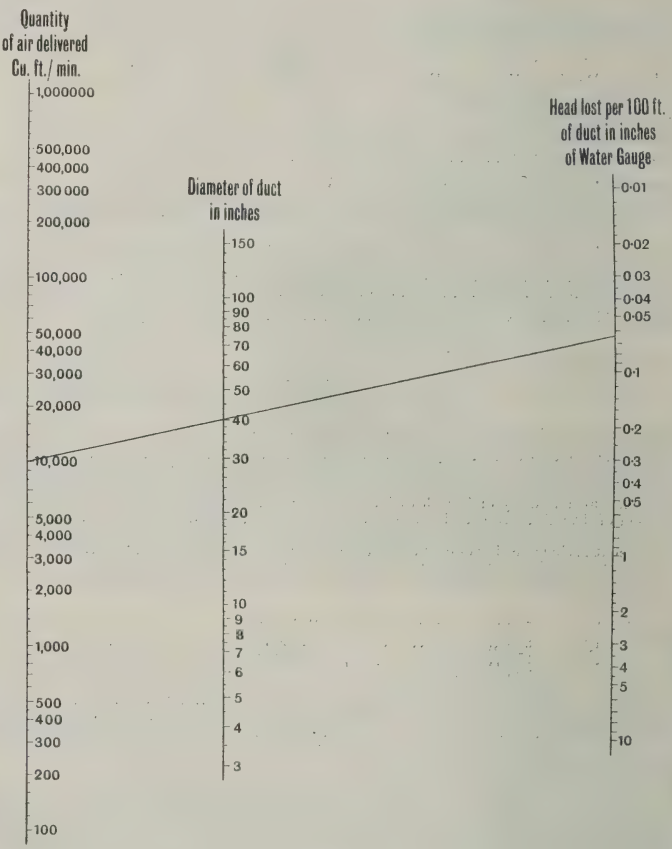

FIG. 1.

EXAMPLE: To find the loss of head in a 40-in. diam. duct carrying 10,000 cu. ft. of air per minute, lay a straight edge as shown connecting 10,000 cu. ft./min. and 40-in. diam., reading the loss of head 0·064 ins., W.G. per 100 ft., on the right.

There is yet a need for research work in connection with the flow of air in ducts, but the following will be found a useful formula for the flow of air through galvanised iron pipes :

$$C = 39d^{2\cdot5} \Big/ \left(\frac{L}{H}\right)^{\frac{1}{2}},$$

where,

C = cubic feet of air per minute ; L = length of pipe in feet ;
d = diameter of pipe in inches ; H = drop of pressure in inches of water.

The values derived from this formula are shown more conveniently in fig. 1.

For resistance in ducts of other materials than galvanised iron, multiply the result obtained from the diagram or by the above formula by the following factors :

Smooth concrete . . . 1·5 Brickwork . . . . . 2·0

When arriving at the total resistance in a duct, allowance must be made for bends and loss due to entry and egress at registers. The loss of a sharp elbow varies from 30 to 60 diameters, a smooth bend 5 diameters and a usual register 80 diameters.

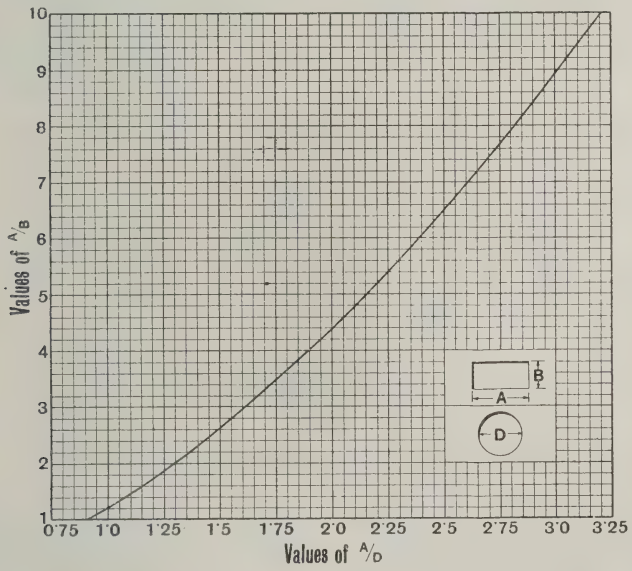

FIG. 2.

Diagram for obtaining equivalent Diameter of Round Duct carrying the same amount of air for the same loss as a Rectangular Duct.

To obtain the total head against which the fan has to work, the velocity head must be added to the resistance in the duct ; this is obtained from the following formula :

$$h = \frac{6D \cdot v^2}{gk},$$

where,

v = velocity in ft. per sec. ; h = velocity head in W.G. ;
g = 32·2 ; D = density of air at temperature required
k = density of water = 62·4 ; = 0·0749 for dry air at 70° F.

All the above is based on circular pipes. In the case of rectangular pipes, find the equivalent

circular pipe to give equal discharge for equal resistance from the following formula, and then use fig. 1 to find the resistance to flow :

$$D = \sqrt[5]{3{\cdot}25 \frac{A^3B^3}{A+B}}$$

where

A = long side of rectangular pipe ; B = short side of rectangular pipe ; D = dia. of equivalent round pipe.

This equivalent diameter can conveniently be found by means of fig. 2.

Movement of Air by Fans.

The choosing of a suitable fan is a most important factor in any scheme of mechanical ventilation.

There are two distinct types of fans used for this work : the propeller and centrifugal, one similar to a ship's propeller, and the other more like a paddle wheel.

A propeller is a very efficient and useful fan if used in the proper way, that is, either with free inlet and outlet, as, for instance, when fixed in a window or wall without any trunking attached, or with short trunking of ample size, causing very little resistance head.

In the average building a fan must run at a low speed to avoid noise. At this speed the efficiency of a propeller fan falls off very considerably against resistance, as will be seen from

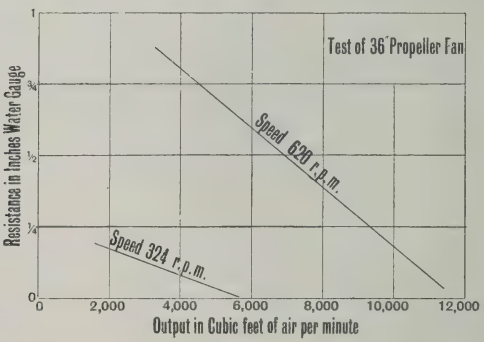

FIG. 3.

Diagram showing how the volume of air delivered by a propeller fan falls off with increased resistance.

fig. 3 (plotted from tests by the author). For factory and similar work where noise and extra power do not matter, the fan may be run at a much higher speed, in which case it can be used at a higher water gauge, see fig. 3, but even then the economical limit is soon reached. It must be remembered also that as the quantity of air decreases, due to resistance, the power increases.

The centrifugal fan can be used up to any reasonable pressure, but for general ventilation, where absence of noise and economy of power is desired, it is good practice not to exceed about 1 in. total head (resistance head + velocity head), the filters, heaters, ducts, etc., being designed accordingly.

When the resistance is increased, the amount of air falls—so also does the power taken. At a lesser resistance the volume of air increases—so also does the power.

Should a centrifugal fan and motor be designed for a given resistance, and then the resistance turns out to be less than expected, there is a great danger of the motor being overloaded, unless a specially large one has been installed. To meet this condition, a special fan has recently been put on the market, and the author's experience of this fan so far has been very satisfactory.

The Fan Standardisation Committee of the Institution af Heating and Ventilating Engineers, after devoting some five or six years to the study of the subject, has issued a very comprehensive report on the testing of fans, terms to be used, and method of cataloguing, etc.* to which the reader is referred.

* ' Report of the Fan Standardisation Committee, 1927 ' (price 2/6). Office of the Institution, 12 Russell Square, London, W.C. 1.

Movement of Air other than by Fans.

As the air in a flue such as a chimney or outlet duct from a warmed room is at a higher temperature than the outside atmosphere, its density is less, and the tendency is for it to rise. The resulting velocity of flow varies within wide limits, but is theoretically given by :

$$V = 480 \sqrt{\frac{h\,(T - t)}{t + 460}}$$

where,

V = velocity of air in feet per minute ; T = temperature of heated air °F ;
h = height of flue in feet ; t = outside temperature °F.

The actual velocity is considerably lower in practice, and the result from the above formula should be multiplied by 0·25 to 0·6, according to size, shape, and materials.

In addition to the movement of air due to difference of temperature, the wind has a considerable aspirating effect on a properly designed ventilator.

The following data are taken from some tables in the ' Robertson Ventilation Data Book ' :*

Temperature Difference, Fahrenheit.	Height of Ventilator above intake.	Wind Velocity in Miles per hour. 2	6	10

Heating units such as gas jets, electric heating, steam or hot water coils, are sometimes used for the purpose of causing an up-draught. These should never be used if any other method is available, as they are very inefficient and costly in up-keep, costing, in the case of steam coils for example, on an average six times that of moving air by fans. (*J. Roger Preston.*)

* H. H. Robertson Co., Pittsburg, Pa., U.S.A.

Blowers and Exhausters.

STURTEVANT BLOWERS AND EXHAUSTERS.

(*Sturtevant Engineering Co. Ltd., London, E.C.* 4.)

The design of a fan depends upon the pressure against which it has to discharge. A blower designed for low pressure is not suitable for high, and *vice versâ*. Figs. 4 to 10 show various types.

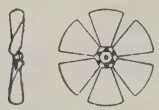

FIG. 4.

AIR PROPELLER.

For moving large volumes of air from one part to another where the resistance is low. Used for ventilating and exhausting.

MULTIVANE CENTRIFUGAL FAN.

For moving large volumes of air against 1 to 4 ins. water gauge. Fan wheel has shallow blades with corrugations to prevent lateral slip. Used for ventilating, drying apparatus, mechanical draught for boilers, etc.

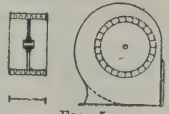

FIG. 5.

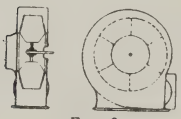

FIG. 6.

STEEL PLATE CASED CENTRIFUGAL FAN.

For air pressures up to 8 or 10 ins. water gauge. The square section steel plate casing is used, but the wheel has deeper blades and side plates (shrouds). Used for dust exhausting, conveying, etc.

CAST IRON CASING FAN.

For obtaining higher pressures up to 15 ins. water gauge, the casing must be more carefully designed and preferably made in cast iron. The wheel is narrower and deeper than that for lower pressures. Used for blowing forges, furnaces, etc.

FIG. 7.

FIG. 8.

HIGH PRESSURE FANS.

For blowing cupolas, etc., requiring air pressures from 12 to 30 ins. water gauge. The scroll must be most carefully designed and the wheel have a greater number of blades. For sizes and capacities of this fan see page 2663.

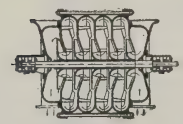

FIG. 9.

MULTISTAGE FANS.

For blowing and exhausting air at pressures up to 3 to 4 lbs. per square inch.

ROTARY BLOWERS.

These are used for many duties, for blowing and exhausting air or gases where pressures up to 5 lbs. per square inch are required.

FIG. 10.

POWER VARIATION OF A BLOWER AT CONSTANT SPEED.

Propeller Fans.—Power rises slightly with pressure; volume decreases rapidly as pressure rises.

Centrifugal Fans.—Power increases as pressure falls, and volume increases.

Rotary Blowers.—Power increases directly with pressure, volume remaining about constant.

The 'Wing' Fan.

(F. W Potter & Soar, Ltd., Phipp St., Great Eastern St., London, E.C. 2.)

The general arrangement of the blades of the Wing fan or air propeller is shown by fig. 11. It is claimed that the Wing fan, for a given amount of power, will move a greater volume of air than any other pattern, owing to the shape, angle, and curvature of the blades, and the method of securing them to the central boss. It has been found that an angle of 27½° to 30° is the best all-round angle for combined output and efficiency.

A distinctive and useful feature of the fan is the adjustability of the angle of the blades, the latter being readily set to any angle. If desired, the direction of the air current may be reversed, this reversal of the air current being effected without impairing the efficiency of the fan.

The blades of the Wing fan are usually made of steel, but for certain purposes they are made of copper, aluminium, or Muntz metal.

The fan wheel is mounted on a spindle running in bearings lined with best quality Babbitt metal, and the framing is constructed of cast iron or wrought iron according to circumstances.

The Wing fan is manufactured in all sizes, arranged with pulley for belt drive, or direct coupled to electric motor.

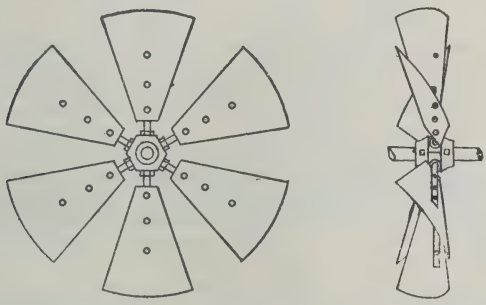

Fig. 11.

Economy of Power.—Where conditions permit of the choice between a propeller type and a centrifugal type of fan, the following rules are useful :—

(*a*) For open ventilation use propeller fans.

(*b*) Make main air duct same diameter as fan, or larger, avoiding acute or sharp angle bends.

(*c*) When small ducts and sharp bends are unavoidable use centrifugal fans.

(*d*) Use large fans at as low a speed as will overcome whatever resistance is in the way of free passage of air.

Example.—A 10 ft. Wing fan at 90 revs. per min. delivers 71,000 cu. ft. of air per min., absorbing 1·2 h.p.

A 5 ft Wing fan at 720 revs. per min. delivers 71,000 cu. ft. of air per min., absorbing 19·2 h.p. Volume for volume, therefore, the smaller fan uses 16 times the power absorbed by the larger fan.

(*e*) Use two fans of the same diameter at low speed instead of one at double the speed.

Example.—A 48 in. Wing fan at 600 revs. per min. delivers 30,200 cu. ft. of air per min., absorbing 3·6 h.p.

Two 48 in. Wing fans at 300 revs. per min. deliver 30,200 cu. ft. of air per min., absorbing ·9 h.p. together.

Volume for volume, therefore, one fan uses four times the power absorbed by two fans.

APPROXIMATE CAPACITIES OF 'WING' FANS (SMALLER SIZES).

MOTORS FOR DRIVING VENTILATING FANS.

Too much cannot be said regarding the location of the motor. On account of the nature of the work it is frequently necessary to place the machine in an out-of-the-way place, although this does not necessarily mean that it must be in an inaccessible location. If it is so placed that it is difficult to care for, it will probably be neglected, with the result that the service will be impaired and the maintenance charge will be high. The placing of a motor in an inconvenient place because nothing else will go there, is false economy generally, and results in dissatisfaction. The question of motor efficiency in regard to fan drives is an important one and involves two factors—the efficiency of the motor when operating under normal speed, and the efficiency at other than normal speeds. Although the latter is, to some extent, influenced by inherent characteristics of the motor, the largest factor is the method of control, especially with direct-current motors. If, on account of its lower cost, a motor is selected, where adjustable speed is required, that will, when operating at normal speed, drive the fan at the maximum required speed, and it is necessary to operate for considerable periods at reduced speed, low efficiency will result.

The cost of the power lost in the armature external resistance will usually pay a handsome dividend on the additional capital required to install a motor and controller that, at normal speed, will drive the fan at the lowest speed required and beyond this point adjust the speed by field control.

The horse-power required to drive a centrifugal fan can be estimated from the following formula:

$$HP = \frac{5 \cdot 2 \times Q \times WG}{33{,}000 \times E}$$

where,

HP = horse-power of motor; Q = cubic feet of air per minute; WG = pressure of air in inches by water gauge; E = efficiency of fan, which is approximately 0·5 for a steel plate fan, 0·65 for Sirocco, and 0·45 for cone type.

The following mathematical relations are theoretically true for all centrifugal fans: Volume of air delivered varies as the speed; pressure of air delivered varies as the square of the speed; horse-power required varies as the cube of the speed. Hence a fan, which, when operated at 100 r.p.m. delivers 8,000 cub. ft. of air at ½ oz. pressure, requires 2 h.p., will, when operated at 200 r.p.m., deliver 16,000 cub. ft. of air at 2-oz. pressure and will require 16 h.p. It is therefore necessary, in selecting a motor for driving a fan, to figure the horse-power requirements at the maximum speed of the fan.

Reduction of the area of the inlet or discharge of a centrifugal fan will reduce the power required, whereas increasing the area of either will increase the power. Disc fans produce a relatively low pressure, and it is customary to figure their output on a basis of velocity. The relations between volume, speed, and horse-power for centrifugal fans hold good for disc fans. However, if the outlet of a disc fan is restricted, the pressure and the power required increase, and with a totally closed outlet the power needed is almost double that with an unrestricted outlet. (*'Power.'*)

Ventilators.

The Boyle 'Air-Pump' Ventilator.

In the latest patented forms of Boyle's patent 'air-pump' ventilators the wind, striking against and being deflected by curved vanes causes a suction effect which draws out the foul air and effects perfect ventilation. One form of the 'air-pump' ventilator, known as the *ridge* ventilator, is shown by fig. 12. The wind blows through the openings, and in passing over the curved plates causes a strong upward draught.

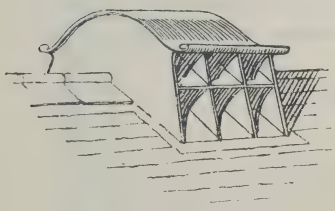

Fig. 12.

No. 175.

Fig. 13.

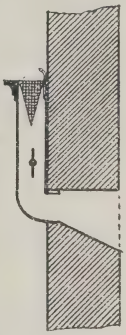

Fig. 14.

In the 'air-pump' ventilator (fig. 13) the curved vanes are set vertically.

For the necessary admission of fresh air to take the place of that extracted by the ventilator, Boyle's Air-Inlet Bracket, shown by fig. 14, may be adopted. The top of the inlet should be about 5 ft. 9 ins. above the level of the floor, and the outside opening should be covered with an iron grating.

The Plenum System.

This system (*The Sturtevant Engineering Co. Ltd.*) is well adapted for the economical warming and ventilation of workshops, large halls, theatres, and other large buildings. The

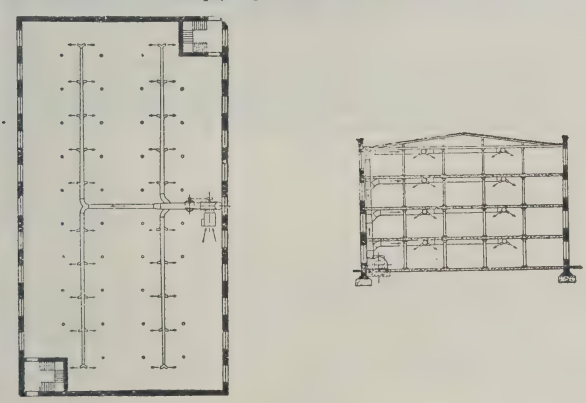

Fig. 15.

apparatus consists of a fan which draws in fresh air, delivering it through a heater where it is warmed to the required temperature, and then evenly distributed through a series of ducts to

every part of the building. The fan is usually of the steel-plate type driven by belt from line shafting, steam engine, or electric motor; the heater is built up with a nest of pipes for use with live or exhaust steam, hot water, furnace gases, etc. Ducts for distributing the air are constructed of galvanised sheet steel, masonry, wood, or other materials, and may be built in the walls or floors, or suspended from the roof or walls.

The system ensures even distribution of warmth throughout the whole building with proper ventilation. In the summer the heater can be eliminated and fresh air distributed throughout the buildings. Workshops can be quickly warmed up in the morning before work is commenced, by recirculating the air. The fan and heater can be installed at one central

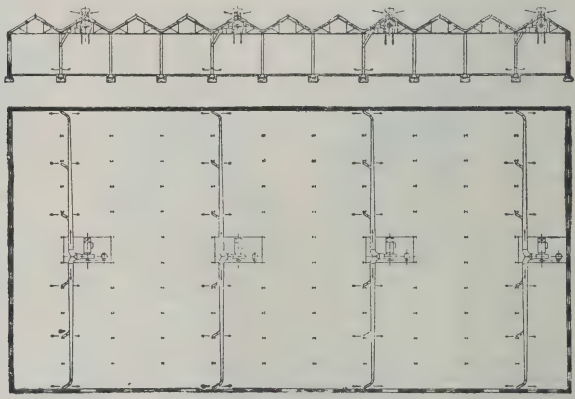

FIG. 16.

point either inside the building or outside, and they are under complete control of one man who can regulate the temperature of the air supply as required.

Two types of buildings equipped with this system are shown by figs. 15 and 16. Fig. 15 illustrates a building of several storeys, in which the apparatus is placed in the basement, one air main being carried up through the building with overhead horizontal distributing pipes on each floor.

Fig. 16 shows a large workshop of considerable height, in which the apparatus is divided into four units in order to keep down the size of the air piping. The sets of apparatus are placed out of the way in the roof, the air being distributed by overhead pipes and discharged at floor level through downtake pipes arranged alongside the column. An alternative arrangement would be to install one set of apparatus and connect it with each of the pipe mains.

SECTION XXXVIII

PART III

LIGHTING

(Revised by W. J. Jones, M.Sc., A.M.I.E.E.)

Terms in Illumination

International Candle.—This is the unit of light intensity standardised in Great Britain, the United States of America, and France (*Bougie decimale*), and is one-tenth the intensity of the standard 10 candle Harcourt Pentane lamp burning under specific conditions of barometric pressure and humidity.

The relationship between the International Candle and other units is shown in the following table:

Unit.	Is Equivalent to:		
	International Candle.	Hefner Candle.	Carcel Unit.
One International Candle .	1·0	1·1	0·104
One Hefner Candle . .	0·9	1·0	0·09375
One Carcel Unit . .	9·6	10·66	1·0

Mean Horizontal Candle Power.—As the intensity of a light source generally varies in all directions, this term is employed to denote the mean candle power obtained by averaging the candle-power readings measured in all directions on a plane passing through the centre of the light source and perpendicular to its axis.

Mean Spherical Candle Power (M.S.C.P.).—This is the mean of the candle powers measured in all directions.

Lumen.—The unit denoting the quantity of light, and is the amount of light flux contained in a unit solid angle of a sphere which has a uniform light source of one candle situated at the centre. A light source of one mean spherical candle emits 4π (12·57) lumens (see fig. 1).

Foot Candle.—The unit of illumination. It corresponds to the light density on a surface. If normal to its surface, every part of an area of 1 square foot receives light of an intensity of one candle; it is said to be illuminated to a density of 1 foot candle.

If a uniform point source of light of 1 candle intensity in all directions is situated at the centre of a sphere of unit radius, every square foot of the spherical surface will be illuminated to a density of 1 foot candle. Alternatively, it may be said that if one lumen illuminates an area of 1 square foot, the average light density will be 1 foot candle.

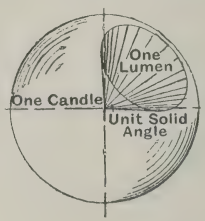

FIG. 1.

Lux or Metre Candle.—The Continental unit of light density is analogous to our foot candle unit. When an area of 1 square metre is illuminated by one lumen, the resultant illumination is 1 lux or metre candle. It follows that 1 foot candle equals 10·76 lux.

Brightness.—The brightness of a surface is the quotient of the luminous flux intensity in a given direction divided by the area of the surface projected on a plane perpendicular to that direction. For electric lamps and fittings this quantity is expressed in candles per square inch, while for large surfaces it is stated in candles per square foot.

Illumination.

Illumination, or the density of light received by an object, is measured in terms of foot candles, and can be shown to be directly proportional to the candle power and inversely proportional to the square of the distance from the light source, *i.e.* $I = \frac{C.P.}{D^2}$.

If a surface is oblique to the rays, $I = \frac{C.P.}{D^2} \cos \theta$, where θ is the angle subtended between the incident light and normal to the surface.

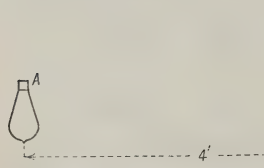

FIG. 2.

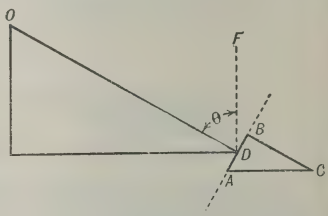

FIG. 3.

Example.—In fig. 2, if A is a lamp (electric or otherwise) giving 16 C.P. in a horizontal direction, the illumination at the point B, 4 ft. away, would be $\frac{16}{4^2} = 1$ foot candle, since the intensity of light varies inversely as the square of the distance. To get the normal illumination at any given point, the candle power in that particular direction must be divided by the square of the distance

to the point illuminated. As previously explained, if the surface illuminated is not at right angles to the direction of the light, the value of the illumination obtained, as above, must be multiplied by a reduction factor, taking into account the angle at which the rays strike. A beam of light coming in the direction of OD (fig. 3) falls upon a plane AB, illuminating it with a density of 1 foot candle, then the illumination on the plane AC, which intercepts the same amount of light as AB, would be less as the light is spread over a larger surface, the reduction being in the ratio of AB to AC, which is the cosine of the angle ODF. Thus the effective illumination on any plane at a given point will be:

$$\frac{\text{C.P}}{\text{distance}^2} \times \cos\theta$$

where θ is the angle between the direction of the ray and a perpendicular to the plane considered.

Brightness.

The brightness of an object under a given illumination depends on the amount of light reflected back by its surface, and this depends on the colour and the nature of its finish. The following table gives the approximate percentage of incident light reflected by various surfaces:

Approximate Reflecting Power of Surfaces.

	Per Cent.		Per Cent.
White, rough	82	Blue paper	25
Cream	80	Wood, dirty	20
White, smooth	70	Brown paper	13
White, printed matter (grey)	60	Brown, dark	4
Wood, clean	50	Black cloth	1·5
Yellow paper (light)	40	Black velvet	0·5
Yellow, dark	30		

Photometry.

As its name implies, photometry deals with the measurement of light. By comparing the unknown light source with a known standard and using the fundamental stated above—that is, that the intensity is inversely proportional to the square of the distance—photometric readings are reduced to the measurement of lengths. In a simple photometer the standard lamp and the light source to be measured are mounted on a horizontal bench with a movable screen placed between them (see fig. 4). The screen is then moved between the lamps until both its sides appear

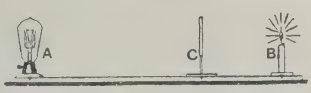

Fig. 4.

to have the same brightness. The distance AB and BC are then measured and the candle power calculated from the fact that:

$$\frac{\text{CP.A}}{\text{AC}^2} = \frac{\text{CP.B}}{\text{BC}^2} \qquad \therefore \text{CP.A} = \text{CP.B} \times \frac{\text{AC}^2}{\text{BC}^2}$$

While making such readings care must be taken that the screen is shielded from any light from other sources.

The Lummer-Brodhun photometer is a more accurate instrument in which prisms are used, so that on looking through a single eyepiece parts of both sides of the screen are seen superimposed; by this means very accurate comparisons of contrast can be made. With this instrument it is not the brightness of the surfaces that are balanced, but their contrasts, as seen in the two halves of the field. Fig. 5 shows a diagram of the Lummer-Brodhun photometer head, and also the appearance of the contrast field when viewed through the eyepiece.

The great difficulty in making candle-power measurements is the difference in the colour of various light sources, and for accurate work special means have to be adopted. One method employs colour filters, but variations in the light absorption with various lights of different complex colour composition renders this method rather unsatisfactory. Another method is to employ a flicker photometer such as the Simmance-Abady Flicker Photometer. This instrument is based on the fact that if a surface is illuminated alternately by two light sources it appears to flicker, due

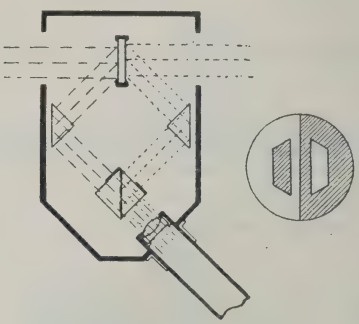

FIG. 5.

both to variations in light intensity and colour. By varying the speed of the alternations it is found that the eye is more sensitive to variations of intensities than to changes of colour; so by using a critical speed of exposure the surface assumes a neutral tint only affected by flicker due to variations in intensity, and so, under these conditions, the illuminations on the screen can be balanced in the usual way.

In the actual instrument these alterations are obtained by rotating a specially shaped disc between the light sources. The rotor is provided with surfaces that slope alternately to either side, so that at any instant during the rotation the portion in front of the eyepiece is only illuminated by one lamp.

INTEGRATING PHOTOMETER.

The sphere photometer is another form of instrument specially designed for measuring the mean spherical candle power of a light source. The apparatus consists of a large sphere with a whitened mat interior surface; the light source being placed in the centre. It can be shown that every part of the interior surface will receive the same amount of light by repeated reflections—in other words, the light is automatically averaged out; by placing a small window of diffusing glass in the side of the sphere this average intensity can be measured by the usual photometer method.

As mentioned, the effect depends on reflections in the interior, and so the window has to be carefully shielded from direct light from the source of light, also the readings must be multiplied by a constant depending on the nature of the internal surface.

See also British Standard Specification for Portable Photometers, No. 230, 1925.

Polar Curves.

Before suitable reflectors can be designed for a given source of light, or in fact before any real idea can be formed as to the characteristics of such a source, it is necessary to know how the light intensity varies in all directions. The polar curve is a very convenient way of showing these variations, and an example is given in fig. 6. The distance scaled along any line from the centre is proportional to the candle power in that particular direction. When handling light sources, the illuminating engineer needs information as to the nature of the light distribution complete with reflector. This data is recorded in a similar type of graph, and fig. 6 also shows how the light distribution has been completely changed by fitting a reflector; curve A shows the light distribution of a particular lamp alone, while curve B gives its distribution after a reflector has been installed. It will be seen that by means of the data from such polar curves, light can be properly controlled both as regards the design of fittings and installation for specific purposes.

Often it is necessary to compute the total lumens output from a polar curve, or more exactly the mean spherical candle power from which the lumens can be easily calculated. If the light source is symmetrical in its horizontal distribution and not too irregular in its vertical variations, this can be readily performed by taking readings at what are known as the Russel Angles; the mean spherical candle power being the average of such readings. Taking the lower vertical ordinate as our zero, readings should be taken at the following angles:

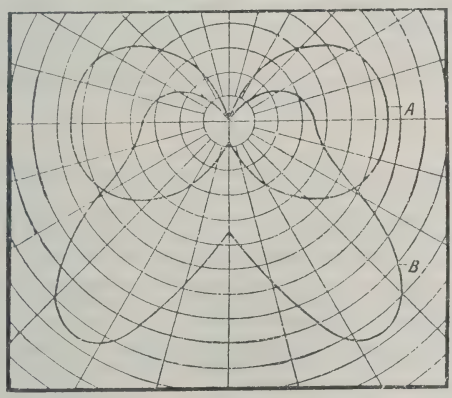

FIG. 6.

Degrees.				
25·8	60·0	84·3	107·5	134·4
55·6	72·5	95·7	120·0	154·2

As explained, the M.S.C.P. is the arithmetic mean of the ten readings; while if the lumen output is required this result has simply to be multiplied by 12·57.

Requirements of Good Illumination.

Illumination must be acceptable to the eye. We should be able to see objects clearly and with a minimum of fatigue. To accomplish this result certain conditions must be fulfilled.

(1) There must be sufficient illumination. Since objects are seen by means of the light which they reflect, more light must be thrown on dark objects than on light ones.

(2) Intensely bright lights in the field of vision should be avoided. The iris closes somewhat in order to afford a protection from such lights, and the amount of light received from illuminated objects is thereby so reduced that they cannot be seen clearly. This accounts for the well-known dazzling effects of searchlights and of many headlights. The intrinsic brilliancy or candle-power per square inch of luminous area should therefore be kept as low as possible; it should not ordinarily be higher than 4 to 6, if the source of light is in the field of vision. Clear bulbs should certainly never be used where the filaments are continuously in view. When reflectors are used it is generally desirable to employ some form of obscured lamp.

(3) Flickering lights should be avoided. Poorly regulated circuits, such as those having varying power loads, cause disagreeable flickering. Metal filament lamps have an inherently better regulation than carbon filament lamps.

(4) The light should have a continuous spectrum, *i.e.* one containing every colour, in order that the relative colour values of objects illuminated may be the same as when seen by daylight. For matching delicate tints, as in silk and paper mills, the light should be as white as possible. while for general illuminating purposes a 'warm' light is best; cold glaring lights too rich in green

and blue are to be avoided. Where colour matching is important special colour matching units should be employed, but for many industrial purposes absolutely correct daylight is not required, and the Daylight lamps can be used.

The size of the units is a question of design. In deciding upon the proper sizes of lamps to use, one must consider the spacing of present outlets, if building is already wired, and the location of pillars, beams, etc. In general the fewest units consistent with good distribution will be the most economical, as the total cost of outlets, fixtures, and lamps, as well as the maintenance charges, will be reduced. In many cases it is preferable to entirely rewire the premises, in order to obtain correct illumination.

Reports of Departmental (Home Office) Committee on Lighting in Factories and Workshops.

(1915–1922.)

Third Report of the Committee, H.M. Stationery Office, Adastral House, Kingsway, W.C. 2.

The minimum intensity of illumination desirable for the sake of general convenience and safety in parts of the workshops where work is normally carried on, and in yards, passages, and open spaces along which people are ordinarily liable to pass, is as follows :—

2. 'Over the "working areas" of workrooms the illumination measured on a horizontal plane at floor level shall be not less than 0·25 foot-candle, without prejudice to the illumination required for the work itself.'

3. 'In all parts of iron foundries in which work is carried on or over which any person is ordinarily liable to pass, the illumination measured on a horizontal plane at floor level shall be not less than 0·4 foot-candle.'

4. 'In all parts of factories and workshops (not included under recommendation 2) over which persons employed are liable to pass, the illumination measured on a horizontal plane at floor level shall be not less than 0·1 foot-candle.'

5. 'In all open places in which persons are employed during the period between one hour after sunset and one hour before sunrise, and in any dangerous parts of the regular road or way over a yard or other space forming the approach to any place of work, the illumination on a horizontal plane at ground level shall be not less than 0·25 foot-candle.'

(*a*) 'Every light source (except one of low brightness *) within a distance of 100 feet from any person employed shall be so shaded that no part of the filament, mantle, or flame is distinguishable through the shade, unless it be so placed that the angle between the line from the eye to an unshaded part of a source and a horizontal plane is not less than 20 deg., or in the case of any person employed at a distance of 6 ft. or less from the source, not less than 30 deg.'

(*b*) 'Adequate means shall be taken, either by suitable placing or screening of the light sources, or by some other effective method, to prevent direct reflection of the light from a smooth or polished surface into the eyes of the worker.'

(*c*) 'Adequate means shall be taken to prevent the formation of shadows which interfere with the safety or efficiency of any person employed.'

(*d*) 'No light sources which flicker or undergo abrupt changes of candle-power in such manner as to interfere with the safety or efficiency of any person employed shall be used for the illumination of a factory or workshop.'

---

* By 'low brightness' is meant an intrinsic brilliance of not more than five candles per square inch. 'Examples of sources of low brightness are a batswing burner, a paraffin flame, etc., and sources of about the same brightness as these are not regarded as coming within the scope of this recommendation.

'It should be remembered that the covering of a brilliant source by a very small shade (such as a silica cup covering a high-pressure gas mantle, or a small opal globe surrounding a high-power electric source) may give this shade or globe a brightness three or four times as great as the five candles per square inch, so that it may cause considerable glare and should consequently be treated as a source of light in itself.'

Two standards 'for fine work' and 'for very fine work' are recommended. For processes grouped in Schedule A the illumination shall not fall below three foot-candles, and for processes grouped in Schedule B shall not fall below five foot-candles.

The schedules give the class of work, and cover a large number of trades.

Illumination Calculations.

During recent years, the 'point-to-point' system referred to in the early part of this section has been abandoned in favour of the 'lumen' method of pre-determining the lighting for an installation. This is essentially due to the fact that, owing to the accumulated experience of illuminating engineers, it has been found possible to take into consideration the contributory effects due to reflection from the ceiling and the walls. The following gives the method of procedure that is adopted generally at the present time :—

Steps in the Design of a Lighting System.

1. *Intensity of Illumination.*

The foot-candle illumination according to present standards for different classes of operations are given on pp. 2533–2534. These values are the minimum to be adhered to if fully satisfactory lighting is to be assured. In many circumstances, particularly where dark materials are being used, or extremely fine work carried out, higher values of illumination are desirable.

2. *Type of Lighting Unit.*

The selection of the lighting unit depends, not only on the requirements of the work, but in some measure on the construction of the room and the colour of the ceiling and walls. For instance, it would be undesirable to install totally indirect lighting equipment where the ceilings are very dark. The choice of a particular fitting would depend as to which of the factors of glare, reflected glare, efficiency, etc., are the more important. For instance, in an office the criteria would rank as follows in importance :—

1. Freedom from direct glare.
2. Freedom from reflected glare.
3. Illumination on the horizontal plane.
4. Softness of shadows.
5. Favourable appearance of room.
6. Maintenance.
7. Illumination on the vertical plane.

In a machine shop the relative importance may be taken as :—

1. Freedom from direct glare.
2. Freedom from reflected glare.
3. Illumination on the horizontal plane.
4. Illumination on the vertical plane.
5. Softness of shadows.
6. Maintenance.
7. Favourable appearance of room.

Various representative types of fittings are rated according to these headings in Table II. on pp. 2535–2536. Four ratings are employed, Excellent, Good, Fair, and Poor. If a unit is rated 'Poor' for any characteristic, an installation of such units will very probably prove unsatisfactory if that particular characteristic is of prime importance for the installation under consideration. On the other hand it will be understood that a unit may not necessarily be disqualified because it is rated as 'Fair,' or even 'Poor,' in certain features, so long as its ratings are 'Excellent' or 'Good' in the essential characteristics for that specific installation.

3. *Location of Unit.*

Table III. shows the desirable spacing of units, according to the permissible mounting height. When these spacings are used, reasonably uniform illumination will result. Consult also the diagrams at bottom of Tables III. (*a*) and III. (*b*) pp. 2537–2538.

4. *Size of Lamp.*

After the position of the units has been settled on the plan according to the space permissible the size of the lamp can be determined by the consideration of the following factors :—

1. *The Room Index.*—In a large room with many points the system would have a higher coefficient of utilisation than in a small room. This is due to the fact that a number of units help to contribute directly the amount of light that reaches the table or bench without loss due to reflection from the walls, etc. The room index should be obtained from p. 2539, taking into consideration the proposed mounting height of a fitting.

2. *Depreciation Factor.*—Due to the settlement of dust and dirt on fittings and the deterioration in reflectivity of the walls and ceiling, the illumination will depreciate in the course of time. It is usual to allow a factor of 1·3 for reasonably clean locations and 1·5 where cleaning is infrequent or in dirty locations.

3. *Coefficient of Utilisation.*—On pp. 2540–2543 coefficiencies of utilisation are given for a particular fitting. Having chosen the fitting and obtained the value of the room index from Table IV., p. 2539, the corresponding coefficient of utilisation, according to the nature of the ceiling and walls can be readily obtained. This figure represents the percentage of the lumen generated by the lamp that reach the plane of work.

$$\left.\begin{matrix}\text{Lamp Lumens required}\\ \text{per sq. ft.}\end{matrix}\right\} = \frac{\text{Foot-candles} \times \text{depreciation factor}}{\text{Coefficient of utilisation}};$$

$$\text{Area in sq. ft. per unit} = \frac{\text{Total floor area in sq. ft.}}{\text{Number of units}};$$

$$\left.\begin{matrix}\text{Lamp Lumens required}\\ \text{per unit}\end{matrix}\right\} = (\text{Area in sq. ft. per unit}) \times (\text{Lamp lumens required per sq. ft.}).$$

Having thus determined the lamp lumens required per point, the wattage of the lamp to be used can be obtained by reference to Table below.

LUMENS RATINGS AND DIMENSIONS OF GAS-FILLED LAMPS.

(1930.)

Volts.	Rated. Watts.	Approx. Rated. Lumens.	Maximum Overall Dimensions. Length.	Dia. of Bulb.	Dia. of Neck.	Light Centre Length with Standard Cap.	Tolerance on Light Centre Length.	Standard Caps.
			mm.	mm.	mm.	mm.		
100 to 130	60	711*	122	65	45	85	± 3	B.C
	75	938*	130	70	51	90	± 3	,,
	100	1,300*	145	80	53	100	± 3	,,
	150	2,070	170	92	45	120	± 4	B.C. or E.S.
	200	2,880	215	103	48	150	± 5	E.S.
	300	4,650	250	113	55	180	± 6	G.E.S
	500	8,450	280	133	60	205	± 6	,,
	1,000	18,700	340	173	70	250	± 8	,,
	1,500	29,400	340	173	70	250	± 8	,,
200 to 260	60	576*	122	65	45	85	± 3	B.C
	75	780*	130	70	51	90	± 3	,,
	100	1,135*	145	80	53	100	± 3	,,
	150	1,875	170	92	45	120	± 4	B.C. or E.S.
	200	2,600	215	103	48	150	± 5	E.S.
	300	4,140	250	113	55	180	± 6	G.E.S
	500	7,500	280	133	60	205	± 6	,,
	1,000	16,900	340	173	70	250	± 8	,,
	1,500	27,000	340	173	70	250	± 8	,,

* Value applies to both Pearl and Clear Lamps.

When the lamp lumens required fall midway between two sizes, then it is usual to choose the larger rather than the smaller, unless it is certain that the less illumination from a smaller lamp will suffice.

ILLUMINATION DESIGN FOR A DEPARTMENTAL STORE MAIN FLOOR.

The following is an example in the procedure of designing illumination for a departmental main store:—

Store is 180 ft. long and 150 ft. wide with a 16-ft. ceiling. Columns divide the area into 15 ft. × 15 ft. bays. Ceiling, walls, and pillars are painted white. Supply voltage, 100. Height of counter, 3 ft.

Summary of Steps in the Design.	Reference.	Required Data.
1. Foot-candles recommended	Table I.	15
2. Type of fitting used	Table II.—p. 2535	Unit No. 16
3. Spacing and mounting height		
Possible mounting height above work	Depends upon ceiling height	12 ft.
Maximum spacing permissible	Table III.(*a*)—p. 2537	18 ft.
Actual spacing to suit interior	Symmetrical layout with respect to bays	15 ft.
Actual mounting height above work	—	10 ft.
Height above floor	—	13 ft.
4. Size of Lamp		
Room index	Table IV.—p. 2539	5·0
Coefficient of utilisation	Table V.—p. 2540	0·52
Depreciation Factor	According to dust and dirt conditions	1·3
Lamp lumens required per point	Formula—p. 2532	8437
Lamp size	Table—p. 2532	500-watt gasfilled

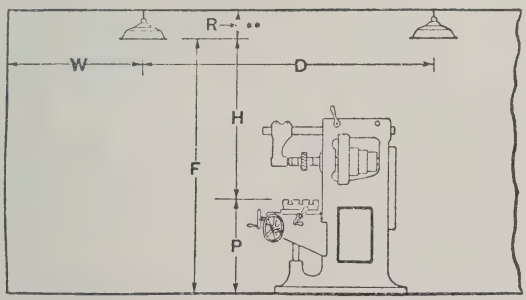
* For luminous bowl type, Rate A.

TABLE III. (*a*).—SPACING—MOUNTING HEIGHT.

Direct Lighting Units, including Semi-Enclosing and Totally Enclosing Units, No. 1 to No. 21.

Mounting Height of Unit.			Distance between Points and Sidewalls.	
Above Plane of Work. (H)	Above Floor.* (F)	Distance between Points. (D)	In Usual Locations where Aisles & Storage are Next to Wall. (W)	In Offices or where Work Benches are Next to Wall. (W)
4	6½	6	3	2
5	7½	7½	3½	2½
6	8½	9	4½	3
7	9½	10½	5	3½
8	10½	12	6	4
9	11½	13½	6½	4½
10	12½	15	7½	5
11	13½	16½	8	5½
12	14½	18	9	6
13	15½	19½	9½	6½
14	16½	21	10½	7
15	17½	22½	11	7½
16	18½	24	12	8
18	20½	27	13½	9
20	22½	30	15	10
22	24½	33	16½	11
24	26½	36	18	12
27	29½	40½	20	13½
30	32½	45	22½	15
35	37½	52½	26	17½
40	42½	60	30	20



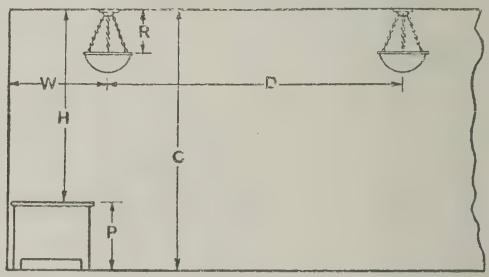
* Plane of work (P) assumed to be 2½ ft. above floor. When the plane of work is higher or lower than 2½ ft. above floor, neglect column (F) and work from column (H).

** Minimum allowance for (R) usually 1 ft.

TABLE III. (*b*) SPACING—MOUNTING HEIGHT.

Semi and Totally Indirect Lighting Units, No. 22 to No. 28.

Ceiling Height.		Spacing Distance Between Points.	Distance Between Points and Sidewalls.		Suspension Distance Ceiling to Top of Reflector.†
Above Plane of Work.	Above Floor.*		In Usual Locations where Aisles and Storage are Next to Wall	In Offices or where Work Benches are Next to Wall	
(H)	(C)	(D)	(W)	(W)	(R)
5	7½	7½	3½	2½	1½
6	8½	9	4½	3	1½
7	9½	10½	5	3½	1½
8	10½	12	6	4	2
9	11½	13½	6½	4½	2¼
10	12½	15	7½	5	2½
11	13½	16½	8	5½	2¾
12	14½	18	9	6	3
13	15⅓	19½	9½	6½	3¼
14	16½	21	10½	7	3½
15	17½	22½	11	7½	3¾
16	18½	24	12	8	4
18	20½	27	13½	9	4½
21	23½	31½	15½	10½	5½
24	26½	36	18	12	6
27	29½	40½	20	13½	6¾
30	32½	45	22½	15	7½
35	37½	52½	26	17½	8½
40	42½	60	30	20	10



* Plane of work (P) assumed to be 2½ feet above floor. When the plane of work is higher or lower than 2½ feet above floor, neglect column (C) and work from column (H).

† Suspension distances (R) in Table are based on best distribution of light and efficiency of utilisation for standard units. In some installations other considerations may require a different suspension distance.

Table IV.—Room Index.

Classify the room according to the proportions and the mounting height above the plane of work. Use upper column headings for direct-lighting units; for semi-indirect and totally indirect units choose column at bottom of page. Wherever the circumstances are such that the room index falls between two given figures, interpolate or use the smaller number.

Room Width.	Room Length.	Direct Lighting Units—Height Above Plane of Work. Feet												
Feet.	Feet.	4	5	6	7	8	9	10	12	14	16	20	24	30	40

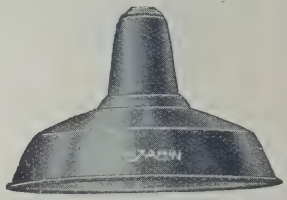

FIG. 8.

Characteristic Curves.

Biflector.

FIG. 9.

R.L.M.

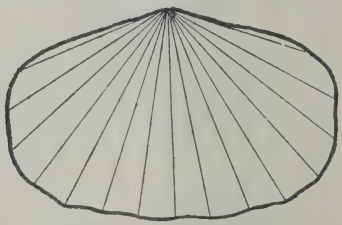

FIG. 10.

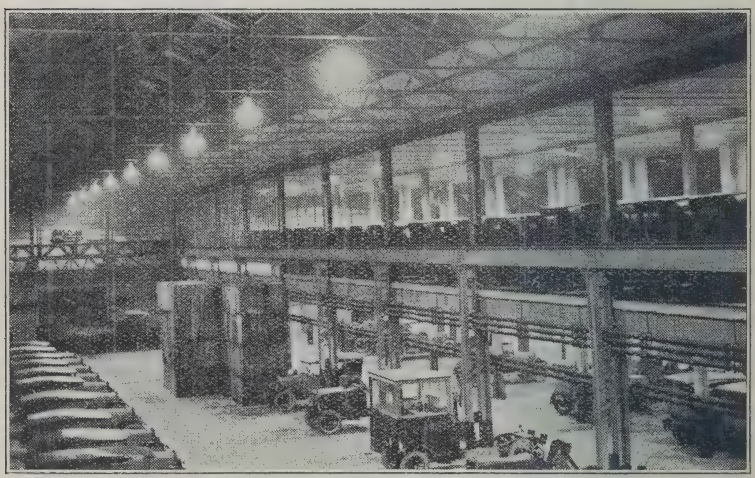

FIG. 11.—General Lighting in a large Motor Works (Benjamin R.L.M. Dispersive Reflectors).

It should be borne in mind that polar distribution curves represent the intensities corresponding with different angles to the vertical or horizontal axis of an illuminant. The area enclosed by such curves must not be associated with the total quantity of light emitted by the source.

Fig. 11 shows the excellent effect of using Benjamin R.L.M. Dispersive Reflectors in a large works.

See also British Standard Specification for Industrial Reflector Fittings for Electric Lighting, No. 232, 1926.

Gas Lighting in Factories.

This may be either of high pressure (60 to 100 inches water gauge) or low pressure (4 to 6 inches water gauge).

The amount of gas that must be consumed to provide a given number of foot-candles of illumination over the area of a workshop may be computed as follows:—

High pressure $\frac{A \times I}{200}$ = c. ft. per hour; Low pressure $\frac{A \times I}{100}$ = c. ft. per hour,

where A is the area to be lighted in square feet and I is the average illumination required in foot-candles.

Thus assume a workshop having a floor area of (say) 2,000 sq. ft., and an average illumination of 4 ft.-candles is required. According to the foregoing formula, the lighting units as a whole would have to consume,

High pressure $\frac{2{,}000 \times 4}{200} = 40$ c. ft. per hr. Low pressure $\frac{2{,}000 \times 4}{100} = 80$ c. ft. per hr.

Generally it will not pay to put in high-pressure plant unless the total candle-power exceeds 1,000 candles.

It remains to subdivide the installation into separate lighting units, so as to ensure as nearly as possible a uniform illumination in order that all parts of the workshop are equally available for practical use.

For instance, to develop the light from 80 cubic feet of low-pressure gas, any one of the following arrangements may be used.

No. of Lamps. . .	20	16	10	8
Cub. ft. per hour, each	4	5	8	10
Total of all Lamps .	80	80	80	80

Even larger lamps may be used, units ranging from 25 to 4,000 candle-power being available. The particular arrangement that may be used will depend partly upon the structural features of the building and the kind of work being done. Sometimes a uniform illumination must be aimed for, or in other cases it may be desirable to have certain areas extra-illuminated, the intervening areas being somewhat subdued.

Generally it is not advisable to rely upon the reflecting power of walls, because in the first place the use of reflecting shades prevents much of the light from the lamps reaching the walls, and secondly, although the whitewashed surfaces have a reflect on coefficient of 80 per cent. when new, this rapidly deteriorates to less than half this value, due to dust created by moving machinery.

The greater the candle-power of the lighting unit used, the higher it should be placed; and in order that the illumination from the separate lamps shall overlap they should be disposed so that the distance between their centres is 1½ to 2 times their height above the level at which work is being done.

The following points may be noted:—

If gas lamps have to be arranged amongst running shafting or belting, remote control may be used to ensure safety in lighting and extinguishing.

If there is excessive vibration the premature fracture of mantles can be prevented by using anti-vibrators.

Gas lamps may be arranged if required for use at various heights.

If the air round the lamps is extraordinarily dusty, the use of Keith-Blackman's 'group' system will ensure their perfect working.

For large work, lamps 9 feet to 10 feet above floor level will be found convenient This would need moderate size lamps, consuming 10 to 15 cubic feet per hour and spaced 9 to 12 feet between centres.

For smaller work, lamps consuming 5 cubic feet per hour, set at 7 to 8 feet above floor level and 6 to 9 feet between centres, will be found suitable.

Artificial Daylight.

On many occasions it is essential that artificial lighting shall approximate in quality to that obtained during the daytime. Particularly is this important in artists' studios and picture galleries, since the light obtained from an incandescent lamp has a greater proportion of red radiation than daylight. This has the effect of the blue and violet colours losing their life and the yellow and red becoming accentuated. Again in dye works and in some shops it is necessary to match colours, and in order to facilitate operation under such circumstances after daylight several expedients have been devised.

A gas-filled lamp is now available in which the filament operates in a selectively tinted blue daylight bulb, which has the effect of filtering the causes of red radiation. It is essential, however, to bear in mind that when daylight lamps of this order are being used that a lamp of sufficient wattage be employed. It is a good rule to bear in mind that, if under ordinary circumstances a 60-watt lamp is required, then in order to produce approximately daylight effects a 100-watt daylight lamp will be required.

A further use for these gas-filled lamps is their employment in the grading of flour or the grading of leather. It sometimes happens that even the colour which is obtained in this way as not sufficiently accurate, in which case special glass filters and reflecting materials have been designed. In such few cases in which they must be employed it is still more important to have an ample size of electric lamp. (See 'Standard Types of Gas-filled Lamps,' p. 2532.)

SECTION XXXVIII

PART IV

FIRE EXTINCTION.

STANDARDS OF FIRE-RESISTANCE.

STANDARD TABLE FOR FIRE-RESISTING SINGLE DOORS, WITH OR WITHOUT FRAMES.

Classification.	Sub-Class.	Duration of Test at Least.	Minimum Temperature.	Thickness of Material.	Minimum Superficial Area under Test.	Minimum Time for Application of Water under Pressure.
		Min.	Deg. F.		Sq. Ft.	Min.
Temporary protective class	A	45	1500	2 in. and under	20	2
	B	60	1500	Optional	20	2
Partial protective class	A	90	1800	2½ in. and under	20	2
	B	120	1800	Optional	20	2
Full protective class	A	150	1800	½ in. and under	25	2
	B	240	1800	Optional	25	5

(*International Fire-prevention Congress.*)

Fire-Resisting Substances.

Exhaustive tests seem to show that sulphate of aluminium is one of the best fire-resisting substances for wood, as it checks combustion by forming an infusible and non-conducting coating, while such substances as ammonium sulphate or ammonium phosphate when heated check combustion by emitting an incombustible gas.

The following is the formula for what is known as the United States 'Government whitewash mixture,' which also acts as a fire-retarding coating over interior wooden surfaces:—Slake a half bushel of quicklime with boiling water, keeping it covered during process; strain and add one peck of salt dissolved in warm water; put 3 lbs. ground rice in water and boil to a thin paste; ½ lb. of powdered Spanish whiting; 1 lb. of clean glue dissolved in hot water. Mix well and let it stand for several days. Keep the mixture in a kettle or receptacle, and apply as hot as possible with a whitewash or paint brush.

(See also p. 333.)

Fire Streams.

TABLE SHOWING PRESSURE REQUIRED AT NOZZLE AND AT PUMP, WITH QUANTITY AND PRESSURE NECESSARY TO THROW GOOD EFFECTIVE STREAMS VARIOUS DISTANCES THROUGH DIFFERENT SIZE NOZZLES, USING 100 FEET OF ORDINARY 2½-INCH RUBBER-LINED HOSE AND SMOOTH NOZZLES.

N.B.—The above pressures are based on the supposition that the hose is coupled direct to the delivery of the pump and while the stream is flowing; if, however, the hose is coupled to a hydrant which is supplied direct from the pump, then the corresponding fire pump pressure must be greater than the hydrant pressure by an amount equal to friction loss and difference of head between hydrant and pump.

The pressures given in the table are *indicated* pressures, not effective pressures; effective pressures would be slightly greater.

The distances given are for *effective* fire *streams* adapted for fire purposes, and are not for mere isolated drops. (*Freeman.*)

Fire Streams and Electric Circuits.

It has always been believed to be dangerous to those handling a hose line to allow the stream to come in contact with an electric circuit. Prof. F. C. Caldwell has found by experiment that there is no danger of shocks when the distance between the nozzle and circuit is more than 25 ft., irrespective of the voltage. (*'Power.'*)

Fire Extinguishers.

Sawdust possesses some special merits as a fire extinguisher when dealing with small outbreaks of liquid combustibles, such as lacquer and petrol, which are usually difficult to extinguish by ordinary means. Sand is generally looked upon as the best substance to use in such cases when it can be applied promptly, but tests have shown sawdust to be superior.

The British Fire-Prevention Committee carried out a series of tests, the results of which tended to prove that sawdust intimately mixed with bicarbonate of soda and applied in bulk has certain advantages over sand and similar materials as an extinguishing medium for comparatively small fires occasioned by the ignition of the vapour of petroleum spirit (petrol) and other inflammable liquids. Ordinary sawdust, as obtained from saw-mills, is the most suitable for this purpose. It must be free from shavings and chips of wood, but it does not require to be either specially dried or to contain added moisture. The addition of bicarbonate of soda, although not essential, is advantageous. The Committee found an effective proportion of bicarbonate of soda to sawdust to be 10 lbs. to 1 bushel (or, say, 12 lbs.) of sawdust. The Committee wished to emphasise the fact that so far their investigations had been limited to small quantities of inflammable liquids, not exceeding 2 gallons, and the areas over which they were spread did not exceed 6 ft. square. These conditions are met with in motor garages and hangars, for which, in the opinion of the Committee, the proposed mixture is applicable and economical. The Committee added that their tests showed that the application of this or any similar mixture in small quantities from tubes or canisters does not give satisfactory results.

Some extensive tests carried out by the Standard Oil Company have proved that the foam method of fighting oil fires is ineffective unless the foam is applied gently at the surface of the burning oil. A 55,000-barrel tank burned right out although enough foam was dropped into it to form a blanket 6 ft. thick. When, however, the foam was applied through asbestos pipes reaching to the surface, experimental fires in the same tank were quickly put out.

British Standard Specification for Materials and Constructional Strength of Chemical Fire Extinguishers.*

(*Abstract.*) (No. 138—1922.)

Definition.

1. The term 'Chemical Fire Extinguisher' under this Specification denotes a vessel or machine manufactured as a Fire Appliance in which the pressure necessary to project the extinguishing fluid is generated automatically either by chemical action or by the release of compressed gas in a capsule within or affixed to the vessel itself.

Size.

2. This Specification applies only to Extinguishers having a fluid capacity of three Imperial gallons and under.

Shape.

3. The shape of the vessel may be cylindrical or conical.

Method of Actuating.

4. The machine may be actuated in any of the following ways :—

(*a*) By breaking a hermetically sealed bottle containing acid and thereby allowing this acid to come into contact with an alkaline solution.

(*b*) By turning over the vessel and thereby spilling acid from a bottle into the alkaline solution.

(*c*) By opening a sealed capsule containing high-pressure gas within or affixed to the vessel.

These operations may be performed by striking a knob on the top of the machine, by a blow on the side, or by other means.

* By permission of the British Engineering Standards Association.

Legal.

DEFINITIONS OF MINERALS AND MINES.

By the term 'mineral,' as used in legal documents, is meant a constituent of the earth's crust which possesses in its severed condition an intrinsic value by virtue of its composition, that is to say, 'any substance that can be got from within the surface of the earth which possesses a value in use apart from its mere possession of bulk and weight' (Lord Fletcher Moulton, Court of Appeal, Nov. 23, 1908). The meaning of the word 'mineral' may be affected by the context; according to Lord Halsbury, in 'a grant of *mines* and *minerals*,' it 'is a question of fact what these words meant in the vernacular of the mining world, the commercial world and landowners at the time when they were used in the instrument' (Lord Provost of Glasgow *v.* Fairie, 13 App. Cas. 1888).

In this country a *mine* is defined as a working for mineral carried on by artificial light without intentionally disturbing the surface, whilst a *quarry* is an excavation for the extraction of mineral open to the day; the distinction is important from a legal point of view. It must be noted that a quarry less than 20 feet deep is by law classed as a factory. In many other countries, notably in the United States of America, the distinction between a 'mine' and a 'quarry' depends not upon the method of working but upon the mineral wrought, any working for e.g. building stone, whether underground or open, being classed as a quarry. In legal instruments 'mine' sometimes has the wider meaning of the space containing the minerals, or even from which the minerals have been extracted.

Ownership of Minerals.

In this country the mineral occurring within any area is the property of the owner of the freehold of the surface, with some few apparent exceptions, the most notable of which are the Forest of Dean and the Isle of Man, where the minerals are Crown property because the Crown owns the surface. Minerals containing precious metals—where these metals form the essential value of the mineral—are the property of the Crown wherever found (except in Scotland). Minerals under copyhold land were mostly the property of the Lord of the Manor, who could not, however, as a rule, deal with them save with the consent of the copyholder. Since by the Law of Property Act, 1922 (12 & 13 Geo. V. ch 16, s. 128), copyhold has been abolished, the minerals are as a rule enfranchised and become the property of the tenant, although the latter may, if he so desire, transfer his right to the lord. This law came into force on January 1, 1926 (Law of Property Act (Postponement) Act, 1924).

Generally speaking, in this country the minerals are leased to those exploiting them. 'A mining lease is really a sale payable by instalments' (Henn Collins, Master of the Rolls, *In re* Aldam's Settled Estates, Chanc. 2, 1902). (See Presidential Address by H. Louis, *Trans. Inst. Min. Eng.*, vol. lxxiv (1928), p. 277.) Most often the so-called rental is based on the tonnage exploited, the rate per ton or *royalty* being fixed. For coal this may range from 2*d.* to 2*s.*, but is usually between 4*d.* and 7*d.*, the average for the United Kingdom having been pre-war probably just about 5½*d.* per ton (Royalties Commission, 1889); it is now (1928) 5·74*d.* including wayleaves

per ton of saleable coal raised. Sometimes the royalty is a fraction of the value of the coal, this ranging from $\frac{1}{2}$ to $\frac{1}{50}$; sometimes the rental is a proportion of the profit made; sometimes it is a price per inch thickness of coal seam per acre wrought out. In addition to royalty, wayleaves have often to be paid for; average wayleave in United Kingdom is about $\frac{1}{4}d.$ per ton (Royalties Commission, 1889).

Royalties on stratified ironstone vary from $2\frac{1}{2}d.$ to 1*s.* 6*d.* per ton, averaging about 6*d.*

In the hæmatite mines of Cumberland and Lancashire the royalties vary normally from 1*s.* to 2*s.*, averaging about 1*s.* 9*d.* In the Forest of Dean royalties on iron ore vary from 3*d.* to 5*d.* per ton.

Royalties in Cornwall on tin and copper ores range from $\frac{1}{10}$ to $\frac{1}{20}$ of the value of the mineral raised.

Royalties on lead and zinc ores range from $\frac{1}{4}$ to $\frac{1}{6}$ of the value of the ore raised.

Royalties are often on a sliding scale, the ratio increasing with the market price of the mineral or of its metallic contents.

List of Principal Legislative Enactments affecting Mines and Minerals.

Land Tax Redemption Act, 1798, and subsequent Acts; 'The Mining Code,' Railway Clauses Consolidation Act, 1845, Ss. 74–85; Waterworks Clauses Consolidation Act, 1847, Ss. 18–27; Public Health (Support of Sewers) Act, 1883—see, however, New Moss Colliery *v.* Manchester Corporation, 1908, and Howley Park Coal and Canal Co. *v.* L. & N.W. Railway, 1912; Copyhold Act, S. 48, 1852; Coal Mines Act, 1866; Metalliferous Mines Acts, 1872, 1875; Explosives Act, 1875; Rating Act, 1874; Stratified Ironstone Mines (Gunpowder) Act, 1881; Conveyancing Act, S. 2, 1881; Slate Mines (Gunpowder) Act, 1882; Coal Mines Regulation Act, 1887; Quarries (Fencing) Act, 1887; Quarries Act, 1894; Coal Mines (Check Weigher) Act, 1894; Workmen's Compensation Act, 1897; Coal Mines (Weighing of Minerals) Act, 1905; Workmen's Compensation Act, 1906; Notice of Accidents Act, 1906; Coal Mines Regulation (Eight Hours) Act, 1908; Small Holdings and Allotments Acts, Schedule I., 1908; Mine Accidents (Rescue and Aid) Act, 1910; Coal Mines Act, 1911; Coal Mines (Minimum Wage) Act, 1912; Coal Mines Act, 1914; Feudal Casualties (Scotland) Act, S. 7, 1914; Price of Coal (Limitation) Act, 1915; Coal Mines Control Agreement (Confirmation) Act, 1917; Coal Mines Regulation (Amendment) Act, 1917; Petroleum (Production) Act, 1918; Coal Mines Act, 1919; Coal Industry Commission Act, 1919; Coal Mines (Emergency) Act, 1920; Mining Industry Act, 1920; Finance (1909–10) Act, 1910, Ss. 1–5, 20–24, 25–27, 33, 34; Finance Act, 1912, S. 11; Finance (No. 2) Act, 1915, S. 43; Finance Act, 1916, S. 46; Finance Act, 1917, S. 21; Income Tax Act, 1918, Schedule III.; Finance Act, 1919, S. 33; Finance Act, 1920, Ss. 49, 7; Mines (Working Facilities and Support) Act, 1923. See Report of Mining Cases decided by the Railway and Canal Commission Court under the Mines (Working Facilities and Support) Act, 1923, by P. G. Bamber. Coal Mines Act, 1926 (Amendment of 1908 Eight Hours' Act for 5 years); Mining Industry Act, 1926; Rating and Valuation Act, 1925; Rating and Valuation (Apportionment) Act, 1928; Coal Mines Act, 1930.

Principal Clauses in Colliery Lease.

Description of contracting parties (lessor and lessee) and of property demised.

Powers granted to lessee:—
- To break surface, make shafts, adits, etc.
- To win and work coal, bring to bank, make merchantable, dispose of.
- To work by instroke or outstroke or both.
- To make and dispose of coke and other products.
- To have necessary surface accommodation.
- To have necessary wayleaves.
- To construct roads, tramways, railways, etc.
- To erect buildings, machinery, plant, etc.
- To work quarries of lime, clay, etc. (sometimes for own use only).
- To remove coals, dead and live stock, plant, etc., after expiration of lease.
- To relinquish at stated times before termination of lease.
- To renew lease for a further period.
- To generally do all things necessary for getting coal, etc.

Reservations to lessor:—
- Of mines and minerals not demised.
- Of certain rights and wayleaves.
- Of use of ways, railways, etc.

'Habendum':—
- Lessee to have and hold property for a fixed term of years.

'Redendum':—
- Annual certain rent or deadrent, usually merging into royalty.
- Royalty per ton or otherwise.
- Rent for surface occupied.
- Rent for wayleaves, waterleaves, or other facilities.

Provisoes:—
- No royalty payable in respect of colliery consumption.
- Power to make up short workings of previous years.
- Power to carry over excess workings to subsequent years.
- For distress in case of default in payments.
- For re-entry if rents, etc., remain unpaid for certain period.

Covenants on part of lessee :—
For due payment of rents and royalties.
For due payment of taxes.
For compensating for damage done to surface or to neighbours.
For erecting (or against erecting) buildings, houses, coke-ovens, etc.
For keeping proper accounts accessible to lessor, and rendering the same.
For keeping proper mine plans, and permitting inspection of mine.
For leaving proper barriers.
For working in approved and miner-like manner.
Against sub-letting without authority.
For giving up possession in good condition at determination of lease.
For keeping mine, plant, buildings, etc., in good repair.
For properly fencing or securing shafts, adit mouths, etc.
For giving lessor power to purchase plant, etc., at a valuation on determination of lease.
Covenants on part of lessor :—
For proper title.
For quiet enjoyment.
Arbitration clause.

Leases of ironstone mines as also of metalliferous mines follow practically the same lines; as regards the latter, it is usually set forth that the royalty shall be a certain part of the value of the minerals, cleaned, dressed, smelted, or otherwise rendered merchantable, as the case may demand, at the expense of the lessee. There are often clauses specifying that a certain amount of development work, driving, sinking, etc., shall be performed.

A tacknote or license to prospect is often granted ; this differs from a lease, inasmuch as it transfers no interest in the property. Its usual form is a license for one year to explore for all or for certain specified minerals within a definite area, usually for a nominal consideration, the licensee making compensation for all damages, and paying a royalty on all minerals gotten and sold. The license is generally renewable at the option of the licensee for a term of years, usually three, and the licensee is entitled to a lease upon conditions specified ; this specification often takes the form of a schedule embodying the conditions of a draft lease.

Classification of Mineral Deposits.

A mineral deposit may be defined as a portion of the earth's crust containing mineral matter of intrinsic value under favourable conditions.

The mineral substances that form the subject of mining operations may be classified as under :—

Group I., Fuels ; II., Ores ; III., Salts ; IV., Gems ; V., Rocks.

Group I. contains the different varieties of coal, asphalts, bitumen, and other solid hydrocarbons, mineral oils, etc., while sulphur may conveniently be included.

Group II. contains the various heavy metals either in the native state or in combination.

Group III. contains the haloids, sulphates, carbonates, silicates, phosphates, borates, etc., of the alkaline earths and alkalies.

Group IV. contains those minerals that are prized as gems on account of their hardness, brilliancy, and transparency, as well as the semi-gems, such as opal, turquoise, etc., which though opaque are prized as precious stones on account of the beauty of their colouring and their rarity.

Group V. comprises the various rock masses, such as granite, slate, limestone, etc., the exploitation of which is more properly considered under quarrying.

With respect to their mode of occurrence, mineral deposits may be classified morphologically as follows :—

Tabular = Beds, veins.
Irregular = Masses, lenses, pipes, etc.

A more complete classification, based on genetic as well as morphological characters, is as follows :—

Class I.—Syphythic; Syngenetic, contemporaneous or stratified
- Group *a*, clastic.
- „ *b*, formed by chemical agencies.
- „ *c*, formed by organic agencies.
- „ *d*, disseminated through beds.

Class II.—Epactic; Epigenetic, subsequent or non-stratified.
- Sub-Class A—Veins.
  - Group *a*, fissure.
  - „ *b*, bedded.
  - „ *c*, contact.
  - „ *d*, gash.
- Sub-Class B—Masses.
  - Group *a*, stockworks.
  - „ *b*, disseminated in igneous rocks.
  - „ *c*, connected with igneous rocks.
  - „ *d*, connected with soluble rocks.

Class I.—Group *a* includes auriferous alluvials, tin-bearing alluvials, ironsands, etc. Group *b* contains deposits due to chemical precipitation, to evaporation or to metasomatic changes. Practically all the stratified ironstones belong to this group. Of group *c* the most important

representative is coal. Group *d* includes the Knottensandstein of Mechernich, the Kupferschiefer of Mansfeld, the Banket beds of Johannesburg, and similar deposits.

Class II.—Sub-Class A. Group *a* includes most of the important vein systems of the world, such as those of Cornwall, etc.

Group *b* includes veins parallel to the stratification.

Group *c* embraces certain veins following the contact of dissimilar rocks.

Group *d* contains veins carrying galena and zinc blende that characterise certain limestone districts, e.g., that of Missouri.

Sub-Class B. Group *a* consists of masses traversed by minute veinlets carrying ore, such as the tin deposits of Saxony.

Group *b* comprises such deposits as the Kimberley diamond-bearing pipes, the copper deposits of Lake Superior, etc.

Group *c* are very largely lenticular in form; the pyrite deposits of the Huelva district are a typical example.

Group *d* may be represented by the red hæmatite deposits of Cumberland and Lancashire.

Branches of Mining.

I. Prospecting, the most important part of which is 'boring.'

II. Exploiting, including the various operations of opening up mineral deposits by shafts or adits, extracting and transporting the mineral, securing, pumping and ventilating the workings, and the proper care of the men employed.

III. Dressing or preparing the mineral extracted for the market.

COAL.

Classification.

Coal is generally classified under the three main heads of 'lignite' or 'brown coal,' 'bituminous coal,' and 'anthracite.' Bituminous coal is further classified according to the purposes for which it is best adapted, such terms as gas coals, house coals, furnace coals, smithy coals, steam coals, etc., being usually employed. A classification that is widely adopted is based upon Gruner's work, and is as follows :—

Description of Coal.	Composition of Ash-free Coal.			Percentage of Fixed Residue.	Nature of Residue.	Calorific Power.
	Carbon.	Hydrogen.	Oxygen.			Cal.
Lignite . .	70–75	5·6	15·25	50	Non-coking .	6,000
Dry coals with long flame (furnace coals)	75–80	4·5–5·5	15–19·5	55–66	Pulverulent or very slightly coking	8,000–8,500
Fat coals with long flame (gas coals)	80–85	5·0–5·8	10·0–14·2	60–68	Completely agglomerated, porous	8,500–8,800
Fat coals proper (smithy coals)	84–89	5·0–5·5	5·5–11·0	68–74	Completely agglomerated, more or less porous	8,800–9,300
Fat coals with short flame (coking coals)	89–91	4·5–5·5	5·5–6·5	74–82	Coked, compact	9,300–9,600
Anthracite .	90–93	4·0–4·5	3·0–5·5	82–90	Pulverulent .	9,200–9,500

Seyler's classification is based upon the percentage of hydrogen in the ash-free coal and the ratio of carbon to hydrogen :—

Genus.	H per cent.	C : H.
1. Anthracite	< 4	> 22
2. Carbonaceous	4–4·5	20·3–23·35
3. Semi-bituminous	4·5–5	16·6–20·4
4. Bituminous	5–5·8	14·6–18·2
5. Per-bituminous	> 5·8	12·9–14·7

(*Strahan & Pollard.*)

CLASSIFICATION OF THE INTERNATIONAL GEOLOGICAL CONGRESS, CANADA.

Class.	Name.	Fuel Ratio.	Composition.			Percentage of Volatile Combustible Matter.	Calorific Power B.Th.U.
			C.	H.	O & N.		
A_1	Anthracite	12 or more	93–95	2–4	3–5	3–5	14,500–15,000
A_2	Semi-Anthracite	7–12	90–93	4 4·5	3–5·5	7–12	15,000–15,500
B_1	High Carbon Bituminous	4–7	80–90	4·5–5	5·5–12	12–15	15,200–16,000
B_2	Bituminous	1·2–7	75·90	4·5–5·5	6–15	12–26	14,000–16,000
B_3	Low Carbon Bituminous	—	70–80	4·5–6	18–20	up to 35	12,000–14,000
C	Cannel	—	—	—	—	30–40	12,000–16,000
D_1	Lignitic	—	60–75	6–6·5	20–30	—	10,000–13,000
D_2	Lignite	—	45–65	6–6·8	30–45	—	7,000–11,000

Class B_2 comprises most of the coking coals; in Class D_1 moisture is 6–20 per cent., in D_2 over 20 per cent.

CLASSIFICATION OF THE IMPERIAL MINERAL RESOURCES BUREAU.

A, Brown coal or lignite; B_1, gas coal and cannel; B_2, coking coal: B_3, house coal; B_4 manufacturing or iron smelting coal; B_5, steam coal; C, anthracite.

Other classifications are also used; one much liked in America is based upon the 'fuel ratio,' that is, the figure obtained by dividing the percentage of fixed carbonaceous residue by the percentage of volatile matter.

CONSTITUTION OF COAL.

The four constituents of coal, as identified by Dr. Marie Stopes, are:—

(1) Fusain. (2) Durain. (3) Clarain. (4) Vitrain.

Some authorities (*e.g.* Stach, *Glückauf*, 1927, p. 759, Kellett, *Trans. Inst. Min. Eng.*, vol. lxxv., 1928, p. 400) hold that Clairain is merely a mixture of Vitrain and Durain. In the U.S.A. these three classes are generally spoken of as Anthraxylon, Attritus, and Fusain. Fusain forms, usually, under 10 per cent. of a coal seam and is the highest in ash, this ash being always high in lime; it also usually carries more salt than the rest of the seam. Vitrain is very low in ash, generally under 0·5 per cent. Durain ash contains mainly silica and alumina. Fusain is non-coking, but its calorific power is high and it is valuable for dust-firing.

CALORIFIC POWER.

The calorific power may be calculated from the ultimate analysis by the 'Deutscher Verband' formula:—

$$\text{Cal. power in calories} = 81\,C + 290\left(H - \frac{O+N}{8}\right) + 25\,S - 6\,W,$$

where C, H, O, N, S, and W are the percentages, respectively, of Carbon, Hydrogen, Oxygen, Nitrogen, Sulphur, and Moisture.

Gontal's formula is applied where only the proximate analysis (percentages of fixed carbon, volatile matter and ash) is known.

Let C be percentage of fixed carbon, V of volatile matter, A of ash; then

$$\text{Cal. power in calories} = 82\,C + a\,V,$$

where a is a coefficient depending upon the percentage of volatile matter in the ash-free coal, *i.e.* upon $\frac{100\ V}{100-A}$ as follows:—

$\frac{100\ V}{100-A}$	5	10	15	20	25	30	35	40
a	145	130	117	109	103	98	94	80

The ash of coals varies usually between 3 and 15 per cent.

1 lb. of ordinary coal requires theoretically 130 cub. ft. of air for complete combustion.

COKE.

Ordinary bituminous coal, containing 25 to 30 per cent. of volatile matter, coked in a modern regenerative bye-product coke-oven plant, yields approximately:—

Coke	70–75 per cent.
Tar	3·5–4·5 „
Ammonia as ammonic sulphate	1–1.25 „
Crude benzol	1 „

Surplus gas, 3,000 to 5,000 cub. ft. per ton of coal.

The composition of this gas is about as follows:—Hydrogen, 48 to 55 per cent.; methane, 25 to 34 per cent.; carbonic oxide, 6 to 8 per cent.; carbonic acid, 2 to 2·5 per cent.; hydrocarbons, 2 to 4 per cent.; nitrogen, etc., 5 to 12 per cent. The calorific power is about 480 to 600 B.Th.U. gross, or 425 to 550 B.Th.U. net.

Weight of Coal.

The specific gravity of coal varies from 1·1 to 1·6, most bituminous coals approximating to 1·3. The following table shows the weight of coal contained in one acre of superficial area per inch thickness of seam.

Table of the Weight of Coal under Different Circumstances.

Specific Gravity.	Weight in the Natural Bed, per Acre, per Inch Thick, in Tons.	Weight of a Cubic Foot in the Broken State, in Lbs.	
		Large Coal.	Small Coal.
1·10	111·411	42·62	37·12
1·15	116·475	44·56	38·81
1·20	121·540	46·50	40·50
1·25	126·604	48·43	42·18
1·30	131·668	50·37	43·87
1·35	136·732	52·31	45·56
1·40	141·796	54·25	47·25
1·45	146·860	56·18	48·93
1·50	151·925	58·12	50·62

Specific gravity × 101·283 = weight in tons per inch thick per acre.

To find the contents of coal of any given specific gravity per acre multiply the figure in the table by the thickness of the seam in inches; the thickness measured along a vertical line should always be taken, as the correct result will thus be obtained, whatever may be the inclination of the coal seam.

The weight of coal in its broken state, that is, as it comes to the surface, in tubs or otherwise, will depend on its largeness; the large has here, however, been computed to weigh in proportion to the solid coal as 62 to 100, and the small as 54 to 100.

The calculation now most commonly adopted in the North of England to ascertain the weight of coal in the solid state is to reckon 19 cwts. per cubic yard = 78·815 lbs. per cubic foot. On this calculation, a seam 1 foot in thickness would contain 1,532 tons 13 cwts. 1 qr. 10 lbs. per acre, and a seam 1 yard thick would contain 4,598 tons per acre.

A summary way of reckoning the quantity of available coal in a given area of a seam is to take an acre of coal 1 inch thick to produce 100 tons. This leaves a sufficient margin for faults and losses in barriers and in working.

Sizing of Coal.

In the coal trade coal is often sold by size, but there is no uniformity in practice even in the same field. Above 4 ins. to 6 ins. is usually sold as Best Coal, House, or Best House; a very general scheme of designations is:—

Cobbles	between 5 ins. to 6 ins.	and about	$3\frac{1}{2}$ ins. to 3 ins.
Treble nuts	„ $3\frac{1}{2}$ „ 3 „	„	$1\frac{1}{2}$ „
Double nuts	„ $1\frac{1}{2}$ ins.	„	1 in. to $\frac{3}{4}$ in.
Single nuts	„ 1 in. to $\frac{3}{4}$ in.	„	$\frac{5}{8}$ in.

Duff, slack or gum below $\frac{5}{8}$ in.

Some collieries also make beans, say about $\frac{5}{8}$ in. to $\frac{3}{4}$ in. and peas, say about $\frac{3}{4}$ in. to $\frac{7}{16}$ in. The dimensions may signify plate screens with round or with square holes, bar screens or wire gauze; in the two latter they may be measured in the clear or centre to centre. All these different methods are in use.

With reasonably closely sized coal of whatever dimensions it is found that as ordinarily heaped the coal occupies 55 per cent. of the total volume of the heap.

METALLIFEROUS MINERALS.

By *metalliferous* minerals or *metallic* minerals are meant those minerals that are technically utilisable for the extraction of the ordinary commercial heavy metals, metals of the alkalies and alkaline earths being excluded; this is almost identical with the meaning of *ores*, or with Group II. of above classification. In United States of America and Canadian statistics, a wider meaning is given to *non-metallic* minerals, which includes all minerals not actually used for the extraction of metals, *e.g.* ochre, although this is an oxide of iron, because it is used as a pigment and not as a source of iron.

COMPOSITION OF MORE IMPORTANT ORES.

Name.	Formula.	Percentage of Metal.
Magnetite	Fe_3O_4	Fe 72·4
Hæmatite	Fe_2O_3	„ 70
Limonite	Fe_2O_3,H_2O	„ 60
Brown hæmatite	Hydrated ferric oxide, with 10-15 per cent. H_2O	„ 45-55
Siderite	$FeCO_3$	„ 48·3
Ilmenite	$(TiFe)_2O_3$	„ 30-40
Pyrites	FeS_2	„ 46·7
Pyrrhotite	Fe_7S_8	„ 60·5
Pyrolusite	MnO_2	Mn 63·3
Manganite	$Mn_2O_3H_2O$	„ 62·5
Wad	Impure hydrated manganese oxide	„ 25-50
Chalcopyrite	$Cu_2SFe_2S_3$	Cu 34·6
Chalcocite	Cu_2S	„ 79·8
Malachite	$2(CuO)CO_2,H_2O$	„ 56
Cinnabar	HgS	Hg 86·2
Galena	PbS	Pb 86·6
Cerussite	$PbCO_3$	„ 77·5
Anglesite	$PbSO_4$	„ 68·3
Blende	ZnS	Zn 67
Calamine	$ZnCO_3$	„ 52
Stibnite	Sb_2S_3	Sb 71·8
Mispickel	$FeAs_2S_2$	As 46
Cassiterite	SnO_2	Sn 78·7
Wolfram	$(FeMn)OWO_3$	W 70
Scheelite	$CaOWO_3$	„ 74·8

IRONSTONE.

Ironstone is the term applied to stratified or symphytic deposits workable for iron, iron ore to epactic deposits, veins or masses. Bessemer ore or hæmatite ore is generally understood to mean iron ore with less than 0·035 per cent. of phosphorus when the ore contains about 50 per cent. of iron. Such ores are usually quoted on a basis of 50 per cent. of iron, with a definite increase or deduction in price for each unit of iron above or below that figure, and a penalty for every unit of silica above a given percentage, often 8 per cent.

The yield of ironstone is often taken roughly at 2,000 tons per foot thick per acre.

HAEMATITES.

These weigh 3–3·5 tons per cubic metre in place, 2¼ tons per cubic metre in mine cars, 2 tons per cubic metre stacked.

TABLE OF BRITISH MESOZOIC IRONSTONES.

Formations.			*Name of Ironstone.*
CRETACEOUS—Neocomian	Wealden	Lower Greensand	Seend, Wiltshire.
		Weald Clay	
		Hastings Sand	Sussex and Kent.
			Westbury, Wiltshire.
			Claxby, Lincolnshire.
JURASSIC	Upper Oolite		
	Middle Oolite	Corallian	Dover, Kent.
		Oxford Clay	Westbury, Wiltshire.
	Lower Oolite	Great Oolite	
		Estuarine Beds	
		Northampton Sands	Northamptonshire.
			Cleveland Dogger or Top Seam.
	Upper Lias	Upper Lias Clay	
		Toarcian	Isle of Raasay.
	Middle Lias	Middle Lias Limestone	Cleveland Main Seam.
			Cleveland Pecten Seam.
			Cleveland Avicula Seam.
		Marlstone	Blenheim, Oxfordshire.
			Melton Mowbray, Leicestershire.
			Caythorpe, Lincolnshire.
	Lower Lias		Frodingham, Lincolnshire.

COMPOSITION OF BRITISH MESOZOIC IRONSTONES, DRIED AT 100° C.

COPPER, TIN, LEAD AND ZINC ORES.

Copper, tin, lead, and zinc ores are usually sold by assay. The value is calculated on the current market price of the metal multiplied by the percentage of metal present less the percentage estimated to be lost in the operation of smelting; from the value thus found there is then deducted the 'returning charge,' being the estimated cost of smelting the ore, including the smelter's profit, etc. The following were the generally accepted (pre-war) methods :—

COPPER ORES.—Weight paid for is gross weight less moisture and less 1 per cent. draftage. Wet assay less 1 per cent. for ores assaying 3–4 per cent. (deduction varied proportionately for richer or poorer ores); for value per unit (1 per cent.) take 0·01 of price of best selected copper, less returning charge of 2*s.* 3*d.* to 2*s.* 6*d.*

Example.—Cargo of 1,000 tons ore assaying 4 per cent. copper, ¼ per cent. moisture. Net weight $= 1{,}000 - \left(\frac{1{\cdot}25}{100} \times 1{,}000\right) = 987{\cdot}5$ tons.

4 per cent. − 1 per cent. = 3 per cent. copper to be paid for.

Best selected quoted that day 82*l.* 10*s.* per ton = 16*s.* 6*d.* per unit, less 2*s.* 3*d.* returning charge = 14*s.* 3*d.* 3 units at 14*s.* 3*d.* = 42*s.* 9*d.* per ton of ore.

Value of cargo 987·5 tons at 42*s.* 9*d.* = 2,110*l.* 15*s.* 7½*d.*

LEAD ORE.—Weight paid for is net dry weight. Percentage paid for is dry assay less 4 units, on basis of soft foreign lead price in London, subtracting 40*s.* per ton for returning charge. Silver above 3 oz. per ton paid for at current rate for fine silver. Price is understood to be delivered smelter's works.

Example.—150 tons net of galena assaying 78 per cent. of lead and 5 oz. of silver per ton quotations being : lead, 20*l.* per ton; silver, 2*s.* 3*d.* per oz. Lead, 150 tons at (78 − 4) per cent. = 111 tons at 20*l.* = 2,220*l.*, less 150 tons at 40*s.* = 1,920*l.* Silver, 150 × (5 − 3) oz. = 300 oz. at 2*s.* 3*d.* = 33*l.* 15*s.* Total value of ore, 1,953*l.* 15*s.*

ZINC ORE.—Weight paid for is net dry weight. From percentage of zinc, as determined by wet assay, subtract 9 units, multiply by $\frac{18}{20}$ of price of spelter, and subtract returning charge of 3*l.*; difference is price per ton delivered smelter's works.

Example.—If ore assays 50 per cent., London quotation for spelter being 18*l.*, the ore is worth $£\left(\left[\frac{50-9}{100} \cdot \frac{18}{20} \cdot 18\right] - 3\right) = 4l.\ 0s.\ 3d.$ per ton.

The general gangue of most ores is quartz; solid quartz averages about 165 lbs. per cub. ft. (13½ cub. ft. to the ton), broken about 100 lbs. (22½ cub. ft. to the ton), but varies considerably, the weight of veinstuff containing metalliferous minerals can be calculated from the specific gravity of the minerals.

TABLE OF SPECIFIC GRAVITIES AND WEIGHTS PER CUBIC FOOT OF MINERALS.

Mineral.	Sp. gr.	Cwts. per cub. ft.	Mineral.	Sp. gr.	Cwts. per cub. ft.
Copper pyrites	4·1–4·3	2·34	Hæmatite	4·5–5·3	2 73
Copper glance	5·5–5·8	3·15	Brown hæmatite	3·4–4·4	2·17
Malachite	3·7–4·0	2·20	Spathic ore	3·4–3·9	2·04
Cinnabar	8·9–9·0	5·00	Pyrolusite	4·8–4·9	2·67
Galena	7·3–7·7	4·18	Cassiterite	6·4–7·1	3·76
Cerussite	6·4–6·5	3·60	Wolfram	7·1–7·6	4·12
Anglesite	6·1–6·4	3·50	Scheelite	5·9–6·1	3·34
Zinc blende	3·9–4·2	2·23	Quartz	2·5–2·8	1·50
Calamine	4·0–4·5	2·40	Calcspar	2·5–2·8	1·50
Stibnite	4·5–4·6	2·50	Dolomite	2·8–2·9	1·56
Pyrites	4·8–5·2	2·78	Fluorspar	3·0–3·2	1·73
Mispickel	6·0–6·4	3·45	Felspar	2·5–2·8	1·50
Magnetite	4·9–5·2	2·80	Barytes	4·3–4·7	2.51
Ilmenite	4·5–5·0	2·64			

A rib of **mineral 1 in. thick** = 3 cub. ft. per square fathom.

Calculation of Mineral Mixtures.

The percentages of two minerals present in a mixture can easily be calculated if the sp. gr. of the mixture and of the ingredients is known. A convenient method is that proposed by R. T. Hancock.

Take a weight of x grms. of the mixture containing two ingredients of sp. gr., a and b respectively, where $\frac{1}{x} = \frac{1}{a} - \frac{1}{b}$ or $x = \frac{ab}{b-a}$; then the volume of this weight of a alone will differ from that of the same weight of b alone by 1 c.c., and for every 1 per cent. of a (the lighter substance) present in the mixture, the volume will be greater by 0·01 c.c. than the volume of b alone and for every 1 per cent. of b present, less by 0·01 c.c. than the volume of b alone. It is usually convenient to take $10x$ grms., when the differences will be 0·1 c.c.

Example.—To determine percentage of cassiterite (sp. gr. 7) and 'black sand' (sp. gr. 4·5) in a mixture of these. Since $\frac{1}{4{\cdot}5} - \frac{1}{7} = \frac{1}{12{\cdot}6}$, take 126 grms. Volume of mixture, measured by pouring the mixture into a burette partly filled with water and noting the difference in the burette readings, = 20 c.c. Volume of 126 grms. of black sand would be $\frac{126}{4{\cdot}5} = 28$ c.c. Hence percentage of cassiterite = 10 (28 − 20) = 80 per cent.

BORING.

Boreholes are put down by one or other of the following methods :—

I. Percussive: (*a*) Using solid rigid rods. (*b*) Using ropes. (*c*) Using hollow rods (water-flush method). (*d*) Using a hydraulic ram.

II. Rotary: A. Core drills. (*a*) Using diamonds. (*b*) Using steel cutting teeth. (*c*) Using chilled shot. B. Hydraulic rotary oil drill.

Generally speaking, percussive methods are used when the primary object is to get a hole down rapidly, where information as to the nature of the ground passed through is of less importance, whilst rotary core drills, by the use of which a more or less continuous core is obtained, are employed when an accurate knowledge of the strata passed through is the first consideration. Sometimes both methods are combined ; thus in some of the boreholes put down in Kent, boring through the secondary rocks was performed by percussion, whilst rotary core-boring was substituted after the coal measures had been reached. Percussion boring by the ordinary 'English' method can be used to depths of about 500 ft., costing about 10*s.* to 20*s.* per foot, and advancing 2 ft. to 6 ft. per twenty-four hours. Beyond this depth a free-falling cutter must be used, and in this way depths of 3,000 ft. or more may be reached.

Rope boring with round ropes on the American system is used almost exclusively in boring for oil, salt, etc. The plant for a hole 2,000 ft. deep would weigh about 80 tons complete and cost about 2,000*l.* ; holes range from 6 ins. to 15 ins. in diameter. In Pennsylvania and Ohio such boring has been done for as little as 2*s.* per foot, and contracts are usually let at prices ranging from 4*s.* to 8*s.* The rate of boring is from 20 ft. per day upwards. In Middlesbrough, 8-in. holes have been put down to depths of about 1,000 ft. at a cost of about 8*s.* per foot with a speed of 60 ft. per day. Boring with flat ropes by the Mather and Platt system is used for very large boreholes, as for instance for waterworks ; holes up to 45 ins. in diameter have been bored by this method.

The water-flush method, of which there are many varieties (Fauck, Raky, etc.), is used in hard rocks for boreholes of medium size (rarely under 8 ins. in diameter). Very fast boring can be done in this way ; e.g. in the Ruhr district a borehole was put down to a depth of nearly 2,000 ft. at an average speed of 157 ft. per twenty-four hours ; 30 to 50 ft. is quite a usual rate down to depths of about 2,000 ft., and over 20 ft. a day has been bored down to a depth of over 3,000 ft.

The hydraulic ram method appears to offer certain important advantages, especially for boreholes of moderately large diameter, but has hardly passed the experimental stage.

Core Boring.

Diamond boring is in use to-day for hard rocks ; the main drawback is the high price of the 'diamonds' (bort, used in the softer rocks, costs 2*l.* to 3*l.** per carat, carbon costs 6*l.* to 12*l.* per carat), which tells severely against boreholes larger than 6 ins. in diameter. The cost of diamond boring in this country is about 7*s.* 6*d.* per foot down to 500 ft. and 12*s.* to 18*s.* down to 1,500 ft. for a 5-in. borehole. A 5-in. borehole put down in Scotland to 1,800 ft. cost only 6*s.* 4*d.* per foot ; the rate of advance was about 6 ft. per day. In British Columbia a borehole 2,200 ft. deep cost 8*s.* 6*d.* per foot, and was bored at the rate of 10 ft. per day. In Victoria the Government does much boring to aid prospectors ; the bores are mostly shallow, but in

* All costs throughout this article refer to prices before 1913.

one case a depth of 1,110 ft. was reached in about 120 days; the average cost of boring in coal measures in 1912 was 9*s.* 3*d.* and in the harder rocks 14*s.* per foot. In Nova Scotia 2 in. diamond boreholes put down by the Government in moderately hard ground to depths of 200 to 400 ft. averaged about 9*s.* per foot in 1913.

Steel cutting teeth can only be used in tolerably soft ground. The cutter should make 15–25 r.p.m. A 10-in. borehole in Kent was put down by this method by the Calyx Company to a depth of 1,400 ft., the speed at times reaching 10 ft. per hour.

The chilled shot method is very generally applicable, and is used for relatively large bore holes in hard ground. The cutter should run at 100–150 r.p.m.; about No. 5 shot is generally used. It is usually somewhat slower but cheaper than diamond boring. The consumption of shot with a cutter 4½ ins. in diameter ranges from 0·15 lb. per foot bored in shale to 1·2 lbs. in hard sandstone, but may be much higher in broken ground, where shot escapes into the fissures. In Nova Scotia 6 in. Government boreholes by this method averaged 10*s.* 6*d.* per foot in 1913.

The hydraulic rotary drill is the name given to a form now much used in boring oil-wells; it cuts out the whole of the material, leaving no core, the debris being brought to the surface by a water-flush. Over 100 ft. per day has been bored by this method.

Boreholes, especially those bored by rotary methods, are apt to deviate from the vertical, and a number of ingenious appliances have been devised for determining the amount and direction of the deviation. This is specially important when boreholes are put down in connection with the freezing method of shaft sinking (see p. 2579).

Location of Bore-holes for Valuation of Alluvial.*

When ground is systematically tested by pits or boreholes at regular intervals, three conventional views are possible:—

1. That there should be so many pits or holes per acre, or
2. That the distance between pits or holes should be so much, or
3. That no point on the ground should lie beyond a certain distance from a pit or hole.

The first two are those most generally held, but the last seems the most logical, and to attain it with the least amount of work the holes should lie at the corners of a series of equilateral triangles, the length of whose sides, or the distance of the pits apart, is equal to the maximum distance under condition (3) multiplied by $\sqrt{3}$. A line is run in any desired direction and staked at intervals equal to the distance between pits. From these stakes lines are turned off at angles of 60° or 120°, and staked at similar intervals starting from the turning-off point. The stakes are numbered to indicate their position on their own line and the number of the turning-off point, so that the pits sunk at them can be readily identified.

The advantages of this method over the more usual square lay-out are considerable. There is 6 per cent. less work involved in the lay-out of the holes, and 23 per cent. less in the sinking and sampling. The computation of values can also be more accurately done. Interpolation of values can be done on the plan, much as in contouring from spot levels, and a reliable assay plan prepared. (*R. T. Hancock.*)

The following is a list of some of the more important boreholes in the world:—

	£ *s.* *d.*

Geophysics for the Location of Minerals.

Magnetic methods; electric methods (self-potential method, equi-potential method, parallel wire method, single electrode method), electro-magnetic methods; gravitational methods (torsion balance); seismic methods; radio-active methods; geothermal methods. A Chair of Geophysics has been established at the Imperial College of Science, South Kensington.

* See 'The Valuation of Alluvial Deposits,' by W. R. Rumbold. *Trans. Inst. Min. Met.*, vol. xxxvii, 1928, p. 437.

Mechanical Drilling.

Drills either rotary or percussive. Rotary drills mostly of the twist-drill type confined to the softer rocks; Steavenson electric drill averages 40 ins. per minute in ironstone, uses 6 h.p. Siemens and others make small electric drills, taking 1 to 2 h.p., boring 6 to 10 ins. per minute in coal. For boring in hard rock the Brandt machine has been used in the Simplon tunnel and in some German collieries; hydraulically driven under head of 1,500 lbs. per sq. in.; bores 15 ft. per hour in gneiss. The Kellow drill used in North Wales is similar; has drilled 5 ft. per minute in slates.

Percussive drills are almost exclusively worked by compressed air. The drills are of two kinds: piston drills, in which the drill bit is rigidly connected with the piston rod, and hammer drills, in which the piston rod strikes on the end of the drill bit, the latter being lighter, smaller, and running at much higher speeds.

Drills may be classified by their valve action :—

1. Valve moved by external tappets.
2. „ „ internal „
3. „ „ air with auxiliary valve moved by tappet.
4. Valve moved by air.
5. Valveless, the piston itself acting as a valve.

Most modern drills belong to Class 3, but several types belonging to Classes 2 and 4 are also in use; very many hammer drills belong to Class 4.

Piston drills are further classified by their piston diameter, ranging from 2 to 4 ins.; 2½-in. drills are largely used for stoping, 2¾ to 3½ ins. for drifting, 3 to 3½ ins. for sinking. In 1902 70 per cent. of the drills in use on the Rand were 3½ drills. Such drills use 60 to 90 cu. ft. of free air per minute at pressures between 60 and 90 lbs. per sq. in. A 3-in. drill evolves about 1¾ h.p., for which about 5 h.p. must be applied to the drill piston and 10 to 25 h.p. to the steam end of a direct-driven air compressor.

At the Rose Deep Mine, Transvaal, a trial run of 31 drills for 6 hours gave air consumption for 3½-in. drills 81 cu. ft. compressed air, free air compressed to 70 lbs. pressure per minute; each drill required the consumption of 43 lbs. coal per hour to supply this air, 3·4 lbs. coal developing 1 h.p. hour. The average power of the compressor engine was 12·7 i.h.p. per drill; average drilling speed 4·5 ft. drill hole per drill per hour.

Relative air consumption of drills :—2½-in. drill, 0·445; 3½-in. drill, 1·000; $3\frac{5}{16}$-in. drill, 1·069; 3¾-in. drill, 1·123.

Average speed of boring, including setting up, is 10 to 25 ft. per 10-hour shift. Costs of boring in hard rock in Sweden are about 8*d.* to 10*d.* per foot bored, of which 40 per cent. is for wages and 30 per cent. for power; average boring speed is 5 ft. 6 ins. to 8 ft. per hour for downward holes and 4 ft. to 6 ft. 6 ins. for upward holes.

Hammer drills use 25 to 50 cubic feet of free air per minute; speed of boring about the same as piston drills, but holes are usually smaller. Hammer drills with a relatively rapid turning action of the bit and using bits with a chisel edge, but specially twisted steel, are used very successfully in coal.

A complete 6-piston-drill plant costs about 500*l.*

Two-stage compressors, delivering air at 100 lbs. gauge pressure, weigh on the average 27 lbs. and cost on the average 12*s.* in the U.S.A. per cubic foot piston displacement.

Sharpening Steel Bits.

A good blacksmith and striker can sharpen 30 to 40 bits per hour.

By the use of power drill-sharpeners, many of the shortcomings attendant upon the hand-sharpening process are got rid of, and drills can be kept true to gauge, with the result that where these machines are used it is possible to accomplish more drilling, whilst the cost of sharpening is considerably reduced.

According to experiment, the fastest cutting bit is the Carr (double chisel bit with central hole), the Z, + and 6 edged star in this order; cutting speed $\propto$ (drill diameter) $^{-2}$; cutting speed $\propto$ air pressure; pressure of 85 lbs. per square inch most generally satisfactory.

(*Bull. Amer. Inst. Min. Eng.*, August 1917, p. 1079.)

The Leyner compressed air operated drill sharpener, which can be handled by one man, is capable of sharpening up to 100 drill bits per hour, the number depending upon the size of the bits and steels to be handled.

In the case of small quarry plants or contract work, where drilling is done in the open, dry steam at a pressure of from 80 to 100 lbs. can be used, but will not give such good results as compressed air. Where a number of drills are used, a compressed air plant should preferably be installed, and is indispensable in underground drilling. With a properly laid pipe line of suitable size, there is very little loss in conveying compressed air from a central plant over very large distances.

Detachable drill bits are giving good results at several large mines, saving in cost of transport of drills. (*Trans. Amer. Inst. Min. Met. Eng.*, 1930 Year-book, p. 139.)

Holman Pedestal Grinder.

With these grinders (fig. 1) it is possible to keep the shanks of drill steels straight and true in addition to trueing up the edges of drill bits and repointing picks when necessary. The machines can be used as general workshop grinders for all kinds of tool grinding.

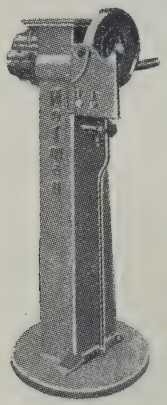

Fig. 1.

The machine does not require any foundation, but will stand wherever required, and is easily moved from place to place.

The machine provides a very economical means for cheap grinding, as it only uses power while the foot control is depressed and when released stops immediately. Full power and speed are attained immediately it is started.

The Holman Twingrip Sharpener.

There are two sizes of the new Twingrip, the smaller being suitable for bits up to 2¾ ins. and the larger for bits up to 5½ ins. in diameter.

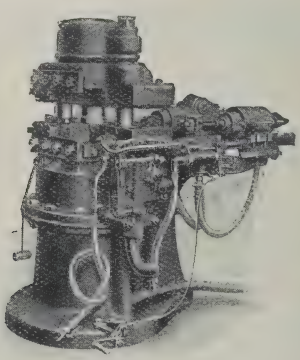

Fig. 2.

All operations except punching are controlled by one handle. A short movement of this towards the rear brings the jaw down to grip the steel in the gripping dies and a further short

EXAMPLE.—Required the amount of free air necessary to operate thirty 5-in. 'H' drills at 9,000 ft. altitude, using to operate these drills air at a gauge pressure of 80 pounds per sq. in.

From Table I we find, when operating the drills at 80 pounds gauge pressure at sea level, that one 5-inch 'H' drill requires 190 cubic feet of free air per minute.

From Table II we also find that the factor for 30 drills at 9,000 feet altitude is 20·38; multiplying 190 cubic feet by 20·38 gives 3,872 cubic feet air per minute, which is the displacement of a compressor for the above outfit under average conditions, to which must be added pipe line losses, such as friction and leakage.

movement in the same direction sets the dollying machine in operation to upset the end of the steel. Swaging and sizing of the bits are performed by moving the handle backwards and forwards, causing the top jaw to strike heavy blows whilst the steel is in the formers or the gauging blocks. To punch the hole in hollow steel after making the bit, the steel is first gripped as for upsetting and the punching machine then brought into operation by depressing the foot pedal. The punch is automatically fed forward by air pressure and when the foot pedal is released it is hammered out, the machine ceasing to operate when the pin is clear of the steel.

In the Twingrip there are two operating pistons—one above and one below the jaws. The advantages of this design are :—

A very great gripping force is obtained ; the pressure on the top piston acting directly on the upper jaw is not transmitted through the rod ; the upper jaw and piston being in one piece, the former is adequately guided and the piston rod thus relieved of bending strains ; correct alignment of the jaws is ensured.

Notes on Rock Drills.

In mining practice, drills are required to be of rapid boring capacity, and at the same time of light weight, so that the work may be both rapidly advanced and the whole outfit moved in awkward places with a minimum of trouble. In driving main headings, the piston type of drill, mounted on columns, is generally used. Where space is limited, it is not uncommon to mount two drills on arms attached to one column, two runners and a helper being sufficient to handle the machines so arranged ; in large tunnels the drills, from 1 to 4 in number, and of heavy pattern, are frequently mounted on drill carriages, thus enabling the equipment to be rapidly moved away from the face when the round of holes is ready for firing, without the necessity of dismantling. In stopes, raises, or small headings, the telescope-feed hammer drill, which is largely used, is a one-man drill, and is a rapid boring machine. Where the rock is of such a nature as to cause a considerable amount of dust, a condition which is to be met with in almost every metalliferous mine, drills having an automatic water feed are used. In the case of the heavy drills, the water is fed through the piston and drill bit under pressure ; of this type is the Leyner-Ingersoll. Telescope-feed stope drills can also be arranged for water feed through the heads and drill bits, which have a central hole running from the shank to the cutting face for this purpose.

For hammer drill work, drill bits are furnished with single chisel, double chisel, 6 point and 'Z' cutters, the steels themselves being sometimes hollow and sometimes round, hexagonal or spiral, the section depending upon the class of rock to be bored.

Compressed Air Drilling Plants.

The Hardy-Simplex Air Hammer Rock Drill (*Patent*).

(*The Hardy Patent Pick Co., Ltd., Sheffield.*)

In this drill, fig 3, the valve action is as follows:—When the air pressure is suddenly reduced at one end of the valve, the piston uncovers the main exhaust ports, and the full pressure acting on the opposite end causes the valve to travel to the other side of the valve box and thereby change the direction of the air pressure and reverse the piston or hammer. The action of the valve does not depend on compression set up by the piston in order to accomplish its reversal. It is not dependent on a tight piston and cylinder. It moves only $\frac{1}{14}$ in. in order to cut off the main air supply, but it has a further considerable travel before readmitting air. By the arrangement, all valve losses are practically eliminated, and the delay in readmitting air in quantity for the reversal of the piston diminishes internal resistance, so that a very powerful blow is given with a very small air consumption.

The valve will preserve its air tightness practically indefinitely, whilst at the same time it is perfectly balanced, and so light as to have great rapidity of action. The cylinder and valve box are forged together in one piece of special steel, bored, case-hardened to a glass hardness, and then accurately ground. The valve and valve bush are both manufactured from special alloy steels, both parts being hardened to suit the demands made on them. The rotation is effected by means of a rifle bar and a ratchet wheel situated at the rear of the machine in combination with a number of straight grooves cut in the piston or hammer working through a steel guide nut, situated in the chuck or drill holder. All parts of the rotation device are of hardened steel and are readily renewable.

The drills are retained by means of a cap which is provided with a strong round thread screwing over the front of the drilling machine and embracing the collar on the drill shank. The cap is slotted its full length, thereby enabling the machine to be at once disengaged from the drill steel should this for any reason become necessary.

The drills are made in three sizes, viz., the B5, B6, and B7, weighing 23 lbs., 27 lbs., and 40 lbs. respectively. The B5 pattern is for all overhead work in any class of rock ; it is also used for coal boring on long wall faces and in headings, etc. The B6 pattern will bore easily

holes up to 10 ft. in depth where necessary, in rock of any hardness, the speed of boring varying from 6 to 8 ins. per min. in hard granite to 30 ins. per min. in soft sandstone, and up to 48 ins. per min. in hard coal. Air at 60 to 80 lbs. per sq. in. The B7 pattern has been designed specially

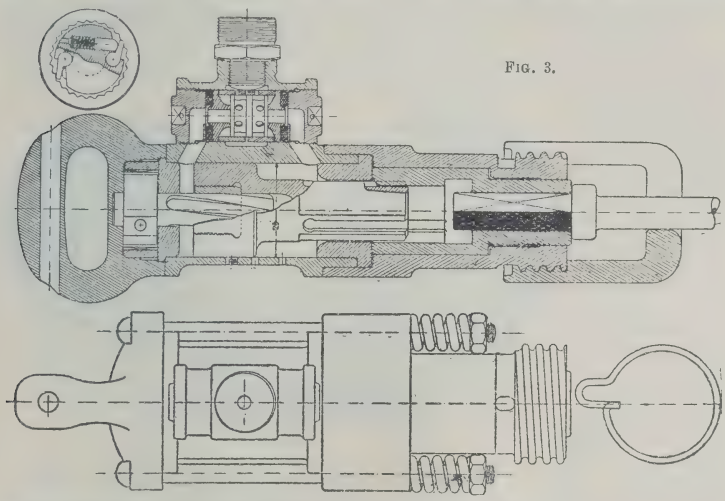

FIG. 3.

for 'down holes' in very hard ground in mine shafts and in quarries. It will easily drill holes up to 25 ft. in depth, starting at 3 ins. in diameter. Its normal boring speed in hard granite is 8 to 10 ins. per min. with air at 80 lbs. per sq. in.

THE HARDY AIR COMPRESSOR.

(Patent.)

(*The Hardy Patent Pick Co., Ltd., Sheffield.*)

This compressor is of the vertical single-acting type, single stage. The idea has been to provide a first-class small compressor of a simple type for driving rock drills, pneumatic hammers, etc., for use in mines, quarries, and engineering shops, and for such purposes up to 80 or 90 lbs. pressure per sq. in.

The lubrication of the whole machine is purely automatic and on the 'splash' principle.

The special feature of this compressor is the valve system. The inlet valve is situated in the piston itself, and consists of a simple ring controlling an annular inlet port in the piston head. This valve opens instantly on the down stroke, and remains open practically until the precise moment when the piston is reversed, admitting air both on its inside and outside peripheries and thereby ensuring a very high volumetric efficiency. The great port opening combined with the absence of spring load, gives an unbreakable inlet valve with a maximum port area and a minimum of complication.

The discharge valve is of the same ring type, made like the inlet valve of a special metal but double-ported and spring-loaded for quick closing to prevent reflux of compressed air after discharge. The discharge valve also uses both inside and outside peripheries, giving an ample port area to prevent undue excess pressure at the moment of discharge. The springs are seated partly in the discharge valve guard and partly in grooves in the discharge valve. They are very light and simple, and may be relied upon to give satisfactory service.

The water-jacketing of the cylinder walls is very thoroughly carried out and results in cool working and moderate discharge temperatures, thereby ensuring a high over-all efficiency of compression. The cylinders are of high-grade iron, crank and connecting rod of forged steel, of full dimensions; large inspecting doors and oil reservoirs are provided. In action the compressor is almost silent.

All machines are now fitted with automatic shut-off valve, closing the suction as soon as the desired pressure is attained; this reopens only when the pressure falls.

The compressors are made in three sizes, giving capacities of 50, 75, and 140 cu. ft., respectively.

The Holman Rock Drills.

The latest Holman drills are known as the 'Streamline' range and consist of various sizes of handrils (hand-held drills) drifters, sinkers and an air feed stoper. The SL 14, an intermediate size drifter, illustrated herewith, may be taken as representing the series.

The almost unbroken exterior of the machine is at once noticeable, the fact accounting for the name 'Streamline.' This feature, apart from other considerations, is of great assistance to the operator, as the absence of projections facilitates the changing of steels and enables holes to be drilled close to the roof, floor or walls of a tunnel. This symmetry is attained by placing the valve at the back end of the cylinder, concentric with the bore.

The valve, which is operated by the difference of pressure on either side as the piston travels backwards and forwards, is 'hat-shaped.' In diameter it is almost as large as the cylinder bore, and as the admission of air is controlled by the circumference, its travel is remarkably small--about 15/1,000 ins. This makes it almost impossible to break a valve in actual work, as the travel is insufficient for it to acquire any great velocity and the impact is consequently light. As the ports are closed by the faces of the valve, wear on the inner and outer circumferences does not cause air leakage.

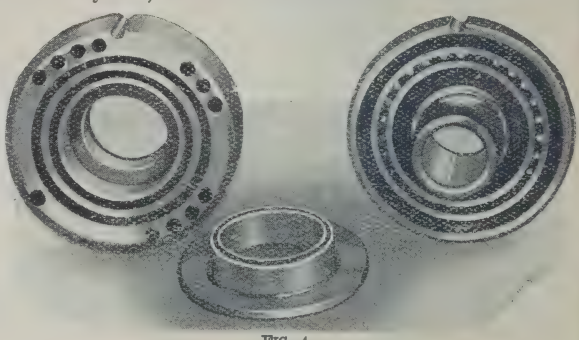

Fig. 4.

On the working stroke, the air passes almost directly on to the piston, the ports being extremely short. This results in a high speed and economy in air consumption. For the return stroke the air has to pass through ports the length of the cylinder, giving the piston time to deliver a full uncushioned blow. The piston of this particular model strikes over 2,000 blows per min. when working at 100 lbs. per sq. in. air pressure.

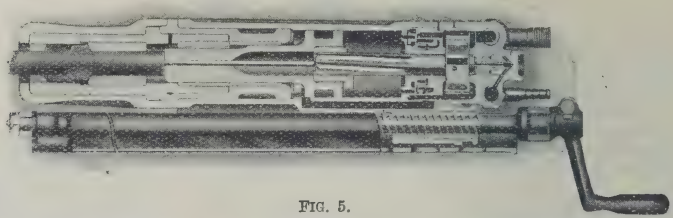

Fig. 5.

Rotation of the drill-steel is effected by the twist bar with spiral flutes working in a twist nut in the rear of the piston. On the forward stroke the twist bar is free to rotate but on the return it is held by the ratchet-gear, and the piston is given a rotary motion. There are straight flutes on the forward end of the piston engaging in corresponding grooves in the chuck guide nut, which transmits the motion of the drill-steel through the chuck, chuck key and bushing, and the lugs formed on the shank of the drill-steel itself.

Water is forced, under pressure, through the water tube, passing through the twist bar and piston and entering a short distance into the hollow drill-steel, right to the bottom of the hole being drilled.

On the cylinder are two machined slides for securing the drill to the cradle. The latter is equipped with a feed screw by which the machine is fed forward as the depth of the hole increases. The cradle is secured by means of a cone clamp to a column for tunnelling work or to a bar or tripod for quarry or open cut working. With the Holman Sliding Cone Cradle, a depth of 56 ins. may be drilled without changing the drill-steel—providing that the rock is such that the wear on the drill bit does not necessitate more frequent changes. This type of cradle also facilitates the 'setting-up' of a drill when starting a new hole.

Metallic Tubing.

Flexible Metallic Tubing (*The United Flexible Metallic Tubing Co. Ltd.*, 112 Queen Victoria Street, London) is specially suitable for mining work. Its durability renders it economic, and it diminishes 'breakdowns,' as the tubing cannot kink and is not easily crushed ; it is also unaffected by changes of atmosphere, or by vermin, white ants, etc.

Wire Clamping Tool for Compressed Air Hose.

Fig. 6 shows a tool in use in a number of the mines for winding wire around the hose to hold the nipple in place, thereby doing away with the usual clamps and bolts.

The dimensions given are approximate for a tool used in clamping a 1-in. four-ply hose. On one end of a piece of ¾-in. pipe 6 ins. long a standard pipe thread is cut, and on the other end a 1½-in. bolt thread about 3 ins. long. The end with the bolt thread is inserted in the hose about 4 ins., and the hose is ready for the wire clamping.

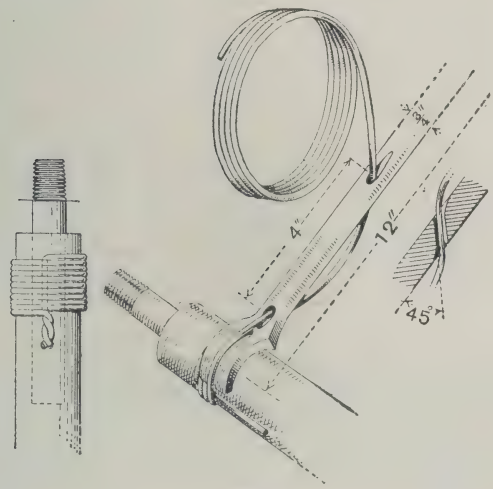

Fig. 6.

A No. 14 Stubs gauge soft steel wire is used. The wire is cut in 9-ft. lengths for winding a 1-in. hose, shorter lengths being used for smaller hose. The wire is first wound up on a piece of 3-in. pipe with a slot cut in it so that the wire can be hooked in it and held in place while the bundle is being wound. When a hose is to be clamped, a bundle of wire is taken and started on the tool as shown in the figure. The wire is fed through the tool until about 4 ins. extends beyond the point of the tool ; this is then bent at a right angle, and is laid on the hose lengthwise. The wire is then wound around the hose layer after layer, and when the final turn is made the two ends are given two twists and the job is done. Any number of lengths of hose may be connected in this manner. The two holes through the handle are drilled at an angle of 45 deg., which gives the proper tension to the wire when winding.

Air Receivers.

An air receiver is not intended so much for storage as to equalise pressure, and to allow of an even flow of air through the pipe, there being a certain amount of pulsation from the air compressor discharge itself. In long pipe lines a smaller receiver should be placed in the pipe line near the point of application of the compressed air, furnished with suitable drain cocks, for the purpose of drawing off the superfluous moisture which might collect, and the consequent

prevention of freezing in the line. The following table gives sizes and details of receivers which are usually considered standard practice :—

TABLE III.—AIR RECEIVERS AND PRESSURE TANKS FOR STANDARD WORKING PRESSURES. Tested to 165 lbs. Water Pressure.

Diam. in Ins.	Length in Ft.	Contents Cub. Ft. (about).	Thickness of Shell. Ins.	Thickness of Heads. Ins.	Weight Lbs. (about).	Diam. of Safety Valve. Ins.	Diam. of Inlet and Discharge Openings. Ins.	Compressor Capacity Receiver is Best Adapted for in Cub. Ft. Free Air per Minute.

(For Air Compressors see p. 1190.)

BLASTING.

Explosives are divided into low explosives, with a slow rending action and fired by simple ignition, and high explosives, with a rapid shattering action, fired by means of a detonator. The rate of explosion of gunpowder, typical of the former, is 3 to 4 metres per second, and of blasting gelatine, typical of the latter, up to 7,000 metres per second.

For blasting in fiery coal-mines explosives known as safety explosives are employed, which have a lower temperature of detonation. No explosive can, however, be considered really safe in a fiery atmosphere. In this country only those explosives are allowed to be used that have passed the Government tests and which are scheduled in the Home Office Order in force for the time being. A shot-hole in coal should never be placed in the solid, i.e. in coal that has not previously been kirved.

If D be the depth of a properly placed shot-hole, the volume of rock blasted out averages with one free face 0·37 D^3 ; with two free faces volume = 0·84 D^3, and with three free faces 1·33 D^3. In drifting and shaft sinking the volume blasted out is approximately 0·75 D^3. If L be the line of least resistance, D=about 1·75 L.

The quantity of explosive required for charging a shot-hole may be calculated by the following formula, modified from Chalon :—

Let Q be the quantity of explosive in lbs., L the line of least resistance in feet, then

$$Q = \epsilon\kappa L^2,$$

where ϵ is a coefficient depending on the explosive and κ a coefficient depending on the character of the rock.

VALUES OF ϵ.

Blasting gelatine	0·14	No. 3 dynamite (33 per cent. nitroglycerine)	0·37
No. 1 gelatine dynamite	0·20	Compressed powder	0·41
Tonite	0·245	Ordinary blasting powder	0·61
Roburite, bellite and similar 'safety' explosives	0·25		

VALUES OF κ.

Very hard rocks, quartzite, hard igneous rocks, etc.	1·0
Hard igneous and metamorphic rocks, etc.	1·0 to 0·8
Schists, crystalline limestones, hard sandstones, etc.	0·8 „ 0·5
Coal measure shales, soft sandstones, etc.	0·5 „ 0·3
Chalk, soft shales, etc.	0·3 „ 0·15
Coal	0·2 „ 0·1
Gravel and other non-coherent rocks	0·1 „ 0·05

Low-tension electric fuses require a tension of about 1 volt; medium, about 4 volts; high, about 100 volts. Low tension fuses best in series, high tension in parallel.

Liquid air is used extensively in the ironstone mines of Lorraine; a cartridge containing sawdust, powdered cork, soot, or a similar substance impregnated with liquid air or liquid oxygen is employed. No detonator is required, but the shot must be fired within 15 minutes of charging. The addition of aluminium powder to the charge greatly increases the detonating action. The quantity of liquid air used is 0·3 litre per ton of ironstone, and the cost of this explosive per ton blasted is given as 0·303 per cent. as against 0·571 per cent. with cheddite and 0·597 per cent. with compressed black powder. Liquid oxygen is preferred to liquid air, because the latter is apt to produce fumes containing oxides of nitrogen which injuriously affect the miners, whereas with the former no noxious gases at all are evolved. It is also used in some of the Lincolnshire * ironstone quarries.

Under Explosives Order No. 1194 of 1921, the production in the mine of an explosive by impregnating carbonaceous material with liquid air or oxygen is now permitted under licence, thus modifying Section 50 of the Explosives Act, 1875. (See p. 2656.)

Detonators.

Detonators.—These are known by numbers, the charge of which varies somewhat. The following is about the average practice:—

Detonator numbers	1	2	3	4	5	6	7	8
Weight of mixture in grains	4½	6	8	10	12	15	23	30

The mixture consists of 80 per cent. fulminate of mercury, 20 per cent. chlorate of potash. Tetryl and Lead Azide mixture are also now used. (See *Proc. Roy. Soc. N.S.W.*, vol. lxiii, p. 35.)

Detonating Cord (Cordeau détonant) consists of a flat tube of lead, tin or aluminium usually 7 mm. wide, 3 mm. thick, filled with nitro-methylaniline or trinitrotoluol, containing usually about 10 grams of explosive per metre. An explosion is propagated through this at a velocity of about 7,000 metres per second. A piece of this cord is attached along a row of blasting cartridges and ensures their complete and instantaneous detonation, even in wet holes. It is stated that the efficiency of the explosive is increased by 20 per cent., and that experiments at Lievin have shown that an explosive mixture of firedamp is not ignited by the detonation of 3 metres of cord.

Ordinary fuse burns at the rate of 30 seconds per foot.

(See also EXPLOSIVES, p. 2797.)

ELIMINATION OF MISFIRING OF CENTRE SHOTS.

As a means towards the elimination of misfiring of centre shots in large-scale blasting in coal mines, the United States Bureau of Mines recommends that the following practices be used whenever shots are to be fired in wet holes: Use waterproofed electric detonators with enamelled leg wires. When making connections with enamelled leg wires, care must be taken to scrape the ends of the wires well, otherwise the enamel will prevent good electrical contact. Fire the shots from an ungrounded power circuit that has a capacity of at least 30 kw. Use extra care when tamping the holes in order not to damage the insulation of the leg wires. Arrange the connections between the detonators so that they are supported clear of the earth or any other conducting medium. (See *Technical Publication* No 257, *Amer. Inst. Min. Met. Eng.*, 1929.)

Drifts.

In collieries, drifts of ordinary size, say 35 to 50 square feet in sectional area in ordinary coal measures, range in price for hand labour in 1913 from 1*s.* to 2*s.* per linear yard for each square foot, according to nature of strata and width of drift, being less the wider the drift. The cost in shale is about two-thirds of the cost in ordinary sandstone. Mean rate of advance of such drifts, about 4 to 6 yards per week in sandstone, 6 to 8 yards per week in shale, 3 shifts per day, two miners in face with two to three labourers.

For inclined drifts rising at high angles the prices will be up to 50 per cent. higher; for drifts dipping at a high angle up to 100 per cent. In very hard sandstone the speed of driving will be about one-half, and the costs about double those given above, and in hard tough igneous rocks, such as basalts, the speed may fall to one-fourth, and the cost rise to four times these figures.

By the use of rock drills the speed may be greatly increased, especially in hard rocks, but the actual drivage costs are not much diminished, except in the harder rocks.

In making height where a top or bottom canch of stone has to be blasted, the price for a top canch of shale ranges from 1½*d.* to 2*d.* per inch for a width of 6 ft.; sandstone, 2*d.* to 3*d.* Bottom canches cost about 20 per cent. more than top canches. These prices include stowing the stone.

Driving in hard carboniferous limestone, drift 30 sq. ft. in cross-section, cost about 60*s.* per yard; three men in three shifts can drive about 4 to 5 yards per week by hand. In one case with

* *Journ. Iron and Steel Inst.*, vol. cxvii., 1928, Pt. I., p. 186.

hand-drilling the cost was 55*s.* per yard, and rate of advance 4 yards per week, and with machine drilling the cost fell to 25*s.* and the rate of advance rose to 10 yards.

In metalliferous mines.—*By hand.*—A drift 5 ft. by 7 ft. in the clear, in rock of medium hardness, can be driven by hand at a rate of 30 to 40 feet per month by employing two ten-hour shifts per twenty-four hours. In soft rock as much as 100 ft. per month can be penetrated. The cost in moderate rock with labour at 12*s.* per shift will average about 2*l.* per foot, including timber and strap rails.

By machine.—A 5-ft. by 7½-ft. drift was run in Colorado, U.S.A., at the rate of 236 feet per month. This speed is above the average and was due to a well-trained crew (three shifts per day) working on a bonus system. Rock was granite, gneiss, and schist, very hard to drill and breaking badly. Labour, 16*s.* per shift. Cost, 2*l.* 14*s.* per foot.

At Cripple Creek, wages 13*s.* 6*d.* per eight-hour shift, ground moderately hard, 896 ft. of 5 ft. by 7 ft. drifts were run by machines, at a cost of 1*l.* 4*s.* per foot; 1,229 ft. of 5 ft. by 7 ft. crosscuts were run at a cost of 1*l.* 9*s.* per foot.

At Park City, Utah, with miners' wages at 12*s.* per eight-hour shift, a timbered drift 7 ft. by 11 ft. was run in quartzite by means of 3½ inch air drill, 3 shifts per 24 hours, at rate of 4·75 ft. per day, at a cost of 2*l.* 4*s.* per foot of drift, or 7*s.* 1*d.* per ton of material broken. No hoisting.

At the same mine crosscuts 7 ft. by 7 ft. in the clear are run by air drills at a rate of 8 ft. per day at a cost of 2*l.* 15*s.* per foot or 15*s.* per ton of material broken.

The Chipeta Adit in Colorado, U.S.A., 7½ ft. by 7½ ft. in clear, was run in hard rock a distance of 1,712½ ft. in 152 days. The best monthly average was 342½. Two 3½ in. air drills were employed. The cost, including track and pipe, power, timber, labour and explosive, was 2*l.* 4*s.* per foot. The amount of powder (40 per cent.) consumed was 14½ lbs. per foot of tunnel. Wages 16*s.* per day.

In Western Australia the drifts vary in size from 5 ft. by 7½ ft. to 6 ft. by 7 ft., and the crosscuts from 5 ft. by 7 ft. to 8 ft. by 8 ft. In eleven of the principal mines the rate of driving and crosscutting varies from 25 ft. to 90 ft. per month, averaging 60 ft. Working costs range from 46*s.* to 103*s.* per foot, averaging 60*s.* The total costs of drives were from 3*l.* 6*s.* to 4*l.* 2*s.* per foot and crosscuts from 3*l.* 3*s.* to 3*l.* 14*s.* At the Braden Copper Mine, Chili, all development work in the nature of drifts, crosscuts and upraises with average section of 4·53 square metres are run at an average cost of 14*s.* per foot driven. This cost includes all labour (native Chilian), supplies, explosives, machinery, and tramming. No timber is used. The work is done under contract and rock is moderately hard and breaks well. Machine drills are used. The rate of progress is about 130 ft. per month or 13 ft. per month per man.

Timbering Drifts.

Props 3 ins. to 5 ins. diameter and crowntrees 5 × 2½ ins. are often used in colliery drifts; in main roads balks of much larger size may be used.

Resistance to crushing of pit props in tons per square inch of small end:

Scandinavian white wood, 1½; Larch, 1½; Scotch Fir, 1½; Oak, 1; Beech, 1⅜.

Prof. Hudson Beare gives the following:—

Scots Pine, 1·767; Spruce, 1·892; Larch, 1·871; Japanese Larch, 1·379; Finnish Red and White Wood, 1·784 tons per square inch of mean area of prop.

In main roads ferro-concrete props are coming into use; their crushing strength is about 1·3 tons per sq. in. Tests by W. A. Machin (*Trans. Nat. Assoc. Col. Man.*, xv., p. 155) gave 1·58 to 1·82 tons per sq. in. on Keedon props 6 ft. long, about 4½ ins. square. Steel props are being largely used often in connection with corrugated steel straps (see *Trans. Inst. Min. Eng.*, vol. lxxvii., 1928–9, p. 158).

Instead of balks, steel H girders are often used. The following are some of the usual sizes:

Depth by width, in ins.	6×6	6×5	6×4	5×4	4½×4
Weight in lbs. per linear foot	31	27	24	22	18
Tons that will be carried in middle by beam 1 ft. long, supported at both ends	160	130	120	105	60

Drystone arching for roadway 6 to 7 ft. high and 3 ft. to 4 ft. 6 ins. wide in Alston district costs about 12*s.* 6*d.* per linear yard for labour. The cost of labour for ordinary arching ranges from 7*s.* to 10*s.* per linear yard. Concrete arching varies from 6*s.* to 10*s.* per cubic yard of concrete put in. Arches of steel H girders supporting galvanised sheets have been used successfully in big drifts. Steel arching, both H and channel, is being extensively used in many collieries (see *Trans. Inst. Min. Eng.*, vol. lxv., 1922–3, p. 124, vol. lxxv., 1927–8, pp. 12 and 93; also *Brit. Eng. Stand. Assoc.*, No. 227, 1926).

A coating of magnesia cement on the timbers of mines is stated to be an economical and efficient assurance against fire, especially in the arid regions where timber becomes highly inflammable and is difficult to replace. It is elastic, adheres firmly to almost any surface, and is stable and durable.

A layer of cement (Gunite) put on by means of a 'cement gun' is sometimes used for covering timbers, also the sides and roofs of drifts, etc.

In drifts in very heavy ground the Schaefer system of lining may be used; this consists of blocks of reinforced concrete, set dry, but keyed into each other, with rows of wooden blocks to take up the squeeze; such linings may deform under heavy pressure, but will keep the drift open. (*Trans. Nat. Assoc. Coll. Managers*, vol. xxiv., 1926-7, p. 122.)

SHAFTS.

(See *' Vertical Shaft Sinking' by G. O. Forster Brown*, 1927.)

Modern shafts are generally either rectangular or circular in cross-section; the former are used in sinking upon narrow veins or seams, where the ground is not very heavy nor the amount of water excessive, or where good timber is cheap; under other conditions round shafts are preferred, but local custom also exercises much influence. Inclined shafts are practically always rectangular; elliptical shafts have been sunk in some places (Forest of Dean) but are now rarely used.

Rectangular Shafts.

Rectangular shafts for large mines may be up to 25 ft. long by 15 ft. wide in the clear. Exceptionally large shafts are used in Pennsylvania, e.g., No. 5 Wilkesbarre anthracite mines, 52 ft. by 12 ft., Exeter Red Ash, 46 ft. 2 ins. by 13 ft. 10 ins.

Round shafts, say from 8 ft. to 24 ft. diameter in the clear; a colliery shaft to wind 1,000 tons per day is usually 16 to 18 ft. diameter.

Rectangular shafts are mostly wood-lined; they are either cribbed or timbered with sets holding lagging in place. In Fifeshire shafts up to 30 ft. by 12 ft. are cribbed with ' barring ' of 9 ins. by 3 ins. up to 6 ins. by 12 ins. The timber for a shaft 23 ft. by 8 ft., including buntons, etc., would amount to about 125 cubic feet, and would cost, including nails, wedges, etc., about 13*l.* 10*s.* per fathom. The cost of sinking (the ground is usually easy) and putting in the timber is about 30*l.* per fathom. In the iron-ore mines of Cumberland and Lancashire shafts about 10 ft. by 5 ft. are cribbed with 10 ins. × 5 ins. plank, the ends being half checked; the total cost including sinking, timbering, timber, stores, etc., is about 30*l.* per fathom, the ground being carboniferous limestone that requires blasting. Sets are made of squared timber 4 ins. × 6 ins. for a small shaft, up to 9 ins. × 15 ins. for a very large one; sets are 3 ft. to 6 ft. apart, held together by hook bolts of 1¼-in. round iron with wing nuts.

Horned sets or bearer sets are put in about every 6 sets or so, depending on the nature of the ground; lagging is often 9 ins. × 3 ins. plank.

Round Shafts.

Round shafts are lined with brick or concrete in ordinary strata; special methods are adopted where shaft traverses water-bearing strata and the lining is required to keep back water. For shafts over 18 ft. in diameter ordinary brick may be used; for smaller shafts wedge bricks should be employed. Let f be the width of the inner face of the brick, b of the outer face, l the length of the brick and R the radius of the shaft. Then $b = \frac{(R + l)f}{R}$; if, as is often the case, $l = 2f$, this becomes $b = f + \frac{2f^2}{R}$. Instead of bricks, firebrick lumps 6 ins. to 8 ins. × 12 ins. to 8 ins. × 10 ins. to 15 ins. may be used. They should also be made wedge shaped in accordance with the above formula. A shaft 10 ft. in diameter lined one brick thick requires about 350 bricks laid in mortar, per foot of depth. The thickness of the lining depends on the nature of the ground and the diameter of the shaft.

COST OF SINKING.

The cost of sinking may be taken as made up of five main items: Supervision, labour, materials, power, and interest on capital expended.

Sinking in ordinary coal measures costs 1*l.* to 2*l.* per fathom for each foot in diameter of the shaft; to this must be added surface labour, fuel, etc., 30*l.* to 50*l.* per week. If more water than 100 gallons per minute is met with, these costs will increase rapidly. Walling, including the cost of the bricks, amounts to between 15*s.* and 30*s.* per cubic yard of brickwork. Walling a shaft 13 ft. in the clear, 15 ft. over all, cost about 15*l.* per fathom = 30*s.* per cubic yard; walling a shaft 22 ft. in the clear, 25 ft. over all, cost 24*l.* 5*s.* per fathom = 15*s.* 6*d.* per cubic yard. A walling curb costs about 10*l.* Sinking a shaft 12 ft. in the clear cost 24*l.* per fathom (sinkers and waiters-on, 13*l.* 10*s.*; general labour, 7*l.* 10*s.*; explosives and stores, 3*l.*). Sinking a shaft 13 ft. in the clear costs 23*l.* to 30*l.* for labour in ordinary strata, and 70*l.* to 100*l.* in basalt, per fathom.

Sinking two shafts at Hylton colliery in 1897–99 cost as follows per fathom:—

	Shaft 20 ft. in the clear.						Shaft 15 ft. in the clear.					
	£	s.	d.	£	s.	d.	£	s.	d.	£	s.	d.
Labour—Sinkers (incl. explosives)	21	0	6				17	0	0			
Wallers	7	7	2				5	11	0			
Miscellaneous	8	7	4				2	16	0			
				36	15	0				25	7	0
Materials—Bricks	9	12	0				5	2	0			
Cement, lime, sand	4	16	0				2	11	0			
Walling cribs	2	6	0				2	0	0			
Miscellaneous	0	15	0				0	10	0			
				17	9	0				10	3	0
Total per fathom				54	4	0				35	10	0

Sinking three 20 ft. shafts at Horden, each 210 fathoms deep, against a flow of 9,000 gallons of water per minute, cost 350,000*l.* (*J. J. Prest.*)

The cost of sinking and tubbing a section of 22-ft. shaft at Blackhall with feeders of water from 300 to 2,885 gallons per minute was as follows :—

	£	s.	d.	
Underground labour	70	10	10	per linear yard.
Surface „	26	13	7	
Materials, coal and stores	87	2	1	
	£184	6	6	

The cost of sinking a 22-ft. shaft through limestone and tubbing it, against feeders of water averaging 3,000 gallons p.m., may be averaged at about 275*l.* per yard of depth.
(*J. J. Prest*, Tr. Inst. M. E. xlvii. p. 611.)

Shafts may be lined with cement, either by setting sheet iron cylinders and ramming concrete round these, lifting the cylinders when the cement has set, or by walling with thin blocks or slabs (about 2 ft. 6 ins. × 3 ft. 6 ins. × 5 ins.), and ramming cement behind this facing ring. The cost of an 18-in. monolithic lining in a 22-ft. finished shaft was made up as follows :—

	s.	d.	
Mixing concrete	1	0	per cub. yd.
Cement	4	2	„
Lining shaft with concrete	2	6	„
Coal and stores	0	9	„
Steel cylinders and other plant	1	4	„
Total	9	9	per cub. yd.

There were 28 cubic yards to the fathom, hence the cost per fathom was 13*l.* 13*s.* It took seven hours to complete the concreting of one fathom.

The cost of walling a similar pit with brickwork was 24*l.* 3*s.* 3*d.*

Lining a 22 ft. shaft at Blackhall with a monolithic cement concrete (6 : 1) lining cost per linear yard :—

	£	s.	d.
Labour in loading sand and gravel	1	18	6
Enginemen and attending mixer	0	4	1
Cement	3	13	6
Interest and depreciation on shuttering, etc.	0	19	0
Coal, stores, etc.	0	10	6
Labour in shaft	3	1	7
	£10	7	2

Lining with concrete blocks 3 ft. 6 ins. × 2 ft. 6 ins. × 5 ins. backed solid by ramming in concrete, all also 6 : 1, cost practically the same. The average cost of sinking and walling with 18 in. concrete was 26*l.* 1*s.* 8*d.* inclusive. Suitable bricks would have cost 45*s.* per 1,000, and at this price brickwork in cement would have cost 15*l.* per running yard. (*Loc. cit.*)

In a 14 ft. pit the total costs of labour for sinking and concreting came to 15*l.* 15*s.* per fathom. The cost of the concrete was about 21*s.*, and the labour of lining the shaft with it about 1*s.* 6*d.*, or altogether 22*s.* 6*d.* per cubic yard. There were 10½ cubic yards per fathom, so that the cost of the concrete lining amounted to 11*l.* 16*s.* per fathom ; with four men at the surface and four men in the pit, the concrete was put in at the rate of a fathom in six hours. At Karwin, Silesia, an 18 ft. shaft was lined with concrete put in from above downwards at the rate of a fathom in fourteen hours at a cost of 62*l.* per fathom complete ; the same shaft lined in the upper part with brickwork had previously cost 132*l.* per fathom. Ferro-concrete has been used in place of simple concrete. At Zweckel, near Gladbeck, a shaft was lined with ferro-concrete slabs backed with concrete, into which the iron framework of the slabs was continued, for 23*l.* per fathom. At Rheinelbe a shaft 20 ft. in diameter was lined with Monier ferro-concrete 11 ins. thick at a cost of 2*l.* 5*s.* 6*d.* per cubic metre of lining, or 30*l.* 12*s.* per fathom of shaft : for a similar shaft at the Hansa Colliery lined 9½ ins. thick the prices were 2*l.* 3*s.* 6*d.* per cubic yard or 29*l.* 14*s.* per fathom.

Shaft Lining.

In heavily watered strata a lining has to be put in strong enough to resist the pressure of water. The thickness of such lining may be calculated as follows :—

Let R be the internal radius of the shaft, s the maximum admissible stress in the wall, p the pressure to be resisted, all to the same units, which are preferably inches and pounds, then :—

$$\text{Thickness of wall} = R\left(\sqrt{\frac{s}{s-2p}}-1\right)$$

(*Aldis*, N.E. Inst. M. E. xxxii. p. 201.)

The resistance to crushing of the various materials used in lining shafts is :—

Common brick	800 to 1,000	lbs.	per square inch.
Fire brick	1,500 to 2,000	,,	,, ,,
Sandstone	2,000 to 5,000	,,	,, ,,
Concrete 1 : 3 : 6 to 1 : 1 : 3.	1,500 to 5,000	,,	,, ,,
Average	3,000	,,	,, ,,
Cast iron	90,000 to 120,000	,,	,, ,,

Safe loads may be taken as $\frac{1}{10}$ of these : for best brick laid in 1 : 3 Portland cement up to 250 lbs.; for ferro-concrete up to 600 lbs. per sq. in.; for frozen sand fully saturated with water at −12° C. up to 340 lbs. per sq. in. (*Alby*, Bull. Soc. Ind. Min. 1895, p. 273.) L. Sauvestre has shown that frozen sand is highly plastic, and that its resistance to crushing increases by 28½ lbs. per sq. in. for each drop of 1° C. (*Annales des Mines*, Ser. xi., vol. ix., 1920, Pt. I, p. 5.)

The pressure to be resisted is usually taken merely as the head of water—namely, 0·434 h lbs. per sq. in., where h is the head expressed in feet. For quicksands Poetsch adopts a formula equivalent to $p = 1{\cdot}042\ h \tan^2\left(45° - \frac{\alpha}{2}\right)$, where α is the angle of repose of the sand ; Poetsch gives $\alpha = 35°$ for fine quicksand, and 20° for coarse sand. These figures are used in calculating the thickness of the ice-wall required in the freezing method of sinking.

Many approximations are used for ordinary shaft linings :—

J. J. Atkinson : Thickness in inches $T = \frac{5{\cdot}2\ R\ h}{s - 0{\cdot}434\ h}$, or for cast iron $T = \frac{5{\cdot}2\ R\ h}{9{,}000 - 0{\cdot}434\ h}$.

Chaudron: for cast iron, $T = 0{\cdot}8 + \frac{0{\cdot}434\ R\ h}{600}$ where $h < 165$ ft. and $T = \frac{130}{h} + \frac{0{\cdot}434\ R\ h}{600}$ where $h > 165$ ft. (here s is taken at only 7,200).

Riemer takes $s = 11{,}400$, and writes :—

$$T = 0{\cdot}8 + \frac{0{\cdot}434\ R\ h}{950} \text{ for } h < 165,$$

$$\text{and } T = \frac{130}{h} + \frac{0{\cdot}434\ R\ h}{950} \text{ for } h > 165.$$

Cast-iron tubbing is always stiffened by ribs and flanges, and these should be taken into account (see *Morrow*, Trans. Inst. M.E. xxxiv. p. 100).

Coffering.

Coffering may be used for moderate pressures and shallow depths ; costs range from 20*l.* 10*s.* per fathom (16-foot shaft) to 38*l.* per fathom (18-foot shaft), being considerably less than cost of cast-iron tubbing.

Tubbing.

Tubbing is put in either by English or German method ; in the former, segments are 2 ft. to 3 ft. deep, flanges are external, not machined, and the joints are made with wood sheeting and wedges ; in the latter, segments are 5 ft. to 6 ft. deep, flanges are internal, are machined, and the joints are made with lead sheeting and bolts. In both forms the tubbing is carried upon wedging curbs, followed usually by a foundation ring. In some few recent cases the wedging curb has been dispensed with, and the tubbing set direct upon a good bed.

Cost of Tubbing.
